

PHARMACOLOGY *for* NURSING CARE

7th ed.

RICHARD A. LEHNE, PhD

formerly, Lecturer, University of Arizona College of Nursing

Lecturer, University of Virginia School of Nursing

Research Assistant Professor, Department of Pharmacology, University of Virginia School of Medicine, Charlottesville, Virginia

IN CONSULTATION WITH

Linda A. Moore, EdD, RN, APRN, BC (GNP/ANP), MSCN

Associate Professor of Nursing, Adult Health Nursing, School of Nursing, University of North Carolina, at Charlotte

Nurse Practitioner, Multiple Sclerosis Center, Carolinas HealthCare Systems, Charlotte, North Carolina

Leanna J. Crosby, DNSc, G/ANP-C

Nurse Practitioner in Primary Care, Southern Arizona Veterans Administration Healthcare System

Adjunct Associate Professor, College of Nursing, University of Arizona, Tucson, Arizona

Diane B. Hamilton, PhD, RN

Professor Emerita, School of Nursing, Western Michigan University, Kalamazoo, Michigan

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the author assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

About the Author

Richard A. Lehne, PhD, earned his BA from Drew University and his PhD in pharmacology from George Washington University. His involvement in nursing education began 30 years ago at the University of Virginia School of Nursing, where he taught undergraduate and graduate pharmacology courses and was voted best teacher by his students. He has also taught at the University of Arizona in both the School of Nursing and School of Pharmacy. For the past 24 years, most of his time has been devoted to creating and revising this book. Dr. Lehne (rhymes with zany or rainy) lives in Charlottesville, VA, where he likes to bike and walk/jog (as age, weather, and editors permit), practice cooking (it's like being back in the lab, but more fun), and cheer on Nancy (his SO) in her equestrian activities.

v

Consultants

Linda A. Moore, EdD, RN, APRN, BC (GNP/ANP), MSCN, is an Associate Professor of Nursing at the University of North Carolina at Charlotte and a Nurse Practitioner in the Multiple Sclerosis Center of Carolinas HealthCare Systems. She received her BSN from Duke University and her MSN and EdD from the University of Virginia. Her teaching responsibilities encompass courses for undergraduate (RN to BSN) and graduate students. Her major clinical and research interests are multiple sclerosis, cardiovascular nursing, and gerontologic nursing. Dr. Moore is a member of the North Carolina Nurses' Association, Sigma Theta Tau, American Academy of Nurse Practitioners, and the International Organization of Multiple Sclerosis Nurses.

Leanna J. Crosby, DNSc, G/ANP-C, received her diploma in nursing from St. Luke's Hospital School of Nursing, her baccalaureate and master's degrees from the University of Virginia, and her doctorate in nursing science from Catholic University of America. Also, she completed the adult nurse practitioner program at the University of Virginia and the gerontologic nurse practitioner program at the University of Arizona. Dr. Crosby has done extensive research in chronic rheumatoid disease, and has taught physiology and pathophysiology to a generation of appreciative graduate and undergraduate students. Currently, she is working as a nurse practitioner within the Department of Veteran Affairs, Southern Arizona Veterans Administration Healthcare System, and is an Adjunct Associate Professor at the University of Arizona College of Nursing. Dr. Crosby is a member of the American Nurses Association, Sigma Theta Tau, and the Arizona Nurses' Association, and serves on the Arizona State Board of Nursing Advanced Practice Committee. In addition, she serves as the VISN 18 (Arizona, Texas, and New Mexico) coordinator for the Advanced Practice Nursing Network. At the local level, she is Membership Chair for the Southern Arizona Nurse Practitioner Association, a member of the Professional Standards Board for Nursing at the Southern Arizona VA Medical Center, and Chair of the Tucson VA IACUC Animal Research Committee.

Diane B. Hamilton, PhD, RN, received her BA from Northwestern University, her BSN from West Texas State University, her MA in Community Mental Health and Gerontologic Nursing from the University of Iowa, and her PhD in Psychosocial Nursing and Nursing History from the University of Virginia. She has extensive experience in psychiatric nursing, including serving as Attending Nurse at the Institute of Psychiatry of the Medical University of South Carolina. She has taught psychiatry and behavioral science to medical students, and gerontology, community health, psychiatric nursing, and nursing history to nursing students. She is a Professor Emerita from the School of Nursing at Western Michigan University, where she taught psychiatric nursing and nursing history and researched nursing history. Dr. Hamilton is a member of the American Nurses' Association, the American Association of the History of Nursing, the American Association for the History of Medicine, the American Association of University Women, and Sigma Theta Tau. In

Pharmacology for Nursing Care, 7th Edition

addition, Dr. Hamilton is a recipient of the Best of *Image* Award in nursing history, the Lavinia Dock Award for historical scholarship, the Best Investigator Award from the University of Rochester, the Golden Apple Teaching Award from the Medical University of South Carolina, and the Distinguished Scholar Award from Western Michigan University.

Welcome to Our Seventh Edition

Welcome to the seventh edition of *Pharmacology for Nursing Care*, the pharmacology text that students *like* to read. Really! This edition, like the first six, was written to be a true textbook—that is, a book that focuses on essentials and plays down secondary details. To give the book focus, four primary techniques are employed: (1) teaching through prototypes, (2) using large print for essential information and small print for secondary information, (3) limiting discussion of adverse effects and drug interactions to information that matters most, and (4) using evidence-based clinical guidelines to determine what content to stress. To reinforce the relationship between pharmacologic knowledge and nursing practice, nursing implications are integrated into the body of each chapter. Also, to provide rapid access to nursing content, nursing implications are summarized at the end of most chapters, using a nursing process format. In addition, key points are summarized at the end of each chapter. As in prior editions, this edition emphasizes conceptual material, thereby reducing rote memorization, promoting comprehension, and increasing reader friendliness. For a description of the book's classic distinguishing features, please refer to the Preface, which follows on page [xii](#).

WHAT'S NEW IN THE BOOK?

Pharmacology for Nursing Care has been revised cover to cover. Topics with significantly expanded coverage include diabetes, drugs affecting the renin-angiotensin-aldosterone system, drug therapy of cancer, and dietary supplements. This edition introduces a host of new drugs and four new Special Interest Topics. In addition, new treatment guidelines have been added, and older guidelines have been updated.

New Drugs

More than new 90 drugs have been added. Among these are

- Varenicline [Chantix], the most effective pharmacologic aid to smoking cessation
- HPV vaccine [Gardasil], the first vaccine to protect against cervical cancer (and genital warts too)
- Sitagliptin [Januvia], the first representative of a new class of antidiabetic drugs, the gliptins
- Ranolazine [Ranexa], the first new type of drug for angina in over 25 years
- Febuxostat [Uloric], the first new drug for gout in over 40 years
- Aliskiren [Tekturna], the first direct renin inhibitor
- Two new types of drugs for HIV infection—maraviroc [Selzentry], the first CCR5 antagonist, and raltegravir [Isentress], the first integrase inhibitor
- Sixteen anticancer drugs, including azacitidine [Vidaza], a hypomethylating agent; sorafenib [Nexavar], an oral tyrosine kinase inhibitor; and lapatinib [Tykerb], an oral HER2 inhibitor

Restructured Content

One chapter from the prior edition—*Drugs for Rheumatoid Arthritis and Gout*—has been divided into two chapters: *Drugs for Arthritis* and *Drugs for Gout*. The title of another chapter—*Herbal Supplements*—has been changed to *Dietary Supplements*, to reflect inclusion of glucosamine and other nonherbal agents that are marketed as supplements. For several chapters, the internal structure has been modified. In most cases, these changes are minor. However, for two chapters—*Anticoagulant, Antiplatelet, and Thrombolytic Drugs* ([Chapter 51](#)) and *Drugs for Asthma* ([Chapter 75](#))—restructuring is extensive. Three appendices—*Weights and Measures*,

Pharmacology for Nursing Care, 7th Edition

Normal Laboratory Values, and *Techniques of Drug Administration*—have been moved from the book to our web site—<http://evolve.elsevier.com/Lehne>, and one appendix—*Poison Control Centers in the United States*—has been dropped, because your local center can now be contacted through a nationwide hotline: 1-800-222-1222.

New Special Interest Topics

This edition has 27 boxes on Special Interest Topics, which address issues that I find especially engaging and think you might too. Some boxes discuss cutting-edge therapies, some discuss ongoing controversies, some discuss topics of general interest, and some discuss issues featured in the popular press. Four boxes are new:

- Did Kisses Kill Calvin?
- Gastroesophageal Reflux Disease
- Chronic Obstructive Pulmonary Disease
- Methicillin-Resistant *Staphylococcus aureus*

Two boxes have been substantially revised:

- Inflammation, C-Reactive Protein, and Cardiovascular Risk
- Emergency Contraception

A complete list of Special Interest Topics appears on the inside back cover.

LEARNING SUPPLEMENTS FOR STUDENTS

Evolve Student Resources

To accompany this edition, we have seven online resources: Flashcards, an Audio Drug Glossary, Key Points (Audio), NCLEX[®] Examination Review Questions, Clinical References (audio and printable), Study Guide Answer Key, and WebLinks. All of these resources are available at <http://evolve.elsevier.com/Lehne>.

- *Flashcards* summarize the need-to-know information for more than 100 key drugs. These printable flashcards include the following for each drug: generic name, trade name, category, mechanism of action, uses, and adverse effects.
- The *Audio Drug Glossary* contains sound files that pronounce the generic names of the 300 most commonly prescribed drugs. As discussed in [Chapter 3](#), if drugs were assigned

x

xi

Pharmacology for Nursing Care, 7th Edition

generic names whose pronunciation was obvious, a glossary such as this would be unnecessary. I look forward to the day when that's the case.

- *Key Points* for each chapter, which can be downloaded to a CD or MP3 player to listen to and review at your leisure. You can also print the Key Points.
- Approximately 700 *NCLEX® Examination Review Questions* help build confidence in test taking and help ensure comprehension in an engaging way.
- *Clinical References* includes a concise overview of drug administration techniques, normal laboratory values, and much more.
- The *Study Guide Answer Key* allows you to compare your answers to the answer guidelines from the Study Guide author.
- The *WebLinks* represent a large and dynamic library of links to drug-related web sites, keyed to the table of contents of this edition.

Pharmacology Online

Pharmacology Online for *Pharmacology for Nursing Care*, 7th edition (ISBN: 978-1-4160-6247-9), is a dynamic, online course resource that includes interactive self-study modules, a collection of interactive learning resources, and a media-rich library of supplemental resources:

- *Self-Study Modules* cover the basic principles of pharmacology and key drug content, with animations and NCLEX examination-style questions to help you assess your understanding of pharmacology concepts.
- *Interactive Case Studies* immerse you in true-to-life scenarios that require you to make important choices in patient care and patient teaching.
- “*Roadside Assistance*” Video Clips use humor and analogy in a uniquely fun and engaging way to teach key concepts.
- Also includes Interactive Learning Activities, Flashcards, Practice Quizzes for the NCLEX Examination, and much more!

Study Guide

The *Study Guide* (ISBN: 978-1-4160-6248-6), which is keyed to the book, includes multiple-choice questions, critical thinking questions, and case studies. Answers are provided on the

Pharmacology for Nursing Care, 7th Edition

Evolve web site. This edition features an increased emphasis on prioritization of nursing care to enhance preparation for the NCLEX exam.

TEACHING SUPPLEMENTS FOR INSTRUCTORS

Evolve Instructor Resources

The Instructor Resources for the seventh edition are available online. There are five components: an Instructor's Manual, a Test Bank, PowerPoint Slides, Audience Response System Questions, and an Image Collection.

- The *Instructor's Manual*, which has been thoroughly revised, emphasizes creative learning strategies to help students apply knowledge of pharmacology to nursing practice. Included for each chapter are learning objectives, key terms, chapter focus, chapter outline, classroom strategies, collaborative/active learning activities, clinical laboratory strategies, web-related activities, quizzes, and critical thinking case studies. Answers for the quizzes and case studies are also provided.
- The *Test Bank* has 1200 NCLEX examination-style questions presented in versatile ExamView software, which allows faculty to customize paper-based and/or online exams through an easy-to-use, intuitive interface. For each question, we indicate the correct answer, rationale, text page reference, cognitive level, nursing process step, and NCLEX® Client Need category.
- The *PowerPoint Slides* have been updated, with images from the book inserted where applicable. The 700 or so slides may be used as-is, or adapted for classroom or online presentation.
- The *Audience Response System Questions* contain approximately 225 questions appropriate for use with clickers/audience response systems.
- The *Image Collection* contains nearly every illustration from the book—about 170 all told, most in full color. The images are presented in electronic format to facilitate classroom projection or online teaching.

Pharmacology for Nursing Care, 7th Edition

Make the most of your time with Evolve eBooks. With easy access from your computer or any Internet browser, you and your students can:

- Search across an entire library of Elsevier e-textbooks simultaneously
- Create focused, customized study documents
- Make and share notes, highlights, and more

Evolve eBooks revolutionizes the way your students study and learn.

To obtain these resources, contact your Elsevier Educational Sales Representative. If you don't know who your rep is, you can find out by checking the Sales Representative Locator at <http://us.elsevierhealth.com/replocator.jsp> or by calling Elsevier Faculty Support at 1-800-222-9570.

PLEASE WRITE

I'd like to hear from you. All feedback is welcome. Suggestions for improving the book are especially helpful, as are reports of mistakes you may spot. Of course, I also like to hear from readers who simply have something nice to say. You can reach me by e-mail at rich@lehne.me¹, or by U.S. Mail at 1619 Willow Dale Lane, Charlottesville, VA, 22911. Or feel free to leave a note on my Facebook page.

Richard A. Lehne

- 1 This e-mail address—rich@lehne.me—is permanent, unlike the address I gave in the sixth edition, which died when my internet service provider was absorbed by a stronger company. I apologize to those of you who tried to contact me and were informed that the e-mail address was no longer valid.

xii

Preface

Pharmacology pervades all phases of nursing practice and relates directly to patient care and patient education. Yet, despite its importance, many students—and even some teachers—are often uncomfortable with the subject. Why? Because, traditional texts have stressed memorizing details rather than understanding. In this text, the guiding principle is to establish a basic understanding of drugs, after which secondary details can be learned as needed. Judging from the acceptance of this book, my departure from tradition has been welcome.

I wrote this text with two major objectives: To help you, the nursing student, establish a knowledge base in the basic science of drugs, and to show you how that knowledge can be applied in clinical

practice. To achieve these goals, I have used several innovative techniques, which are described below.

Laying Foundations in Basic Principles

In order to understand drugs, you need a solid foundation in basic pharmacologic principles. To establish this foundation, I have dedicated major chapters to the following topics: basic principles that apply to all drugs ([Chapter 4](#) through [8](#)), basic principles of drug therapy across the life span ([Chapters 9](#) through [11](#)), basic principles of neuropharmacology ([Chapter 12](#)), basic principles of antimicrobial therapy ([Chapter 82](#)), and basic principles of cancer chemotherapy ([Chapter 100](#)).

Reviewing Physiology and Pathophysiology

To understand the actions of a drug, you must first understand the biologic systems that the drug influences. Accordingly, for all major drug families, relevant physiology and pathophysiology are reviewed. In almost all cases, these reviews are presented at the beginning of each chapter, rather than in a systems review at the beginning of a unit. This juxtaposition of pharmacology, physiology, and pathophysiology is designed to help you understand how these topics interrelate.

Teaching Through Prototypes

Within each drug family, we can usually identify a prototype: a representative agent that characterizes all members of the group. Because other family members are very similar to the prototype, to know the prototype is to know the basic properties of all family members.

The benefits of teaching through prototypes can be appreciated with an example. Let's consider the nonsteroidal anti-inflammatory drugs (NSAIDs), a family that includes aspirin, ibuprofen [Motrin, others], naproxen [Aleve, others], celecoxib [Celebrex], and more than 20 other drugs.

Traditionally, information on these drugs is presented in a series of paragraphs describing each drug in turn. When attempting to study from such a list, students are likely to learn many drug names and little else; the important concept of similarity among family members is easily lost. In this text, the family prototype—aspirin—is discussed first and in depth. After this, instruction is completed by pointing out the relatively minor ways in which individual NSAIDs differ from aspirin. Not only is this approach more efficient than the traditional approach, it is also more effective, in that similarities among family members are emphasized.

Large Print and Small Print: A Way to Focus on Essentials

Pharmacology is exceptionally rich in detail. There are many drug families, each with multiple members and each member with its own catalogue of indications, contraindications, adverse

effects, and drug interactions. This abundance of detail confronts teachers with the difficult question of what to teach, and confronts students with the equally difficult question of what to study. Attempting to answer these questions can frustrate teachers and students alike. Even worse, in the presence of myriad details, basic concepts can be obscured.

To help you focus on essentials, I use two sizes of type. Large type is intended to say, “On your first exposure to this topic, this is the core of information you should learn.” Small type is intended to say, “Here is additional information that you may want to learn after mastering the material in large type.” As a rule, I reserve large print for prototypes, basic principles of pharmacology, and reviews of physiology and pathophysiology. Small print is used for secondary information about the prototypes and for discussion of drugs that are not prototypes. This technique allows the book to contain a large body of detail without having that detail cloud the big picture. Furthermore, because the technique highlights essentials, it minimizes questions about what to teach and what to study.

The use of large and small print is especially valuable for discussing adverse effects and drug interactions. Most drugs are associated with many adverse effects and interactions. As a rule, however, only a few of these are noteworthy. In traditional texts, practically all adverse effects and interactions are presented, creating long and tedious lists. In this text, I use large print to highlight the few adverse effects and interactions that are especially characteristic; the rest are noted briefly in small print. The result? Rather than overwhelming you with long and forbidding lists, this text delineates a moderate body of information that's truly important, and thereby facilitates comprehension.

Using Clinical Reality to Prioritize Content

This book contains two broad categories of information: pharmacology (ie, basic science about drugs) and therapeutics (ie, clinical use of drugs). To ensure that content is clinically relevant, I use evidence-based treatment guidelines as a basis for deciding what to stress and what to play down. Unfortunately, clinical practice is a moving target: When effective new drugs are introduced, and when clinical trials reveal new benefits or new risks of older drugs, the guidelines change—and hence large sections of this book must be rewritten. Consider the following examples:

- When the first edition of this book published, heart failure was considered an absolute contraindication to the use of beta blockers. After all, in patients with heart failure, cardiac contractility is greatly reduced, and beta blockade can reduce contractility even further. Nonetheless, we now know that, when dosed properly, beta blockers can be of great benefit

xii

xiii

in heart failure, and hence these drugs are now considered first-line therapy—rather than drugs to be avoided.

- When the third edition of this book published, experts recommended that all postmenopausal women consider using estrogen replacement therapy long term to prevent osteoporosis and heart disease; adverse effects were considered trivial. Today, we know that the benefits of postmenopausal estrogen therapy are much smaller than previously believed, and the risks are greater. As a result, guidelines now recommend that estrogen therapy be used only to relieve severe menopausal symptoms, and that women use the lowest dosage possible for the shortest time necessary.

These examples illustrate two problems. First, because clinical practice is subject to change, I have to work hard to keep this book current. Second, despite my best efforts, the book and clinical reality may not agree: Some treatments discussed here will be considered inappropriate before the eighth edition comes out. Furthermore, in areas where there is controversy, the treatments discussed here may be considered inappropriate by some clinicians right now.

Nursing Implications: Demonstrating the Application of Pharmacology in Nursing Practice

The principal reason for asking you to learn pharmacology is to enhance your ability to provide patient care and education. To show you how pharmacologic knowledge can be applied to nursing practice, nursing implications are integrated into the body of each chapter. That is, as specific drugs and drug families are discussed, the nursing implications inherent in the pharmacologic information are discussed side-by-side with the basic science. To facilitate access to nursing content, nursing implications are also summarized at the end of most chapters. These summaries serve to reinforce the information presented in the chapter body.

In chapters that are especially brief or that address drugs that are infrequently used, summaries of nursing implications have been omitted. However, even in these chapters, nursing implications are incorporated into the chapter body.

About Dosage Calculations

Unlike many nursing pharmacology texts, this one has no section on dosage calculation. Why? First, adequate discussion of this important subject simply isn't feasible in a text dedicated to the basic science of drugs; the amount of space that can be allotted is too small. Second, thanks to the availability of excellent publications on the subject (eg, *Calculate with Confidence*, 4th edition, by Deborah Gray Morris), there is no need to include this content in a pharmacology text.

Ways to Use This Textbook

Thanks to its focus on essentials, this text is especially well suited to serve as the primary text for a course dedicated specifically to pharmacology. In addition, the book's focused approach makes it a valuable resource for pharmacologic instruction within an integrated curriculum and for self-directed learning by students, teachers, and practitioners.

Richard A. Lehne

xiii

Acknowledgments

xiv

I want to begin by thanking all involved members of my extended publishing family at Elsevier Health Sciences. For 24 years, these good people have provided support, encouragement, and guidance, along with the latitude to write the book I had hoped to create. Of equal importance, they committed the human and monetary resources required to make a high quality product—a concept that seems almost quaint in today's grab-all-the-bucks-you-can world.

Of course, to make a good product, you need a good team. For this edition, the Dream Team, who gave you the sixth edition, returned en masse. Who are these winners? Well, playing senior editor, we have Kristin—The Longsuffering—Geen; in the senior developmental editor slot, there's Lauren—The Comforting—Lake; as senior project manager, there's Anne—Mistress of Detail—Konopka; our proofreader is Judi—The Awe-inspiring—May; playing copyeditor, for her fifth season, is Megan—The Incomparable—Westerfeld; and in the role of publishing services manager, we have Jeff—Keeper of Rules—Patterson. Our executive publisher is Loren Wilson, and our designer, once again, is Teresa McBryan, senior book designer.

My appreciation and respect for the Dream Team is hard to describe. By the time they begin work on this project, I've already devoted nearly a year of full-time work to revising the manuscript, which means I'm on the verge of exhaustion—with very little energy left for production. Happily, because of the Dream Team, I don't need much. These guys are so good at their jobs, that I feel 100% comfortable turning my baby over to their capable hands. The result, which you hold in *your* hands, is, I believe, the best that any publishing team could produce. If you agree, you too can thank the Dream Team—for their dedication, proficiency, and commitment to quality.

For this edition, it's been my pleasure to work with five contributors: Marshal Shlafer, PhD ([Chapters 49](#) and [56](#), Marilynn Frederiksen, MD ([Chapters 60](#) and [61](#), Jack Le Frock, BA, MSC, PhD, MN, CPE ([Chapters 92](#) and [93](#), Tim McGuire, PharmD, BCOP, FCCP ([Chapters 100](#), [101](#), and [102](#)), and Susan Paulsen, PharmD ([Chapter 107](#)), Four of these people—Drs Frederiksen, Le Frock, McGuire, and Paulsen—are experts in the areas they wrote about. The fifth contributor—Marshal

Pharmacology for Nursing Care, 7th Edition

Shlafer—although not an expert in the areas he wrote about (diabetes and hyperlipidemias), is someone even more valuable: a beloved and respected teacher, and an accomplished author in his own right (the first edition of *his* pharmacology text published a few months before the first edition of *this* text). The input of all five contributors has greatly improved the chapters they revised.

In addition to the Dream Team and the contributors, I want to recognize the following people for their contributions:

- I profoundly thank *Stephen Setter, PharmD, DVM, CDE, CGP, FASCP*, and his colleague, *Joshua Neumiller, PharmD, CDE, CGP, FASCP*, for reviewing every chapter to ensure that information on drug formulations, dosages, and usage is accurate, current, and complete. Their Herculean efforts have contributed hugely to the quality of this book.
- I thank *Sherry Neely, MSN, RN, CRNP*, who wrote the Study Guide for this edition (as well as the prior edition), and I thank all of the other people, whose names are presented on pages [vii-viii](#), who wrote other ancillary materials that accompany this edition.
- I thank Alfred J. Rémillard, PhD, who wrote the appendix on Canadian drug information for the first edition of this book, and has revised that appendix for each edition since.
- I am grateful for the suggestions offered by a small army of reviewers, whose names are listed on page [ix](#). All of these experts are practicing clinicians. As a result, their input has helped keep the book in tune with current clinical reality.
- I thank *Alan Agins, PhD*, my friend and colleague, for the use of his drug animations. Alan created these clips to illustrate his lectures on pharmacology, which he delivers to nursing audiences around the country. So, if you need a great speaker, look him up.
- And I thank all members of the Elsevier educational sales force, whose professionalism and determination have contributed immeasurably to the book's continued success.

Finally, I thank you, Nancy, for your support, patience, and love—all of which were mightily tested over the course of this revision.

PART III. URINE CHEMISTRY

f5

For some procedures the reference values may vary depending on the method used.

	Conventional Units	SI Units*
Acetone and acetoacetate, qualitative	Negative	Negative
Albumin		
Qualitative	Negative	Negative
Quantitative	10–100 mg/24 hr	0.15–1.5 micromole/day
Aldosterone	3–20 mcg/24 hr	8.3–55 nmol/day
Delta-aminolevulinic acid (delta-ALA)	1.3–7 mg/24 hr	10–53 micromole/day
Amylase	<17 U/hr	<17 U/hr
Amylase/creatinine clearance ratio	0.01–0.04	0.01–0.04
Bilirubin, qualitative	Negative	Negative
Calcium (regular diet)	<250 mg/24 hr	<6.3 mmol/day
Catecholamines		
Epinephrine	<10 mcg/24 hr	<55 nmol/day
Norepinephrine	<100 mcg/24 hr	<590 nmol/day
Total free catecholamines	4–126 mcg/24 hr	24–745 nmol/day
Total metanephrines	0.1–1.6 mg/24 hr	0.5–8.1 micromole/day
Chloride (varies with intake)	110–250 mEq/24 hr	110–250 mmol/day
Copper	0–50 mcg/24 hr	0.0–0.80 micromole/day
Cortisol, free	10–100 mcg/24 hr	27.6–276 nmol/day
Creatine		
Males	0–40 mg/24 hr	0.0–0.30 mmol/day
Females	0–80 mg/24 hr	0.0–0.60 mmol/day
Creatinine	15–25 mg/kg/24 hr	0.13–0.22 mmol/kg/day
Creatinine clearance (endogenous)		
Males	110–150 mL/min/1.73 m ²	110–150 mL/min/1.73 m ²
Females	105–132 mL/min/1.73 m ²	105–132 mL/min/1.73 m ²
Cystine or cysteine	Negative	Negative
Dehydroepiandrosterone		
Males	0.2–2 mg/24 hr	0.7–6.9 micromole/day
Females	0.2–1.8 mg/24 hr	0.7–6.2 micromole/day
Estrogens, total		
Males	4–25 mcg/24 hr	14–90 nmol/day
Females	5–100 mcg/24 hr	18–360 nmol/day

Pharmacology for Nursing Care, 7th Edition

Glucose (as reducing substance)	<250 mg/24 hr	<250 mg/day	
Hemoglobin and myoglobin, qualitative	Negative	Negative	
Homogentisic acid, qualitative	Negative	Negative	
17-Hydroxycorticosteroids			
Males	3–9 mg/24 hr	8.3–25 micromole/day	
Females	2–8 mg/24 hr	5.5–22 micromole/day	
5-Hydroxyindoleacetic acid

Techniques of Drug Administration

LINDA A. MOORE, MSN, EDD, RN

Type of Administration	Technique to Use
ORAL	
Liquids	General Considerations 1. Perform any required dilution using appropriate liquid. Avoid liquids that can reduce drug absorption (eg, milk will decrease absorption of tetracyclines). 2. Measure using medicine cup or device supplied with medication. 3. Pour medication away from label/directions. 4. Read amount at bottom of meniscus (see diagram below). 5. Do not leave patient before medication is taken. Infants Do not mix medication with formula or juice in bottle (you cannot be sure of amount taken if all of the liquid is not swallowed). Nasogastric Tube Administration 1. Ensure correct location of the tube. 2. Follow directions for diluting (eg, Metamucil becomes thick rapidly and should be mixed at time of administration, not before). 3. Follow with sufficient liquid to clear the tube (stay within fluid restrictions). Tablets, Capsules 1. If possible, have the patient in a sitting position to facilitate swallowing. 2. Check requirement for administration with food or liquids (eg, medications that irritate often need to be given with food; some medications may have decreased absorption with food). 3. Provide proper liquid for swallowing (stay within fluid restrictions, or, if patient needs increased fluids, this is a good time to provide extra fluid). Chewable Tablets Be sure tablet is completely chewed before it is swallowed. SUBLINGUAL AND BUCCAL Sublingual 1. Place tablet under tongue, and instruct patient to hold it there until dissolved. 2. Swallowing of residual should then occur. Buccal 1. Instruct patient to hold medication between gums and cheek until it is dissolved. 2. Residual can then be swallowed. RECTAL (SUPPOSITORY)

	1. Patient is to lie in left lateral Sims' position. 2. Nurse to wear gloves during procedure. 3. Lubricate suppository and glove fingertip with water-soluble lubricant. 4. Insert suppository when rectal sphincter is relaxed (see diagram below).	f1b f2b
		
VAGINAL	5. Instruct patient as to length of time to retain medication (about 20 to 30 minutes for defecation stimulation and about 60 minutes for systemic absorption). 1. Wear gloves during procedure. 2. Insert foam or suppository into vagina. 3. Instruct patient as to length of time to remain lying down.	
TOPICAL	1. Wear gloves when applying any topical ointment. 2. Apply with applicator, gauze, or gloved hand. 3. Apply a thin layer by patting, not rubbing. 4. Take care to protect the patient's clothing. 5. Certain medications require plastic wrap to increase absorption (eg, nitroglycerin ointment).	
OTIC		

- 1. Medication should be at body temperature.
- 2. Patient should lie on side with appropriate ear up.
- 3. Instill drops toward auditory canal wall, not on eardrum. Procedure varies for adults and children. *Adults:* The auricle is pulled back and posteriorly. *Children:* The auricle is pulled down and posteriorly (see diagram below).

f2b

f3c

- 4. Rest hand administering drops lightly against the patient's head to prevent injury from dropper should the patient suddenly move.
- 5. After instillation, the patient should remain in this position for about 15 minutes.

OPTIC

- 1. Have patient lying on back with eyes facing up.
- 2. Do not touch tip of dropper to patient or to any object.
- 3. Have tissues available to blot any overflow from eyes (use separate tissue for each eye).
- 4. Rest hand instilling drops on patient's forehead to stabilize dropper and to prevent injury due to sudden patient movement.
- 5. Instill drops into conjunctival pouch while patient looks upward (see diagram below).

- 6. To decrease systemic absorption, light pressure may be applied to lacrimal sac for about a minute.
- 7. *Ointment* is applied as a thin "ribbon" along inner aspect of lower lid. Do not touch tube to eye or other surface.

INTRADERMAL 1. Select an appropriate site. (Usual sites for *skin testing* are shown in the diagram below.)

2. Use a short-bevel (26-gauge, 3/8-inch) needle.

3. Amount of medication is limited to 1 mL or less.

4. If skin testing is being done, have emergency medication (epinephrine) available.

5. With bevel of needle pointed up, inject medication into layers of the skin (see diagram below).

6. Use dry wipe to wipe area following injection.

SUBCUTANEOUS

1. Select a needle size (usually 25 to 27 gauge, $\frac{1}{2}$ to $\frac{5}{8}$ inch).

2. Select a site that has adequate subcutaneous tissue and that is away from bony prominences, major nerves, and blood vessels (see diagram below).

3. Angle of needle insertion depends on size of the individual. Obese people will require needle inserted at 90° angle, whereas very thin people will require pinching of the skin, with insertion at a 90° angle to the pocket pinched. Individuals who are neither fat nor very thin require a 45° angle for needle insertion (see diagram below).

4. Aspiration for blood depends on substance being injected. Follow protocol.

5. Do not rub most subQ injection sites.

INTRAMUSCULAR

1. Select a needle length appropriate to size of patient. The needle should be long enough to reach to the middle of the muscle. Measure the circumference of the arm and select appropriate needle length. The average person requires a 1½- to 2-inch needle. Muscular males require 2- to 3-inch needles or as long as 3 to 5 inches in some cases.

2. Select technique of injection.

a. *Standard*—insert needle at 90° angle to the muscle after area is cleaned.

b. *Z-track method*—pull tissue to one side, insert needle, inject medication, and allow tissue to return to original position as needle is removed. (Used for medications that damage tissue and as a method to decrease pain of injection.)

3. Select site of injection:

a. *Dorsogluteal*—to locate, draw a diagonal line between the superior iliac spine and the greater trochanter of the femur (see diagram below). Patient should be prone with toes turned inward. Do not use this site for children less than 2 years of age or for children who are emaciated.
- f4c
- f5b
-
-
- b. *Ventrogluteal*—to locate, place palm of hand over the greater trochanter of the femur with thumb pointing to patient's abdomen, index finger placed over the anterior iliac spine, and middle finger spread back toward the iliac crest. The V-shaped area between the fingers is the ventrogluteal site. Direct needle toward largest muscle mass (see diagram below).
-
-
- Front Matter
- Page 36 of 38

c. *Anterolateral thigh*—area is one-third the distance from the greater trochanter to the knee and is between the midline of the anterior and lateral thighs (see diagram below). This is a good site for infants and children.

d. *Deltoid*—area is bordered above by 2 fingerbreadths below the acromion process and below by 2 fingerbreadths above the insertion of the deltoid (see diagram below). Injection site must be in lateral aspect of the arm.

4. Insert needle at 90° angle. Aspirate to be sure the needle is not in a blood vessel. Inject slowly. Withdraw needle, and apply pressure to site. Inject slowly. Withdraw needle, and apply pressure to site.

INTRAVENOUS

1. Only clinicians with specific training should inject medication intravenously.
2. Medications can be administered into a continuous IV or a heparin lock designed for intermittent administration. Be sure medication is compatible with solution being infused. Check for infiltration prior to administering medication.
3. Do not administer medications that have precipitates or discoloration.
4. Dilute according to directions. Certain medications are not to be diluted. Be sure to check specifics.
5. If "piggybacking" medication, set drip rate for proper infusion time. Note drip rate on IV tubing package.
6. Tape IV line securely but with some flexibility in the tubing.
7. Check IV frequently for correct infusion rate. Discontinue when complete dose has been delivered.
8. Record the name of the medication and volume of fluid administered.

¹ CHAPTER 1 Orientation to Pharmacology

If you are a typical nursing student, by now you've been hitting the books for 14 or so years and have probably asked yourself, "What's the purpose of all this education?" In the past your question may have lacked a satisfying answer. Happily, now you have one: The reason you've spent most of your life in school was to get ready to study pharmacology!

There's good reason why you haven't approached pharmacology before now. Pharmacology is a science that draws on information from multiple disciplines, among them anatomy, physiology, psychology, chemistry, and microbiology. Consequently, before you could study pharmacology, you had to become familiar with these other sciences. Now that you've established the requisite knowledge base, you're finally ready to learn about drugs.

^{1.1} FOUR BASIC TERMS

At this point it will help to define four basic terms: *drug*, *pharmacology*, *clinical pharmacology*, and *therapeutics*. As we go through these definitions, we will also consider the kinds of drug-related information that this text does and does not address.

^{1.1.1} Drug.

A drug is defined as *any chemical that can affect living processes*. By this definition, virtually all chemicals can be considered drugs, since, when exposure is sufficiently high, all chemicals will have some effect on life. Clearly, it is beyond the scope of this text to address all compounds that fit the definition of a drug. Accordingly, rather than discussing all drugs, we will focus primarily on drugs that have therapeutic applications.

^{1.1.2} Pharmacology.

Pharmacology can be defined as *the study of drugs and their interactions with living systems*. Given this definition, the science of pharmacology can claim a huge body of knowledge as its own. Under our definition, pharmacology encompasses the study of the physical and chemical properties of drugs as well as their biochemical and physiologic effects. In addition, pharmacology includes knowledge of the history, sources, and uses of drugs as well as knowledge of drug absorption, distribution, metabolism, and excretion. Because pharmacology encompasses such a broad spectrum of information, it would be inappropriate (not to mention impossible) to address the entire scope of pharmacology in this text. Consequently, consideration is limited to information that is clinically relevant.

1.1.3 Clinical Pharmacology.

Clinical pharmacology is defined as *the study of drugs in humans*. This discipline includes the study of drugs in *patients* as well as in *healthy volunteers* (during new drug development). Because clinical pharmacology encompasses all aspects of the interaction between drugs and people, and since our primary interest is the use of drugs to treat patients, clinical pharmacology includes some information that is outside the scope of this text.

1.1.4 Therapeutics.

Therapeutics, also known as *pharmacotherapeutics*, is defined as *the use of drugs to diagnose, prevent, or treat disease or to prevent pregnancy*. Alternatively, therapeutics can be defined simply as *the medical use of drugs*.

In this text, therapeutics is our principal concern. Accordingly, much of our discussion focuses on the basic science that underlies the clinical use of drugs. This information is intended to help you understand how drugs produce their effects—both therapeutic and adverse; the reasons for giving a particular drug to a particular patient; and the rationale underlying selection of dosage, route, and schedule of administration. This information will also help you understand the strategies employed to promote beneficial drug effects and to minimize undesired effects. Armed with this knowledge, you will be well prepared to provide drug-related patient care and education. In addition, by making drugs less mysterious, this knowledge should make working with them more comfortable, and perhaps even more satisfying.

1.2 PROPERTIES OF AN IDEAL DRUG

If we were developing a new drug, we would want it to be the best drug possible. In order to approach perfection, our drug should have certain properties, such as effectiveness and safety. In the discussion below, we consider these two characteristics as well as others that an ideal drug might have. Please note, however, that the ideal medication exists in theory only: In reality, *there's no such thing as a perfect drug*. The truth of this statement will become apparent as we consider the properties that an ideal drug should have.

1.2.1 The Big Three: Effectiveness, Safety, and Selectivity

The three most important characteristics that any drug can have are effectiveness, safety, and selectivity.

1.2.1.1 Effectiveness.

An effective drug is one that elicits the responses for which it is given. *Effectiveness is the most important property a drug can have.* Regardless of its other virtues, if a drug is not effective—that is, if it doesn't do anything useful—there is no justification for giving it. Current U.S. law requires that all new drugs be proved effective prior to release for marketing.

1.2.1.2 Safety.

A safe drug is defined as one that cannot produce harmful effects—even if administered in very high doses and for a very long time. *There is no such thing as a safe drug.* All drugs have the ability to cause injury, especially with high doses and prolonged use. The chances of producing adverse effects can be reduced by proper drug selection and proper dosing. However, the risk of adverse effects can never be eliminated. The following examples illustrate this point:

- Certain anticancer drugs (eg, cyclophosphamide, methotrexate), at usual therapeutic doses, always increase the risk of serious infection.
- Opioid analgesics (eg, morphine, meperidine), at high therapeutic doses, can cause potentially fatal respiratory depression.
- Aspirin and related drugs, when taken chronically in high therapeutic doses, can cause life-threatening gastric ulceration, perforation, and bleeding.

Clearly, drugs are not safe. This fact may explain why the Greeks chose the word *pharmakon*, which can be translated as *poison*, as a name for these agents.

1.2.1.3 Selectivity.

A selective drug is defined as one that elicits only the response for which it is given. A selective drug would not produce side effects. *There is no such thing as a selective drug: All medications cause side effects.* Common examples include the drowsiness that can be caused by many antihistamines; the morning sickness, cramps, and depression that can be caused by oral contraceptives; and the sexual dysfunction (eg, impotence, anorgasmia) commonly caused by fluoxetine [Prozac] and related antidepressants.

1.2.2 Additional Properties of an Ideal Drug

1.2.2.1 Reversible Action.

For most drugs, it is important that effects be reversible. That is, in most cases, we want drug actions to subside within an appropriate time. General anesthetics, for example, would be useless if patients never woke up. Likewise, it is unlikely that oral contraceptives would find wide acceptance if they caused permanent sterility. And, despite what some gentlemen (and gentlewomen) might think, sildenafil [Viagra] would be more curse than blessing if it produced a perpetual gallant salute. For a few drugs, however, reversibility is not desirable. With antibiotics, for example, we want toxicity to microbes to endure.

1.2.2.2 Predictability.

It would be very helpful if, prior to drug administration, we could know with certainty just how a given patient will respond. Unfortunately, since each patient is unique, the accuracy of such predictions cannot be guaranteed. Accordingly, in order to maximize the chances of eliciting desired responses, we must tailor therapy to the individual.

1.2.2.3 Ease of Administration.

An ideal drug should be simple to administer: The route should be convenient, and the number of doses per day should be low. Diabetic patients, who must inject insulin multiple times a day, are not likely to judge this drug ideal. Similarly, nurses who must set up and monitor IV infusions are unlikely to consider intravenous drugs ideal.

In addition to convenience, ease of administration has two other benefits: (1) it can enhance patient adherence and (2) it can decrease administration errors. Patients are more likely to adhere to a dosing schedule that consists of one daily dose rather than several. Similarly, hospital personnel are less likely to commit medication errors when administering oral drugs than when preparing and administering intravenous formulations.

1.2.2.4 Freedom from Drug Interactions.

When a patient is taking two or more drugs, those drugs can interact. These interactions may either augment or reduce drug responses. For example, respiratory depression caused by diazepam [Val-ium], which is normally minimal, can be greatly *intensified* by alcohol. Conversely, the antibacterial effects of tetracycline can be greatly *reduced* by taking the drug with iron or calcium supplements. Because of the potential for interaction among drugs, when a patient is taking more

than one agent, the possible impact of drug interactions must be considered. An ideal drug would not interact with other agents. Unfortunately, few medicines are devoid of significant interactions.

1.2.2.5 Low Cost.

An ideal drug would be easy to afford. The cost of drugs can be a substantial financial burden. As an extreme example, 1 year of therapy with natalizumab [Tysabri], a new drug for multiple sclerosis, can cost \$25,000 or more. More commonly, expense becomes a significant factor when a medication must be taken chronically. For example, people with hypertension, arthritis, or diabetes must take medications lifelong. The cumulative expense of such treatment can be huge—even for drugs of moderate price.

1.2.2.6 Chemical Stability.

Some drugs lose effectiveness during storage. Others that may be stable on the shelf can rapidly lose effectiveness when put into solution (eg, in preparation for infusion). These losses in efficacy result from chemical instability. Because of chemical instability, stocks of certain drugs must be periodically discarded. An ideal drug would retain its activity indefinitely.

1.2.2.7 Possession of a Simple Generic Name.

Generic names of drugs are usually complex, and hence difficult to remember and pronounce. As a rule, the trade name for a drug is much simpler than its generic name. Examples of drugs that have complex generic names and simple trade names include acetaminophen [Tylenol], ranitidine [Zantac], and simvastatin [Zocor]. Since generic names are preferable to trade names (for reasons discussed in [Chapter 3](#)), an ideal drug should have a generic name that is easy to recall and pronounce.

1.2.3 Because No Drug Is Ideal ...

From the preceding, we can see that available medications are not ideal. No drug is safe. All drugs produce side effects. Drug responses may be difficult to predict and may be altered by drug interactions. Drugs may be expensive, unstable, and hard to administer. Because medications are not ideal, all members of the healthcare team must exercise care to promote therapeutic effects and minimize drug-induced harm.

Figure 1-1 Factors that determine the intensity of drug responses.

(Adapted from Koch-Weser J: Drug therapy: serum drug concentrations as therapeutic guides. N Engl J Med 287:227, 1972.)

1.3 THE THERAPEUTIC OBJECTIVE

The objective of drug therapy is to provide maximum benefit with minimum harm. If drugs were ideal, we could achieve this objective with relative ease. However, because drugs are not ideal, we must exercise skill and care if treatment is to result in more good than harm. As detailed in [Chapter 2](#), you have a critical responsibility in achieving the therapeutic objective. In order to meet this responsibility, you must understand drugs. The primary purpose of this text is to help you achieve that understanding.

1.4 FACTORS THAT DETERMINE THE INTENSITY OF DRUG RESPONSES

Multiple factors determine how an individual will respond to a prescribed dose of a particular drug ([Fig. 1-1](#)). By understanding these factors, you will be able to think rationally about how drugs produce their effects. As a result, you will be able to contribute maximally to achieving the therapeutic objective.

Our ultimate concern when administering a drug is the intensity of the response. Working our way up from the bottom of [Figure 1-1](#), we can see that the intensity of the response is determined by the concentration of a drug at its sites of action. As the figure suggests, the primary determinant of this concentration is the administered dose. When administration is performed correctly, the dose that was given will bear a close relationship to the dose that was prescribed. The steps leading from prescribed dose to intensity of the response are considered below.

1.4.1 Administration

Dosage size and the route and timing of administration are important determinants of drug responses. Accordingly, the prescriber will consider these variables with care. Unfortunately, because of poor patient adherence and medication errors by hospital staff, drugs are not always administered as prescribed. The result may be toxicity (if the dosage is too high) or treatment failure (if the dosage is too low). To help minimize errors caused by poor adherence, you should give patients complete instruction about their medication and how to take it.

Medication errors made by hospital staff may result in a drug being administered by the wrong route, in the wrong dose, or at the wrong time; the patient may even be given the wrong drug. These errors can be made by pharmacists, physicians, and nurses. Any of these errors will detract from achieving the therapeutic objective. Medication errors are discussed at length in [Chapter 7](#).

1.4.2 Pharmacokinetics

Pharmacokinetic processes determine how much of an administered dose gets to its sites of action. There are four major pharmacokinetic processes: (1) drug absorption, (2) drug distribution, (3) drug metabolism, and (4) drug excretion. Collectively, these processes can be thought of as the *impact of the body on drugs*. The pharmacokinetic processes are discussed at length in [Chapter 4](#).

1.4.3 Pharmacodynamics

Once a drug has reached its sites of action, pharmacodynamic processes determine the nature and intensity of the response. Pharmacodynamics can be thought of as the *impact of drugs on the body*. In most cases, the initial step leading to a response is the binding of a drug to its receptor. This drug-receptor interaction is followed by a sequence of events that ultimately results in a response. As indicated in [Figure 1-1](#), the patient's "functional state" can influence pharmacodynamic processes. For example, a patient who has developed tolerance to morphine will respond less intensely to a particular dose than will a patient who lacks tolerance. Placebo (psychologic) effects also help determine the responses that a drug elicits. Pharmacodynamics is discussed at length in [Chapter 5](#).

3

4

1.4.4 Sources of Individual Variation

Characteristics unique to each patient can influence pharmacokinetic and pharmacodynamic processes and, by doing so, can help determine the patient's response to a drug. As indicated in [Figure 1-1](#), sources of individual variation include drug interactions; physiologic variables (eg, age, gender, weight); pathologic variables (especially diminished function of the kidneys and liver, the major organs of drug elimination); and genetic variables. Genetic factors can alter the metabolism of drugs and can predispose the patient to unique drug reactions. Because individuals differ from one another, no two patients will respond identically to the same drug regimen. Accordingly, in order to achieve the therapeutic objective, we must tailor drug therapy to the individual. Individual variation in drug responses is the subject of [Chapter 8](#).

1.5 SUMMARY

Whenever medicines are used, our goal is to promote desired effects and minimize adverse effects. In order to achieve this objective, we need to understand pharmacokinetics and pharmacodynamics, the principal determinants of drug responses. In addition, we must account for potential sources of individual variation in drug responses. When all of these considerations are made, the resulting regimen will be tailored to the individual, and hence should produce maximum benefit with minimum harm.

1.5.1 KEY POINTS

- The most important properties of an ideal drug are effectiveness, safety, and selectivity.
- If a drug is not effective, it should not be used.
- There is no such thing as a safe drug: All drugs can cause harm.
- There is no such thing as a selective drug: All drugs can cause side effects.
- The objective of drug therapy is to provide maximum benefit with minimum harm.
- Because all patients are unique, drug therapy must be tailored to each individual.

² CHAPTER 2 Application of Pharmacology in Nursing Practice

Our principal goal in this chapter is to answer the question “Why should a nursing student learn about drugs?” By exploring this question, I want to give you some extra motivation to study pharmacology. Why do I think you might need some motivation? Because I have known many students who, at the beginning of my pharmacology course, questioned the value of learning the material. With some luck, when you complete the chapter, you will be convinced that understanding drugs is essential for nursing practice, and hence that putting time and effort into learning about drugs will be a worthwhile investment. If you are already convinced that understanding pharmacology is important, then just scan the chapter quickly. However, if you are skeptical, then read it carefully. Hopefully, doing so will help you see the light, and thereby boost your motivation for the job ahead.

^{2.1} EVOLUTION OF NURSING RESPONSIBILITIES REGARDING DRUGS

In the past, a nurse's responsibility regarding medications focused mainly on the *Five Rights of Drug Administration*, namely, give the *right drug* to the *right patient* in the *right dose* by the *right route* at the *right time*. More recently, a Sixth Right—right documentation—was added. Clearly, the Six Rights are important. However, although these basics are important, much more is required to achieve the therapeutic objective. The Six Rights guarantee only that a drug will be administered as prescribed. Correct administration, without additional interventions, cannot ensure that treatment will result in maximum benefit and minimum harm.

The limitations of the Six Rights can be illustrated with this analogy: The nurse who sees his or her responsibility as being done following correct drug administration would be like a major league baseball pitcher who felt that his responsibility was over once he had thrown the ball toward the batter. As the pitcher must be ready to respond to the consequences of the interaction between ball and bat, you must be ready to respond to the consequences of the interaction between drug and patient. Put another way, although both the nurse and the pitcher have a clear obligation to deliver their respective “pills” in the most appropriate fashion, proper delivery is only the beginning of their responsibilities: *Important events will take place after the “pill” is delivered, and these must be responded to*. Like the pitcher, the nurse can respond rapidly and effectively only by anticipating (knowing in advance) what the possible reactions to the pill might be.

In order to anticipate possible reactions, both the nurse and the pitcher require certain kinds of knowledge. Just as the pitcher must understand the abilities of the opposing batter, you must understand the patient and the disorder for which he or she is being treated. As the pitcher must know the most appropriate pitch (eg, fast ball, curve, slider) to deliver in specific circumstances, you must

Pharmacology for Nursing Care, 7th Edition

know what medications are appropriate for the patient and must check to ensure that the medication ordered is among them. Conversely, as the pitcher must know what pitches *not* to throw at a particular batter, you must know what drugs are *contraindicated* for the patient. As the pitcher must know the most likely outcome after the ball and bat interact, you must know the probable consequences of the interaction between drug and patient.

Although this analogy is not perfect (the nurse and patient are on the same team, whereas the pitcher and batter are not), it does help us appreciate that the nurse's responsibility extends well beyond the Six Rights. Consequently, in addition to the limited information needed to administer drugs in accordance with the Six Rights, you must acquire a broad base of pharmacologic knowledge so as to contribute fully to achieving the therapeutic objective.

In drug therapy today, nurses, together with physicians and pharmacists, participate in a system of checks and balances designed to promote beneficial effects and minimize harm. Nurses are especially important in this system because it is the nurse—not the physician or pharmacist—who follows the patient's status most closely. As a result, you are likely to be the first member of the healthcare team to observe and evaluate drug responses, and to intervene if required. In order to observe and evaluate drug responses, and in order to intervene rapidly and appropriately, you must know *in advance* the responses that a medication is likely to elicit. Put another way, in order to provide professional care, you must understand drugs; the better your knowledge of pharmacology, the better you will be able to *anticipate* drug responses and not simply react to them after the fact.

Within our system of checks and balances, the nurse has an important role as patient advocate. It is your responsibility to detect mistakes made by pharmacists and physicians—and mistakes *will* be made. For example, the physician may overlook potential drug interactions, or may be unaware of alterations in the patient's status that would preclude use of a particular drug, or may select the correct drug but may order an inappropriate dosage or route of administration. Because the nurse actually administers drugs, the nurse is the last person to check medications before they are given. Consequently, *you are the patient's last line of defense against medication errors*. It is ethically and legally unacceptable for you to administer a drug that is harmful to the patient—even though the medication has been prescribed by a licensed physician and dispensed by a licensed pharmacist. In your role as patient advocate, you must protect the patient against medication errors made by other members of the healthcare team. In serving as patient advocate, it is impossible to know too much about drugs.

2.2 APPLICATION OF PHARMACOLOGY IN PATIENT CARE

The two major areas in which you can apply pharmacologic knowledge are patient care and patient education. Patient care is considered in this section. Patient education is considered in the section after this. In discussing the applications of pharmacology in patient care, we will focus on seven aspects of drug therapy: (1) preadministration assessment, (2) dosage and administration, (3) evaluating and promoting therapeutic effects, (4) minimizing adverse effects, (5) minimizing adverse interactions, (6) making PRN decisions, and (7) managing toxicity.

2.2.1 Preadministration Assessment

All drug therapy begins with assessment of the patient. Assessment has three basic goals: (1) collecting baseline data needed to evaluate therapeutic and adverse responses, (2) identifying high-risk patients, and (3) assessing the patient's capacity for self-care. The first two goals are highly specific for each drug. Accordingly, we cannot achieve these goals without understanding pharmacology. The third goal applies generally to all drugs, and hence it does not usually require specific knowledge of the drug you are about to give. Preadministration assessment is discussed further under *Application of the Nursing Process in Drug Therapy*.

2.2.1.1 Collecting Baseline Data.

Baseline data are needed to evaluate drug responses, both therapeutic and adverse. For example, if we plan to give a drug to lower blood pressure, we must know the patient's blood pressure prior to treatment. Without these baseline data, we would have no way of determining the effectiveness of our drug. Similarly, if we are planning to give a drug that can damage the liver, we need to obtain baseline liver function test results in order to evaluate this potential toxicity. Obviously, in order to collect appropriate baseline data, we must first know the effects that our drug is likely to produce.

2.2.1.2 Identifying High-Risk Patients.

Multiple factors can predispose an individual to adverse reactions from specific drugs. Important predisposing factors are pathophysiology (especially liver and kidney impairment), genetic factors, drug allergies, pregnancy, old age, and extreme youth.

Patients with penicillin allergy provide a dramatic example of those at risk: Giving penicillin to these people can kill them. Accordingly, whenever treatment with penicillin is under consideration, we must determine if the patient has had an allergic reaction to a penicillin in the

past. If there is a history of penicillin allergy, an alternative antibiotic should be employed. If there is no effective alternative, facilities for managing a severe reaction should be in place before the drug is given.

From the preceding example, we can see that, when planning drug therapy, we must identify patients who are at high risk of reacting adversely. To identify such patients, we use three principal tools: the patient history, physical examination, and laboratory data. Of course, if identification is to be successful, you must know what to look for (ie, you must know the factors that can increase the risk of severe reactions to the drug in question). Once the high-risk patient has been identified, we can take steps to reduce the risk. We might select an alternative drug, or, if no alternative is available, we can at least prepare in advance to manage a possible adverse event.

2.2.2 Dosage and Administration

Earlier we noted the Six Rights of Drug Administration and agreed on their importance. Although you can implement the Six Rights without a detailed knowledge of pharmacology, having this knowledge can help reduce your contribution to medication errors. The following examples illustrate this point:

- Certain drugs have more than one indication, and dosage may differ depending on which indication the drug is used for. Aspirin, for example, is given in low doses to relieve pain and in high doses to suppress inflammation (eg, in patients with arthritis). If you don't know about these differences, you might administer too much aspirin to the patient with pain or too little to the patient with inflammation.
- Many drugs can be administered by more than one route, and dosage may differ depending upon the route selected. Morphine, for example, may be administered by mouth or by injection (eg, subcutaneous, intramuscular, intravenous). Oral doses are generally much larger than injected doses. Accordingly, if a large dose intended for oral use were to be mistakenly administered by injection, the result could prove fatal. The nurse who understands the pharmacology of morphine is unlikely to make this error.
- Certain intravenous agents can cause severe local injury if the line through which they are being infused becomes extravasated. Accordingly, when such drugs are given, special care must be taken to prevent extravasation. The infusion must be monitored closely, and, if extravasation occurs, corrective steps must be taken immediately to minimize harm. The nurse who doesn't understand these drugs will be unprepared to work with them safely.

6

7

The following basic guidelines can help ensure correct administration:

- Read the medication order carefully. If the order is unclear, verify it with the prescriber.
- Verify the identity of the patient by comparing the name on the wristband with the name on the drug order or medication administration record.
- Read the medication label carefully. Verify the identity of the drug, the amount of drug (per tablet, volume of liquid, etc.), and its suitability for administration by the intended route.
- Verify dosage calculations.
- Implement any special handling the drug may require.
- Don't administer any drug if you don't understand the reason for its use.

Measures to minimize medication errors are discussed further in [Chapter 7](#) (Adverse Drug Reactions and Medication Errors).

2.2.3 Evaluating and Promoting Therapeutic Effects

2.2.3.1 Evaluating Therapeutic Responses.

Evaluation is one of the most important aspects of drug therapy. After all, this is the process that tells us whether or not a drug is doing anything useful. Because the nurse follows the patient's status most closely, the nurse is in the best position to evaluate therapeutic responses.

In order to make an evaluation, you must know the rationale for treatment and the nature and time course of the intended response. If you lack this knowledge, you will be unable to evaluate the patient's progress. When beneficial responses develop as hoped for, ignorance of expected effects might not be so bad. However, when desired responses do not occur, it may be essential to identify the failure quickly, so that timely implementation of alternative therapy may be ordered.

When evaluating responses to a drug that has more than one application, you can do so only if you know the specific indication for which the drug is being used. Nifedipine, for example, is given for two cardiovascular disorders: hypertension and angina pectoris. When the drug is used to treat hypertension, you should monitor for a reduction in blood pressure. In contrast, when this drug is used to treat angina, you should monitor for a reduction in chest pain. Clearly, if you are to make the proper evaluation, you must understand the reason for drug use.

2.2.3.2 Promoting Patient Adherence.

Adherence—also known as compliance or concordance—may be defined as the extent to which a patient's behavior coincides with medical advice. If we are to achieve the therapeutic objective, adherence is essential. Drugs that are self-administered in the wrong dose, by the wrong route, or at the wrong time cannot produce maximum benefit—and may even prove harmful. Obviously, successful therapy requires active and informed participation by the patient. By educating patients about the drugs they are taking, you can help elicit the required participation. Promoting adherence is discussed further below.

2.2.3.3 Implementing Nondrug Measures.

Drug therapy can often be enhanced by nonpharmacologic measures. Examples include (1) enhancing drug therapy of asthma through breathing exercises, biofeedback, and emotional support; (2) enhancing drug therapy of arthritis through exercise, physical therapy, and rest; and (3) enhancing drug therapy of hypertension through weight reduction, smoking cessation, and sodium restriction. As a nurse, you may provide these supportive measures directly, through patient education, or by coordinating the activities of other healthcare providers.

2.2.4 Minimizing Adverse Effects

All drugs have the potential to produce undesired effects. Common examples include gastric erosion caused by aspirin, sedation caused by antihistamines, hypoglycemia caused by insulin, and excessive fluid loss caused by diuretics. When drugs are employed properly, the incidence and severity of such events can be reduced. Measures to reduce adverse events include identifying high-risk patients through the patient history, ensuring proper administration through patient education, and forewarning patients about activities that might precipitate an adverse effect.

When untoward effects cannot be avoided, discomfort and injury can often be minimized by appropriate intervention. For example, timely administration of glucose will prevent brain damage from insulin-induced hypoglycemia. In order to help reduce adverse effects, you must know the following about the drugs you are working with:

- The major adverse effects the drug can produce
- When these reactions are likely to occur
- Early signs that an adverse reaction is developing

- Interventions that can minimize discomfort and harm

2.2.5 Minimizing Adverse Interactions

When a patient is taking two or more drugs, those drugs may interact with one another to diminish therapeutic effects or intensify adverse effects. For example, the ability of oral contraceptives to protect against pregnancy can be reduced by concurrent therapy with carbamazepine (an antiseizure drug), and the risk of thromboembolism from oral contraceptives can be increased by smoking cigarettes.

As a nurse, you can help reduce the incidence and intensity of adverse interactions in several ways. These include taking a thorough drug history, advising the patient to avoid over-the-counter drugs that can interact with the prescribed medication, monitoring for adverse interactions *known* to occur between the drugs the patient is taking, and being alert for as-yet *unknown* interactions.

2.2.6 Making PRN Decisions

A PRN medication order is one in which the nurse has discretion regarding how much drug to give and when to give it. (PRN stands for *pro re nata*, a Latin phrase meaning *as needed* or *as the occasion arises*.) PRN orders are most common for hypnotics (sleeping pills). In order to implement a PRN order rationally, you must know the reason for drug use and be able to assess the patient's medication needs. Clearly, the better your knowledge of pharmacology, the better your PRN decisions are likely to be.

2.2.7 Managing Toxicity

Some adverse drug reactions are extremely dangerous. Hence, if toxicity is not diagnosed early and responded to quickly, irreversible injury or death can result. In order to minimize harm, you must know the early signs of toxicity and the procedure for toxicity management.

2.3 APPLICATION OF PHARMACOLOGY IN PATIENT EDUCATION

Very often, the nurse is responsible for educating patients about medications. In your role as educator, you must give the patient the following information:

- Drug name and therapeutic category (eg, penicillin: antibiotic)
- Dosage size
- Dosing schedule

- Route and technique of administration
- Expected therapeutic response and when it should develop
- Nondrug measures to enhance therapeutic responses
- Duration of treatment
- Method of drug storage
- Symptoms of major adverse effects, and measures to minimize discomfort and harm
- Major adverse drug-drug and drug-food interactions
- Whom to contact in the event of therapeutic failure, severe adverse reactions, or severe adverse interactions

In order to communicate this information effectively and accurately, you must first understand it. That is, to be a good drug educator, you must know pharmacology.

In the discussion below, we consider the relationship between patient education and the following aspects of drug therapy: dosage and administration, promoting therapeutic effects, minimizing adverse effects, and minimizing adverse interactions.

2.3.1 Dosage and Administration

2.3.1.1 Drug Name.

The patient should know the name of the medication he or she is taking. If the drug has been prescribed by trade name, the patient should be given its generic name too. This information will reduce the risk of overdose that can result when a patient fails to realize that two prescriptions that bear different names actually contain the same medicine.

2.3.1.2 Dosage Size and Schedule of Administration.

Patients must be told how much drug to take and when to take it. For some medications, dosage must be adjusted by the patient. Insulin is a good example. For insulin therapy to be most beneficial, the patient must adjust doses to accommodate changes in caloric intake. How to make this adjustment is taught by the nurse.

With PRN medications, the schedule of administration is not fixed. Rather, these drugs are taken as conditions require. For example, some people with asthma experience exercise-induced bronchospasm. To minimize such attacks, they can take supplementary medication prior to anticipated exertion. It is your responsibility to teach patients when PRN drugs should be taken.

The patient should know what to do if a dose is missed. With oral contraceptives, for example, if one dose is missed, the omitted dose should be taken together with the next scheduled dose. However, if three or more doses are missed, a new cycle of administration must be initiated.

Some patients have difficulty remembering whether or not they have taken their medication. Possible causes include mental illness, advanced age, and complex regimens. To facilitate accurate dosing, you can provide the patient with a pill box that has separate compartments for each day of the week, and then teach him or her to load the compartments weekly. To determine if they have taken their medicine, patients can simply examine the box.

2.3.1.3 Technique of Administration.

Patients must be taught how to administer their drugs. This is especially important for routes that may be unfamiliar (eg, sublingual for nitroglycerin) and for techniques that are difficult (eg, subcutaneous injection of insulin). Patients taking oral medications may require special instructions. For example, some oral preparations must not be chewed or crushed; some should be taken with fluids; and some should be taken with meals, whereas others should not. Careful attention must be paid to the patient who, because of disability (eg, visual or intellectual impairment, limited manual dexterity), may find self-medication difficult.

2.3.1.4 Duration of Drug Use.

Just as patients must know when to take their medicine, they must know when to stop. In some cases (eg, treatment of acute pain), patients should discontinue drug use as soon as symptoms subside. In other cases (eg, treatment of hypertension), patients should know that therapy will probably continue lifelong. For other conditions (eg, gastric ulcers), medication may be prescribed for a specific time interval, after which the patient should return for re-evaluation.

2.3.1.5 Drug Storage.

Certain medications are chemically unstable and hence deteriorate rapidly if stored improperly. Patients who are using unstable drugs must be taught how to store them correctly (eg, under refrigeration, in a light-proof container). All drugs should be stored where children can't reach them.

2.3.2 Promoting Therapeutic Effects

In order to participate fully in achieving the therapeutic objective, patients must know the nature and time course of expected beneficial effects. With this knowledge, patients can help evaluate the success or failure of treatment. By recognizing treatment failure, the informed patient will be able to seek timely implementation of alternative therapy.

With some drugs, such as those used to treat depression and schizophrenia, beneficial effects are delayed, taking several weeks to become maximal. Awareness that treatment may not produce immediate results allows the patient to have realistic expectations and helps reduce anxiety about therapeutic failure.

As noted, nondrug measures can complement drug therapy. For example, although drugs are useful in managing high cholesterol, exercise and diet are also important. Teaching the patient about nondrug measures can greatly increase the chances of success.

2.3.3 Minimizing Adverse Effects

Knowledge of adverse drug effects will enable the patient to avoid some adverse effects and minimize others through early detection. The following examples underscore the value of educating patients about the undesired effects of drugs:

- Insulin overdose can cause blood glucose levels to drop precipitously. Early signs of hypoglycemia include sweating and increased heart rate. The patient who has been taught to recognize these early signs can respond by ingesting glucose-rich foods, thereby restoring blood sugar to a safe level. In contrast, the patient who fails to recognize evolving hypoglycemia and does not ingest glucose may become comatose, and may even die.
- Many anticancer drugs predispose patients to acquiring serious infections. The patient who is aware of this possibility can take steps to avoid contagion (eg, avoiding contact with people who have an infection; avoiding foods likely to contain pathogens). In addition, the informed patient is in a position to notify the prescriber at the first sign that an infection is developing, thereby allowing rapid treatment. In contrast, the patient who has not received adequate education is at increased risk of illness or death from an infectious disease.
- Some side effects, although benign, can be disturbing if they occur without warning. For example, rifampin (a drug for tuberculosis) imparts a harmless red-orange color to urine, sweat, saliva, and tears. Your patient will appreciate knowing about this in advance.

2.3.4 Minimizing Adverse Interactions

Patient education can help avoid hazardous drug-drug and drug-food interactions. For example, phenelzine (an antidepressant) can cause dangerous elevations in blood pressure if taken in combination with certain drugs (eg, amphetamines) or certain foods (eg, figs, avocados, most cheeses). Accordingly, it is essential that patients taking phenelzine be given explicit and emphatic instruction regarding the drugs and foods they must avoid.

2.4 APPLICATION OF THE NURSING PROCESS IN DRUG THERAPY

The nursing process is a conceptual framework that nurses employ to guide healthcare delivery. In this section we consider how the nursing process can be applied in drug therapy.

2.4.1 Review of the Nursing Process

Before discussing the nursing process as it applies to drug therapy, we need to review the process itself. Since you are probably familiar with the process already, this review is brief.

In its simplest form, the nursing process can be viewed as a cyclic procedure that has five basic steps: (1) assessment, (2) analysis (including nursing diagnoses), (3) planning, (4) implementation, and (5) evaluation.

2.4.1.1 Assessment.

Assessment consists of collecting data about the patient. These data are used to identify actual and potential health problems. The database established during assessment provides a foundation for subsequent steps in the process. Important methods of data collection are the patient interview, medical and drug-use histories, the physical examination, observation of the patient, and laboratory tests.

2.4.1.2 Analysis: Nursing Diagnoses.

In this step, the nurse analyzes the database to determine actual and potential health problems. These problems may be physiologic, psychologic, or sociologic. Each problem is stated in the form of a *nursing diagnosis*, which can be defined as an actual or potential health problem that nurses are qualified and licensed to treat.

A complete nursing diagnosis consists of two statements: (1) a statement of the patient's actual or potential health problem, followed by (2) a statement of the problem's probable cause or risk

factors. Typically, the statements are separated by the phrase *related to*, as in this example of a drug-associated nursing diagnosis: “noncompliance with the prescribed regimen [the problem] related to inability to self-administer medication [the cause].”

2.4.1.3 Planning.

In the planning step, the nurse delineates specific interventions directed at solving or preventing the problems identified in analysis. The plan must be individualized for each patient. When creating a care plan, the nurse must define goals, set priorities, identify nursing interventions, and establish criteria for evaluating success. In addition to nursing interventions, the plan should include interventions performed by other healthcare providers. Planning is an ongoing process that must be modified as new data are gathered.

2.4.1.4 Implementation (Intervention).

Implementation begins with carrying out the interventions identified during planning. Some interventions are collaborative while others are independent. Collaborative interventions require a physician's order, whereas independent interventions do not. In addition to carrying out interventions, implementation involves coordinating actions of other members of the healthcare team. Implementation is completed by observing and recording the outcomes of treatment. Records should be thorough and precise.

2.4.1.5 Evaluation.

This step is performed to determine the degree to which treatment has succeeded. Evaluation is accomplished by analyzing the data collected during implementation. Evaluation should identify those interventions that should be continued, those that should be discontinued, and potential new interventions that might be implemented. Evaluation completes the initial cycle of the nursing process and provides the basis for beginning the cycle anew.

2.4.2 Applying the Nursing Process in Drug Therapy

Having reviewed the nursing process itself, we can now discuss the process as it pertains to drug therapy. Recall that the overall objective in drug therapy is to produce maximum benefit with minimum harm. To accomplish this, we must take into account the unique characteristics of each patient. That is, we must individualize therapy. The nursing process is well suited to this goal. As the discussion below indicates, in order to apply the nursing process in drug therapy, you must first have a solid knowledge of pharmacology. You will also see that applying the nursing process to drug therapy is, in large part, an exercise in common sense.

2.4.2.1 Preadministration Assessment

Preadministration assessment establishes the baseline data needed to tailor drug therapy to the individual. By identifying the variables that can affect an individual's responses to drugs, we can adapt treatment so as to maximize benefits and minimize harm. Preadministration assessment has four basic goals:

- Collection of baseline data needed to evaluate therapeutic responses
- Collection of baseline data needed to evaluate adverse effects
- Identification of high-risk patients
- Assessment of the patient's capacity for self-care

The first three goals are specific to the particular drug being used. Accordingly, in order to achieve these goals, you must know the pharmacology of the drug under consideration. The fourth goal applies more or less equally to all drugs—although this goal may be more critical for some drugs than others.

Important methods of data collection include interviewing the patient and family, observing the patient, performing a physical examination, ordering laboratory tests, and taking the patient's medical and drug histories. The drug history should include prescription drugs, over-the-counter drugs, herbal remedies, and drugs taken for nonmedical purposes (alcohol, nicotine, caffeine, illicit drugs). Prior adverse drug reactions should be noted, including drug allergies and idiosyncratic reactions (ie, reactions unique to the individual).

2.4.2.1.1 Baseline Data Needed to Evaluate Therapeutic Effects.

Drugs are administered to achieve a desired response. In order to know if we have produced that response, we need to establish baseline measurements of the parameter that therapy is directed at changing. For example, if we are giving a drug to lower blood pressure, we need to know what the patient's blood pressure was prior to treatment. Without this information, we have no basis for determining the effect of our drug. And if we can't determine whether or not a drug is working, there's little justification for giving it. From the above example, it should be obvious that, in order to know what baseline measurements to make, you must first know the reason for drug use. This knowledge comes from studying pharmacology.

2.4.2.1.2 Baseline Data Needed to Evaluate Adverse Effects.

All drugs have the ability to produce undesired effects. In most cases, the adverse effects that a particular drug can produce are known. In many cases, development of an adverse effect will be completely obvious in the absence of any baseline data. For example, we don't need special baseline data to know that hair loss following cancer chemotherapy was caused by the drug. However, in other cases, baseline data are needed to determine whether or not an adverse effect has occurred. For example, some drugs can impair liver function. In order to know if a drug has compromised liver function, we need to know the state of liver function prior to drug use. Without this information, we can't tell from later measurements whether apparent liver dysfunction was pre-existing or caused by the drug. Clearly, in cases like this, baseline data are needed. As noted earlier, knowing what data to collect comes directly from your knowledge of the drug under consideration.

2.4.2.1.3 Identification of High-Risk Patients.

Because of his or her individual characteristics, a particular patient may be at high risk of experiencing an adverse response to a particular drug. Just which individual characteristics will predispose a patient to an adverse reaction depends on the drug under consideration. For example, if a drug is eliminated from the body primarily by renal excretion, an individual with impaired kidney function will be at risk of having this drug accumulate to a toxic level. Similarly, if a drug is eliminated by the liver, an individual with impaired liver function will be at risk of having that drug accumulate to a toxic level. The message here is that, in order to identify the patient at risk, you must know the pharmacology of the drug to be administered.

Multiple factors can increase the patient's risk of adverse reactions to a particular drug. Impaired liver and kidney function were just mentioned. Other factors include age, body composition, pregnancy, diet, genetic heritage, other drugs being used, and practically any pathophysiologic condition. These factors are discussed at length in [Chapter 6](#) (Drug Interactions), [Chapter 7](#) (Adverse Drug Reactions and Medication Errors), [Chapter 8](#) (Individual Variation in Drug Responses), [Chapter 9](#) (Drug Therapy During Pregnancy and Breast-Feeding), [Chapter 10](#) (Drug Therapy in Pediatric Patients), and [Chapter 11](#) (Drug Therapy in Geriatric Patients).

When identifying factors that put the patient at risk, you should distinguish between factors that put the patient at extremely high risk versus factors that put the patient at moderate or low risk. The terms *contraindication* and *precaution* can be used for this distinction. A

contraindication is defined as a pre-existing condition that precludes use of a particular drug under all but the most desperate circumstances. For example, a previous severe allergic reaction to penicillin (which can be life threatening) would be a contraindication to using penicillin again—unless the patient has a life-threatening infection that cannot be controlled with another antibiotic. A *precaution*, by contrast, can be defined as a pre-existing condition that significantly increases the risk of an adverse reaction to a particular drug, but not to a degree that is life threatening. For example, a previous mild allergic reaction to penicillin would constitute a precaution to using this drug again. That is, the drug may be used, but greater than normal caution must be exercised. Preferably, an alternative drug would be selected.

2.4.2.1.4

Assessment of the Patient's Capacity for Self-Care.

If drug therapy is to succeed, the outpatient must be willing and able to self-administer medication as prescribed. Accordingly, his or her capacity for self-care must be assessed. If assessment reveals that the patient is incapable of self-medication, alternative care must be arranged.

Multiple factors can affect the capacity for self-care and the probability of adhering to the prescribed regimen. Patients with reduced visual acuity or limited manual dexterity may be unable to self-medicate, especially if the technique of administration is complex. Patients with limited intellectual ability may be incapable of understanding or remembering what they are supposed to do. Patients with severe mental illness (eg, depression, schizophrenia) may lack the understanding or motivation needed to self-medicate. Some patients may lack the money to pay for drugs. Others may fail to take medications as prescribed because of individual or cultural attitudes toward drugs. Among geriatric patients, a common cause for failed self-medication is a conviction that the drug was simply not needed in the dosage prescribed. A thorough assessment will identify all of these factors, thereby enabling you to account for them when formulating nursing diagnoses and the patient care plan.

10

TABLE 2-1 Examples of Nursing Diagnoses That Can Be Derived from Knowledge of Adverse Drug Effects

Drug	Adverse Effect	Related Nursing Diagnosis
Amphetamine	CNS stimulation	Disturbed sleep pattern related to drug-induced CNS excitation
Aspirin	Gastric erosion	Pain related to aspirin-induced gastric erosion
Atropine	Urinary retention	Urinary retention related to drug therapy
Bethanechol	Stimulation of GI smooth muscle	Bowel incontinence related to drug-induced increase in bowel motility
Clonidine	Impotence	Sexual dysfunction related to drug-induced impotence
Cyclophosphamide	Reduction in white blood cell counts	Risk for infection related to drug-induced neutropenia
Digoxin	Dysrhythmias	Ineffective tissue perfusion related to drug-induced cardiac dysrhythmias
Furosemide	Excessive urine production	Deficient fluid volume related to drug-induced diuresis
Gentamicin	Damage to the eighth cranial nerve	Disturbed sensory perception: hearing impairment related to drug therapy
Glucocorticoids	Thinning of the skin	Impaired skin integrity related to drug therapy
Haloperidol	Involuntary movements	Low self-esteem related to drug-induced involuntary movements
Nitroglycerin	Hypotension	Risk for injury related to dizziness caused by drug-induced hypotension
Propranolol	Bradycardia	Decreased cardiac output related to drug-induced bradycardia
Warfarin	Spontaneous bleeding	Risk for injury related to drug-induced bleeding
CNS = central nervous system, GI = gastrointestinal.		

2.4.2.2 Analysis and Nursing Diagnoses

With respect to drug therapy, the analysis phase of the nursing process has three objectives. First, you must judge the appropriateness of the prescribed regimen. Second, you must identify potential health problems that the drug might cause. Third, you must determine the patient's capacity for self-care.

As the last link in the patient's chain of defense against inappropriate drug therapy, you must analyze the data collected during assessment to determine if the proposed treatment has a reasonable likelihood of being effective and safe. This judgment is made by considering the medical diagnosis, the known actions of the prescribed drug, the patient's prior responses to the drug, and the presence of contraindications to the drug. You should question the drug's appropriateness if (1) the drug has no actions that are known to benefit individuals with the patient's medical diagnosis, (2) the patient failed to respond to the drug in the past, (3) the patient had a serious adverse reaction to the drug in the past, or (4) the patient has a condition or is using a drug that contraindicates the prescribed drug. If any of these conditions apply, you should consult with the prescriber to determine if the drug should be given.

Analysis must identify potential adverse effects and drug interactions. This is accomplished by synthesizing knowledge of the drug under consideration and the data collected during assessment. Knowledge of the drug itself will indicate adverse effects that practically all patients are likely to experience. Data on the individual patient will indicate additional adverse effects and interactions to which the particular patient is predisposed. Once potential adverse effects and interactions have been identified, pertinent nursing diagnoses can be easily formulated. For example, if treatment is likely to cause respiratory depression, an appropriate nursing diagnosis would be “impaired gas exchange related to drug therapy.” [Table 2-1](#) presents additional examples of nursing diagnoses that can be readily derived from your knowledge of adverse effects and interactions that treatment may cause.

Analysis must characterize the patient's capacity for self-care. The analysis should indicate potential impediments to self-care (eg, visual impairment, reduced manual dexterity, impaired cognitive function, insufficient understanding of the prescribed regimen) so that these factors can be addressed in the care plan. To varying degrees, nearly all patients will be unfamiliar with self-medication and the drug regimen. Accordingly, a nursing diagnosis applicable to almost every patient is “deficient knowledge related to the drug regimen.”

2.4.2.3 Planning

Planning consists of defining goals, establishing priorities, identifying specific interventions, and establishing criteria for evaluating success. Good planning will allow you to promote beneficial drug effects. Of equal or greater importance, good planning will allow you to anticipate adverse effects—rather than react to them after the fact.

2.4.2.3.1 Defining Goals.

In all cases, the goal of drug therapy is to produce maximum benefit with minimum harm. That is, we want to employ drugs in such a way as to maximize therapeutic responses while preventing or minimizing adverse reactions and interactions. The objective of planning is to formulate ways to achieve this goal.

2.4.2.3.2 Setting Priorities.

This requires knowledge of the drug under consideration and the patient's unique characteristics—and even then, setting priorities can be difficult. Highest priority is given to life-threatening conditions (eg, anaphylactic shock, ventricular fibrillation). These may be drug induced or the result of disease. High priority is also given to reactions that cause severe, acute discomfort and to reactions that can result in long-term harm. Since we cannot manage all problems simultaneously, less severe problems must wait until the patient and care provider have the time and resources to address them.

2.4.2.3.3 Identifying Interventions.

The heart of planning is identification of nursing interventions. These interventions can be divided into four major groups: (1) drug administration, (2) interventions to enhance therapeutic effects, (3) interventions to minimize adverse effects and interactions, and (4) patient education (which encompasses information in the first three groups).

11

12

When planning drug administration, you must consider dosage size and route of administration as well as less obvious factors, including timing of administration with respect to meals and with respect to administration of other drugs. Timing with respect to side effects is also important. For example, if a drug causes sedation, it may be desirable to give the drug at bedtime, rather than in the morning or during the day.

Nondrug measures can help promote therapeutic effects and should be included in the plan. For example, drug therapy of hypertension can be combined with weight loss (in overweight patients), salt restriction, and smoking cessation.

Interventions to prevent or minimize adverse effects are of obvious importance. When planning these interventions, you should distinguish between reactions that develop quickly and reactions that are delayed. A few drugs can cause severe adverse reactions (eg, anaphylactic shock) shortly after administration. When planning to administer such a drug, you should ensure that facilities for managing possible reactions are immediately available.

Delayed reactions can often be minimized, if not avoided entirely. The plan should include interventions to do so.

Well-planned patient education is central to success. The plan should account for the patient's capacity to learn, and it should address the following: technique of administration, dosage size and timing, duration of treatment, method of drug storage, measures to promote therapeutic effects, and measures to minimize adverse effects. Patient education is discussed at length above.

2.4.2.3.4 Establishing Criteria for Evaluation.

The need for objective criteria by which to measure desired drug responses is obvious: Without such criteria we could not determine if our drug was doing anything useful. As a result, we would have no rational basis for making dosage adjustments or for deciding how long treatment should last. If the drug is to be used on an outpatient basis, follow-up visits for evaluation should be planned.

2.4.2.4 Implementation

Implementation of the care plan in drug therapy has four major components: (1) drug administration, (2) patient education, (3) interventions to promote therapeutic effects, and (4) interventions to minimize adverse effects. These critical nursing activities are discussed at length above.

2.4.2.5 Evaluation

Over the course of drug therapy, the patient must be evaluated for (1) therapeutic responses, (2) adverse drug reactions and interactions, (3) adherence to the prescribed regimen, and (4) satisfaction with treatment. How frequently evaluations are performed depends on the expected time course of therapeutic and adverse effects. Like assessment, evaluation is based on laboratory tests, observation of the patient, physical examination, and patient interviews. The conclusions drawn during evaluation provide the basis for modifying nursing interventions and the drug regimen.

Therapeutic responses are evaluated by comparing the patient's current status with the baseline data. In order to evaluate treatment, you must know the reason for drug use, the criteria for success (as defined during planning), and the expected time course of responses (some drugs act within minutes, whereas others may take weeks to produce beneficial effects).

The need to anticipate and evaluate adverse effects is self-evident. To make these evaluations, you must know which adverse effects are likely to occur, how they manifest, and their probable time course. The method of monitoring is determined by the expected effect. For example, if hypotension is expected, blood pressure is monitored; if constipation is expected, bowel function is monitored; and so on. Since some adverse effects can be fatal in the absence of timely detection, it is impossible to overemphasize the importance of monitoring and being prepared for rapid intervention.

Evaluation of adherence is desirable in all patients—and is especially valuable when therapeutic failure occurs or when adverse effects are unexpectedly severe. Methods of evaluating adherence include measurement of plasma drug levels, interviewing the patient, and counting pills. The evaluation should determine if the patient understands when to take medication, what dosage to take, and the technique of administration.

Patient satisfaction with drug therapy increases quality of life and promotes adherence. If the patient is dissatisfied, an otherwise effective regimen may not be taken as prescribed. Factors that can cause dissatisfaction include unacceptable side effects, inconvenient dosing schedule, difficulty of administration, and high cost. When evaluation reveals dissatisfaction, an attempt should be made to alter the regimen to make it more acceptable.

2.4.3 Use of a Modified Nursing Process Format to Summarize Nursing Implications in This Text

Throughout this text, nursing implications are *integrated into the body of each chapter*. The reason for integrating nursing information with basic science information is to reinforce the relationship between pharmacologic knowledge and nursing practice. In addition to being integrated, nursing implications are *summarized at the end of most chapters*. The purpose of the summaries is to provide a concise and readily accessible reference on patient care and patient education related to specific drugs and drug families.

The format employed for summarizing nursing implications reflects the nursing process ([Table 2-2](#)). However, as you can see, I have modified the headings somewhat. This was done to accommodate the needs of pharmacology instruction and to keep the summaries concise. The components of the format are discussed below.

2.4.3.1 Preadministration Assessment.

This section summarizes the information you should have before giving a drug. Each section begins by stating the reason for drug use. This is followed by a summary of the baseline data needed to evaluate therapeutic and adverse effects. After this, contraindications and precautions are summarized, under the heading *Identifying High-Risk Patients*.

2.4.3.2 Implementation: Administration.

This section summarizes routes of administration, guidelines for dosage adjustment, and special considerations in administration, such as timing with respect to meals, preparation of intravenous solutions, and unusual techniques of administration.

12

Evaluating Therapeutic Effects
Minimizing Adverse Effects
Minimizing Adverse Interactions
Managing Toxicity

2.4.3.3 Implementation: Measures to Enhance Therapeutic Effects.

This section addresses issues such as diet modification, measures to increase comfort, and ways to promote adherence to the prescribed regimen.

2.4.3.4 Ongoing Evaluation and Interventions.

This section summarizes nursing implications that relate to drug responses, both therapeutic and undesired. As indicated in [Table 2-2](#), the section has five subsections: (1) summary of monitoring, (2) evaluating therapeutic effects, (3) minimizing adverse effects, (4) minimizing adverse interactions, and (5) managing toxicity. The monitoring section summarizes the physiologic and psychologic parameters that must be monitored in order to evaluate therapeutic and adverse responses. The section on therapeutic effects summarizes criteria and procedures for evaluating therapeutic responses. The section on adverse effects summarizes the major adverse reactions that should be monitored for and presents interventions to minimize harm. The section on adverse interactions summarizes the major drug interactions to be alert for and gives interventions to minimize them. The section on toxicity describes major symptoms of toxicity and treatment.

2.4.3.5 Patient Education.

This topic does not have a section of its own. Rather, patient education is integrated into the other sections. That is, as we summarize the nursing implications that relate to a particular topic, such as drug administration or a specific adverse effect, patient education related to that topic is discussed concurrently. This integration is done to promote clarity and efficiency of communication. In order to make this important information stand out, it appears in colored type.

2.4.3.6 What About Diagnosis and Planning?

These headings are not used in the summaries. There are several reasons for the omission, the dominant one being efficiency of communication.

Nursing diagnoses have been left out because they are extremely numerous and largely self-evident. Yes, I could have included a list of diagnoses for each drug. However, since nursing diagnoses derive from drug effects, and since all drugs cause many effects (primarily adverse), the list of diagnoses for each drug would be very long. Accordingly, since nursing diagnoses can be readily formulated from one's knowledge of pharmacology, and since a long list of diagnoses

would dilute the impact of other important information, I decided to omit nursing diagnoses from the summaries.

Planning has not been used as a heading for three reasons. First, planning applies primarily to the overall management of the disorder for which a particular drug is being used—and much less to the drug itself. Second, because planning is discussed at length and more appropriately in nonpharmacology nursing texts, such as those on medical-surgical nursing, there is no need to repeat this information here. Third, most planning is done with the aid of standardized nursing care plans—either computerized or in print format. These standardized plans are sufficient for most drug-related planning. Please note, however, that although we don't have a separate heading for planning, critical issues in planning are nonetheless included.

2.5 SUMMARY

We began this chapter by asking, “Why should a nursing student learn pharmacology?” To answer the question, we explored the applications of pharmacology in nursing practice. We observed that nursing responsibilities regarding drugs go far beyond the Six Rights of Drug Administration. We observed also that the nurse has a critical role as patient advocate, serving as the patient's last line of defense against medication errors. We then discussed multiple ways in which pharmacologic knowledge can be put to practical use in patient care and patient education. We saw that, by applying knowledge of pharmacology, you can have a positive influence on virtually all aspects of drug therapy, thereby helping to maximize benefits and minimize harm. Hopefully, your appreciation of the importance of pharmacology in nursing practice, coupled with your desire to provide optimal patient care, will provide the motivation you will need to develop an in-depth understanding of drugs.

2.5.1 KEY POINTS

- Nursing responsibilities with regard to drugs extend far beyond the Six Rights of Drug Administration.
- You are the patient's last line of defense against medication errors.
- Your knowledge of pharmacology has a wide variety of practical applications in patient care and patient education.
- By applying your knowledge of pharmacology, you will make a large contribution to achieving the therapeutic objective of maximum benefit with minimum harm.

- Application of the nursing process in drug therapy is directed at individualizing treatment, which is critical to achieving the therapeutic objective.

- The goal of preadministration assessment is to gather data needed for (1) evaluation of therapeutic and adverse effects, (2) identification of high-risk patients, and (3) assessment of the patient's capacity for self-care.

13

14

- The analysis and diagnosis phase of treatment is directed at (1) judging the appropriateness of the prescribed therapy, (2) identifying potential health problems treatment might cause, and (3) characterizing the patient's capacity for self-care.
- Planning is directed at (1) defining goals, (2) establishing priorities, and (3) establishing criteria for evaluating success.
- In the evaluation stage, the objective is to evaluate (1) therapeutic responses, (2) adverse reactions and interactions, (3) patient adherence, and (4) patient satisfaction with treatment.

³ CHAPTER 3 Drug Regulation, Development, Names, and Information

In this chapter we complete our introduction to pharmacology by considering five diverse but important topics. These are (1) drug regulation, (2) new drug development, (3) the annoying problem of drug names, (4) over-the-counter drugs, and (5) sources of drug information.

3.1 LANDMARK DRUG LEGISLATION

The history of drug legislation in the United States reflects an evolution in our national posture toward regulating the pharmaceutical industry. That posture has changed from one of minimal control to one of extensive control. For the most part, increased regulation has been beneficial, resulting in safer and more effective drugs.

The first American law to regulate drugs was the *Federal Pure Food and Drug Act* of 1906. This law was very weak: It required only that drugs be *free of adulterants*. The law said nothing about safety or effectiveness.

The *Food, Drug and Cosmetic Act*, passed in 1938, was much stronger than the Pure Food and Drug Act, and was the first legislation to address drug safety. The motivation behind the 1938 law was a tragedy in which more than 100 people died following use of a new medication. The lethal preparation contained an antibiotic (sulfanilamide) plus a solubilizing agent (diethylene glycol). Tests showed that the solvent was the cause of death. (Diethylene glycol is commonly used as automotive antifreeze.) To reduce the chances of another such tragedy, Congress required that all new drugs undergo testing for toxicity. The results of these tests were to be reviewed by the *Food and Drug Administration* (FDA), and only those drugs judged safe would receive FDA approval for marketing.

In 1962, Congress passed the *Harris-Kefauver Amendments* to the Food, Drug and Cosmetic Act. This law was created in response to the thalidomide tragedy that occurred in Europe in the early 1960s. Thalidomide is a sedative now known to cause birth defects. Because the drug was used widely by pregnant women, thousands of infants were born with phocomelia, a rare birth defect characterized by the gross malformation or complete absence of arms or legs. This tragedy was especially poignant in that it resulted from nonessential drug use: The women who took thalidomide could have done very well without it. Thalidomide was not a problem in the United States because the drug had been withheld by the FDA (see [Chapter 106](#), [Box 106-1](#)).

Because of the European experience with thalidomide, the Harris-Kefauver Amendments sought to strengthen all aspects of drug regulation. A major provision of the bill required that drugs be proved

effective before marketing. Remarkably, this was the first law to demand that drugs actually offer some benefit. The new act also required that all drugs that had been introduced between 1932 and 1962 undergo testing for effectiveness; any drug that failed to prove useful would be withdrawn. Lastly, the Harris-Kefauver Amendments established rigorous procedures for testing new drugs. These procedures are discussed below under *New Drug Development*.

In 1970, Congress passed the *Controlled Substances Act* (Title II of the Comprehensive Drug Abuse Prevention and Control Act). This legislation set rules for the manufacture and distribution of drugs considered to have the potential for abuse. One provision of the law defines five categories of controlled substances, referred to as Schedules I, II, III, IV, and V. Drugs in Schedule I have no accepted medical use in the United States and are deemed to have a high potential for abuse. Examples include heroin, mescaline, and lysergic acid diethylamide (LSD). Drugs in Schedules II through V have accepted medical applications but also have the potential for abuse. The abuse potential of these agents becomes progressively less as we proceed from Schedule II to Schedule V. The Controlled Substances Act is discussed further in [Chapter 37](#) (Drug Abuse I: Basic Considerations).

In 1992, FDA regulations were changed to permit *accelerated approval* of drugs for acquired immunodeficiency syndrome (AIDS) and cancer. Under these guidelines, a drug could be approved for marketing prior to completion of Phase III trials (see below), provided that rigorous follow-up studies (Phase IV trials) were performed. The rationale for this change was that (1) medications are needed, even if their benefits may be marginal, and (2) the unknown risks associated with early approval are balanced by the need for more effective drugs. Although accelerated approval seems like a good idea, in actual practice, it has two significant drawbacks. First, manufacturers often fail to conduct or complete the required follow-up studies. Second, if the follow-up studies—which are more rigorous than the original—fail to confirm a clinical benefit, the guidelines have no clear mechanism for removing the drug from the market.

The *Prescription Drug User Fee Act* (PDUFA), passed in 1992, was a response to complaints that the FDA takes too long to review applications for new drugs. Under the Act, drug sponsors pay the FDA fees (about \$500,000 per drug) that are used to fund additional reviewers. In return, the FDA must adhere to strict review timetables. Because of PDUFA, new drugs now reach the market much sooner than in the past.

The *Food and Drug Administration Modernization Act* (FDAMA) of 1997—an extension of the Prescription Drug User Fee Act—called for widespread changes in FDA regulations. Implementation is in progress. For health professionals, four provisions of the act are of particular interest:

- The fast-track system created for AIDS drugs and cancer drugs now includes drugs for other serious and life-threatening illnesses.
- Manufacturers who plan to stop making a drug must inform patients at least 6 months in advance, thereby giving them time to find another source.
- A clinical trial database will be established for drugs directed at serious or life-threatening illnesses. These data will allow clinicians and patients to make informed decisions about using experimental drugs.
- Drug companies can now give prescribers journal articles and certain other information regarding “off-label” uses of drugs. (An “off-label” use is a use that has not been evaluated by the FDA.) Prior to the new act, clinicians were allowed to prescribe a drug for an off-label use, but the manufacturer was not allowed to promote the drug for that use—even if promotion was limited to providing potentially helpful information. In return for being allowed to give prescribers information regarding off-label uses, manufacturers must promise to do research to support the claims made in the articles.

Two laws—the *Best Pharmaceuticals for Children Act* (BPCA), passed in 2002, and the *Pediatric Research Equity Act* (PREA) of 2003—were designed to promote much-needed research on drug efficacy and safety in children. The BPCA offers a 6-month patent extension to manufacturers who evaluate a drug already on the market for its safety, efficacy, and dosage in children. The PREA gives the FDA the power, for the first time, to require drug companies to conduct pediatric clinical trials on new medications that might be used by children. (In the past, drugs were not tested in children. Hence, there is a general lack of reliable information upon which to base therapeutic decisions.)

In 2007, Congress passed the *FDA Amendments Act* (FDAAA), the most important legislation on drug safety since the Harris-Kefauver Amendments of 1962. The FDAAA expands the mission of the FDA to include rigorous oversight of drug safety *after* a drug has been approved. (Prior to this act, the FDA focused on drug efficacy and safety *prior* to approval, but had limited resources and authority to address drug safety after a drug was released for marketing.) Under the new law, the FDA has the legal authority to require postmarketing safety studies, to order changes in a drug's label to include new safety information, and to restrict distribution of a drug based on safety concerns. In addition, the FDA is required to establish an active postmarketing risk surveillance system, mandated to include 25 million patients by July 2010, and 100 million by July 2012. Because of the FDAAA, adverse effects that were not discovered prior to drug approval will come to light much sooner than

in the past, and the FDA now has the authority to take action (eg, limit distribution of a drug) if postmarketing information shows a drug to be less safe than previously understood.

3.2 NEW DRUG DEVELOPMENT

The development and testing of new drugs is an expensive and lengthy process, requiring 6 to 12 years for completion. Of the thousands of compounds that undergo testing, only a few enter clinical trials, and of these, only 1 in 5 gains approval. Because of this high failure rate, the cost of developing a new drug can exceed \$800 million.

Rigorous procedures for testing have been established so that newly released drugs might be both safe and effective. Unfortunately, although testing can determine effectiveness, it cannot guarantee that a new drug will be safe: Significant adverse effects may evade detection during testing, only to become apparent after a new drug has been released for general use.

3.2.1 The Randomized Controlled Trial

Randomized controlled trials (RCTs) are the most reliable way to objectively assess drug therapies. Accordingly, RCTs are used to evaluate all new drugs. RCTs have three distinguishing features: use of controls, randomization, and blinding. All three serve to minimize the influence of personal bias on the results.

3.2.1.1 Use of Controls.

When a new drug is under development, we want to know how it compares with a standard drug used for the same disorder, or perhaps how it compares with no treatment at all. In order to make these comparisons, some subjects in the RCT are given the new drug and some are given either (1) a standard treatment or (2) a placebo (ie, an inactive compound formulated to look like the experimental drug). Subjects receiving either the standard drug or the placebo are referred to as *controls*. Controls are important because they help us determine if the new treatment is more (or less) effective than standard treatments, or at least if the new treatment is better (or worse) than no treatment at all. Likewise, controls allow us to compare the safety of the new drug with that of the old drug, a placebo, or both.

3.2.1.2 Randomization.

In an RCT, subjects are randomly assigned to either the control group or the experimental group (ie, the group receiving the new drug). The purpose of randomization is to prevent allocation bias, which results when subjects in the experimental group are different from those in the

control group. For example, in the absence of randomization, researchers could load the experimental group with patients who have mild disease and load the control group with patients who have severe disease. In this case, any differences in outcome may well be due to the severity of the disease rather than differences in treatment. And even if researchers try to avoid bias by purposely assigning subjects who appear similar to both groups, allocation bias can result from *unknown* factors that can influence outcome. By assigning subjects randomly to the control and experimental groups, all factors—known and unknown, important and unimportant—should be equally represented in both groups. As a result, the influences of these factors on outcome should tend to cancel each other out, leaving differences in the treatments as the best explanation for any differences in outcome.

16

17

3.2.1.3 Blinding.

A blinded study is one in which the people involved do not know to which group—control or experimental—individual subjects have been randomized. If only the subjects have been “blinded,” the trial is referred to as *single blind*. If the researchers as well as the subjects are kept in the dark, the trial is referred to as *double blind*. Of the two, double-blind trials are more objective. Blinding is accomplished by administering the experimental drug and the control compound (either placebo or comparison drug) in identical formulations (eg, green capsules, purple pills) that bear a numeric code. At the end of the study, the code is accessed to reveal which subjects were controls and which received the experimental drug. When subjects and researchers are not blinded, their preconceptions about the benefits and risks of the new drug can readily bias the results. Hence, blinding is done to minimize the impact of personal bias.

3.2.2 Stages of New Drug Development

The testing of new drugs has two principal steps: *preclinical testing* and *clinical testing*. Preclinical tests are performed in animals. Clinical tests are done in humans. The steps in drug development are outlined in [Table 3-1](#).

3.2.2.1 Preclinical Testing

Preclinical testing is required before a new drug may be tested in humans. During preclinical testing, drugs are evaluated for *toxicities*, *pharmacokinetic properties*, and *potentially useful biologic effects*. Preclinical tests may take 1 to 5 years. When sufficient preclinical data have been gathered, the drug developer may apply to the FDA for permission to begin testing in humans. If the application is approved, the drug is awarded *Investigational New Drug* status and clinical trials may begin.

3.2.2.2 Clinical Testing

Clinical trials occur in four phases and may take 2 to 10 years to complete. The first three phases are done before a new drug is marketed. The fourth is done after marketing has begun.

3.2.2.2.1 Phase I.

Phase I trials are usually conducted in *healthy volunteers*. However, if a drug is likely to have severe side effects, as many anticancer drugs do, the trial is done in volunteer patients who have the disease under consideration. Phase I testing has three goals: evaluating drug metabolism, pharmacokinetics, and biologic effects.

3.2.2.2.2 Phases II and III.

In these trials, drugs are tested in *patients*. The objective is to determine therapeutic effects, dosage range, safety, and effectiveness. During Phase II and Phase III trials, only 500 to 5000 patients receive the drug, and only a few hundred take it for more than 3 to 6 months. Upon completing Phase III, the drug manufacturer applies to the FDA for conditional approval of a *New Drug Application*. If conditional approval is granted, Phase IV may begin.

TABLE 3-1 Steps in New Drug Development

3.2.2.2.3 Phase IV: Postmarketing Surveillance.

In Phase IV, the new drug is released for general use, permitting observation of its effects in a large population. Under the FDAAA of 2007, postmarketing surveillance will be much more effective than in the past.

3.2.3 Limitations of the Testing Procedure

It is important for nurses and other healthcare professionals to appreciate the limitations of the drug development process. Two problems are of particular concern. First, until recently, information on drug use in women and children has been limited. Second, new drugs are likely to have adverse effects that were not detected during clinical trials.

3.2.3.1 Limited Information in Women and Children

3.2.3.1.1 Women.

Until recently, very little drug testing was done in women. In almost all cases, women of child-bearing age were excluded from early clinical trials. The rationale for excluding women was concern for fetal safety. Unfortunately, FDA policy took this concern to an extreme, effectively barring *all* women of child-bearing age from Phase I and Phase II trials—even if the women were not pregnant and were using adequate birth control. The only women allowed to participate in early clinical trials were those with a life-threatening illness that might respond to the drug under study.

Because of limited drug testing in women, we don't know with precision how women will respond to drugs. We don't know if beneficial effects in women will be equivalent to those seen in men. Nor do we know if adverse effects will be equivalent to those in men. We don't know how timing of drug administration with respect to the menstrual cycle will affect

17

18

beneficial and adverse responses. We don't know if drug disposition (absorption, distribution, metabolism, and excretion) will be the same in women as in men. Furthermore, of the drugs that might be used to treat a particular illness, we don't know if the ones that are most effective in men will also be most effective in women. Lastly, we don't know about the safety of drug use during pregnancy.

During the 1990s, the FDA issued a series of guidelines mandating participation of women (and minorities) in trials of new drugs. In addition, the FDA revoked a 1977 guideline that barred women from most trials. Because of these changes, the proportion of women in trials of most new drugs now equals the proportion of women in the population. The data generated since the implementation of the new guidelines have been reassuring: Most gender effects have been limited to pharmacokinetics, and more importantly, for most drugs, gender has shown little impact on efficacy, safety, or dosage. However, although the new guidelines are an important step forward, even with them, it will take a long time to close the gender gap in our knowledge of drugs.

3.2.3.1.2 Children.

Until recently, children, like women, had been excluded from clinical trials. As a result, information on dosage, therapeutic responses, and adverse effects in children has been limited. As noted above, the FDA can now force drug companies to conduct clinical trials in children. However, it will still be a long time before we have the information needed to use drugs safely and effectively in young patients.

TABLE 3-2 Some New Drugs That Were Withdrawn from the U.S. Market for Safety Reasons

Drug	Indication	Year Introduced/ Year Withdrawn	Months on the Market	Reason for Withdrawal
Rotigotine* [Neupro]	Parkinson's disease	2007/2008	10	Patch formulation delivered erratic dosages
Tegaserod† [Zelnorm]	Irritable bowel syndrome	2002/2007	56	Risk of cardiovascular events
Natalizumab† [Tysabri]	Multiple sclerosis	2004/2005	3	Progressive multifocal leukoencephalopathy
Valdecoxib [Bextra]	Arthritis, pain	2001/2005	41	Myocardial infarction, stroke
Rofecoxib [Vioxx]	Arthritis, pain	1999/2004	64	Myocardial infarction, stroke
Rapacuronium [Raplon]	Neuromuscular blockade	1999/2001	19	Bronchospasm, unexplained fatalities
Alosetron† [Lotronex]	Irritable bowel syndrome	2000/2000	9	Ischemic colitis, severe constipation; deaths have occurred
Troglitazone [Rezulin]	Type 2 diabetes	1999/2000	12	Fatal liver failure
Grepafloxacin [Raxar]	Infection	1997/1999	19	Severe cardiovascular events, including seven deaths
Bromfenac [Duract]	Acute pain	1997/1998	11	Severe hepatic failure
Mibefradil [Posicor]	Hypertension, angina pectoris	1997/1998	11	Inhibits drug metabolism, causing toxic accumulation of many drugs
Dexfenfluramine [Redux]	Obesity	1996/1997	16	Valvular heart disease
Flosequinan [Manoplax]	Heart failure	1992/1993	4	Increased hospitalization; decreased survival
Temafloxacin [Omniflox]	Infection	1992/1992	4	Hypoglycemia; hemolytic anemia, often associated with renal failure, hepatotoxicity, and coagulopathy

* Note that rotigotine was withdrawn because the *formulation* was unsafe, and not because the drug itself is inherently dangerous.

† Alosetron, natalizumab, and tegaserod were returned to the market in 2002, 2006, and 2007, respectively. These are the only drugs the Food and Drug Administration has ever reapproved after withdrawing them for safety reasons. With all three drugs, risk management guidelines must be followed.

3.2.3.2 Failure to Detect All Adverse Effects

The testing procedure cannot detect all adverse effects before a new drug is released. There are three reasons why: (1) during clinical trials, a relatively small number of patients are given the drug; (2) because these patients are carefully selected, they do not represent the full spectrum of individuals who will eventually take the drug; and (3) patients in trials take the drug for a relatively short time. Because of these unavoidable limitations in the testing process, effects that occur infrequently, effects that take a long time to develop, and effects that occur only in certain types of patients can go undetected. Hence, despite our best efforts, when a new drug is released, it may well have adverse effects of which we are as yet unaware. In fact, about half of the drugs that reach the market have serious adverse effects that were not detected until after they were released for general use.

The hidden dangers in new drugs are illustrated by the data in [Table 3-2](#). This table presents information on 14 drugs that were withdrawn from the U.S. market soon after receiving FDA approval. In all cases, the reason for withdrawal was a serious adverse effect that went undetected in clinical trials. Admittedly, only a few hidden adverse effects are as severe as the ones in the table. Hence, most do not necessitate drug withdrawal. Nonetheless, the drugs in the table should serve as a strong warning about the unknown dangers that a new drug may harbor.

Because adverse effects may go undetected, when working with a new drug, you should be

18

especially watchful for previously unreported drug reactions. If a patient taking a new drug

19

begins to show unusual symptoms, it is prudent to suspect that the new drug may be the cause—even though the symptoms are not yet mentioned in the literature.

3.2.4 Exercising Discretion Regarding New Drugs

When thinking about prescribing a new drug, clinicians would do well to follow this guideline: *Be neither the first to adopt the new nor the last to abandon the old*. Recall that the therapeutic objective is to produce maximum benefit with minimum harm. To achieve this objective, we must balance the potential benefits of a drug against its inherent risks. As a rule, new drugs have actions

very similar to those of older agents. That is, it is rare for a new drug to be able to do something that an older drug can't do already. Consequently, the need to treat a particular disorder seldom constitutes a compelling reason to select a new drug over an agent that has been available for years. Furthermore, new drugs generally present greater risks than the old ones. As noted, at the time of its introduction, a new drug is likely to have adverse effects that have not yet been reported, and these effects may prove very bad for some patients. In contrast, older, more familiar drugs are less likely to cause unpleasant surprises. Consequently, when we weigh the benefits of a new drug against its risks, it is likely that the benefits will be insufficient to justify the risks—especially when an older drug, whose properties are well known, would probably provide adequate treatment. Accordingly, when it comes to the use of new drugs, it is usually better to adopt a wait-and-see policy, letting more adventurous prescribers discover the hidden dangers that a new drug may hold.

3.3 DRUG NAMES

The topic of drug names is important and confusing. The topic is important because the names we employ affect our ability to communicate about medicines. The subject is confusing because we have evolved a system in which any drug can have a large number of names.

In approaching drug names, we begin by defining the types of names that drugs have. After that we consider (1) the complications that arise from assigning multiple names to a drug, and (2) the benefits of using just one name: the generic (nonproprietary) name.

3.3.1 The Three Types of Drug Names

Drugs have three types of names: (1) a chemical name, (2) a generic or nonproprietary name, and (3) a trade or proprietary name. Examples appear in [Table 3-3](#). All of the names in the table are for the same drug, a compound most familiar to us under the trade name *Tylenol*.

3.3.1.1 Chemical Name.

The chemical name constitutes a description of a drug using the nomenclature of chemistry. As you can see from the example in [Table 3-3](#), a drug's chemical name can be long and complex. Because of their complexity, chemical names are inappropriate for everyday use. For example, few people would communicate using the chemical term *N-acetyl-para-aminophenol* when a more simple generic name (*acetaminophen*) or trade name (eg, *Tylenol*) could be used.

TABLE 3-3 The Three Types of Drug Names

	
Type of Drug Name	Examples
Chemical Name	<i>N</i> -acetyl- <i>para</i> -aminophenol
Generic Name (nonproprietary name)	Acetaminophen
Trade Name (proprietary name)	Acephen, Aminophen, Apap, Cetafen, Ed-Apap Children's, Feverall, Genapap, Genebs, Infantaire Drops, Mapap Regular Strength, Masophen, Nortemp Children's, Pain and Fever, Pain Reliever, Q-Pap, Quick Melts Children's Non-Aspirin, Silapap, Tylenol, Valorin
The chemical, generic, and trade names listed are all names for the drug whose structure is pictured in this table. This drug is most familiar to us as Tylenol, one of its trade names.	

3.3.1.2 Generic Name.

The generic name of a drug is assigned by the United States Adopted Names Council. Each drug has only one generic name. The generic name is also known as the *nonproprietary* name or *United States Adopted Name*. Generic names are less complex than chemical names but typically more complex than trade names. For reasons presented below, generic names are preferable to trade names for general use.

3.3.1.3 Trade Name.

Trade names, also known as *proprietary* or *brand* names, are the names under which a drug is marketed. These names are created by drug companies with the intention that they be easy for nurses, physicians, pharmacists, and consumers to recall and pronounce. Since any drug can be marketed in different formulations and by multiple companies, the number of trade names that a drug can have is large. By way of illustration, [Table 3-3](#) gives the 19 trade names, including Tylenol, that currently exist for the drug whose generic name is *acetaminophen*.

Trade names must be approved by the FDA. The review process tries to ensure that no two trade names are too similar. In addition, trade names cannot imply unlikely efficacy—which may explain why sibutramine (a new diet pill) is named *Meridia* rather than something more suggestive, like *Fat-B-Gone* or *Pounds Off*.

3.3.2 Which Name To Use, Generic or Trade?

We employ drug names in two ways: (1) for written and oral communication about medicines and (2) for labeling medication containers. In both cases, accurate communication is imperative. For communication to be accurate, when we read or hear a drug name, we must know what compound that name is referring to. We can't know what's in a pill if we don't know what the name on its bottle means. Likewise, we can't communicate orally about drugs if the names we employ go unrecognized. Clearly, if we are to communicate accurately, name recognition is essential. As discussed below, name recognition would be facilitated through universal use of generic names.

TABLE 3-4 Generic Names and Trade Names of Some Common Drugs

Generic Name	Trade Name
Acetaminophen	Tylenol
Ciprofloxacin	Cipro
Fluoxetine	Prozac
Furosemide	Lasix
Ibuprofen	Motrin
Sildenafil	Viagra

3.3.2.1 The Little Problems with Generic Names

In almost all cases, the generic name for a drug is more complicated than its trade name. This fact is illustrated in [Table 3-4](#), which compares the generic and trade names for six common drugs. A simple analysis reveals that the average generic name in the table has 4.3 syllables. In contrast, the average trade name has only 2.3 syllables. That is, the generic names are nearly twice as long as the trade names.

Because generic names are more complex than trade names, generic names can be more difficult to remember and pronounce. As an exercise, try pronouncing the names in [Table 3-4](#). While trade names like *Motrin* and *Prozac* roll off the tongue with ease, their generic counterparts—*ibuprofen* and *fluoxetine*—tend to tie the tongue in knots.

Why is it that generic names are more complicated than trade names? One reason is that the pharmaceutical industry has an important role in establishing generic names. When a pharmaceutical company has developed a new drug, that company submits a suggested generic name to the United States Adopted Names Council, the body responsible for assigning a drug its generic name. As a rule, the Council adopts the name the company suggests. Since, from a marketing perspective, it is to the company's advantage to have a product whose trade name is more easily recognized than its generic name, it seems unlikely that a company will suggest a simple, euphonious generic name. Also contributing to the complexity of generic names are the guidelines established by the Council for naming drugs.

3.3.2.2 The Big Problems with Trade Names

3.3.2.2.1 A Single Drug Can Have Multiple Trade Names.

The principal objection to trade names is their vast number. Although a drug can have only one generic name, it can have unlimited trade names. As the number of trade names for a single drug expands, the burden of name recognition becomes progressively heavier. By way of illustration, the drug whose generic name is acetaminophen has at least 19 trade names (see [Table 3-3](#)). Although most clinicians will recognize this drug's generic name, few are familiar with all the trade names. As you can see, recalling a single generic name—even if it's complex—is still easier than recalling a host of trade names. Accordingly, if generic names were employed universally, accurate communication would be facilitated. Conversely, using multiple trade names does nothing but create confusion.

TABLE 3-5 Some Pharmaceutical Products That Share the Same Trade Name

Product Name	Drugs in the Product
Monistat	Miconazole
Monistat 1	Tioconazole
Tavist	Clemastine
Tavist Sinus	Acetaminophen + pseudoephedrine
Sudafed	Pseudoephedrine
Sudafed PE	Phenylephrine
4-Way 12-Hour Nasal Spray	Oxymetazoline
4-Way Fast-Acting Nasal Spray	Phenylephrine
Excedrin Tablets	Acetaminophen + aspirin + caffeine
Excedrin PM	Acetaminophen + diphenhydramine

By clouding communication about drugs, use of trade names can result in “double medication”—with potentially disastrous results. Because patients frequently see more than one physician or nurse practitioner, it is possible for a patient to be given prescriptions for the same drug by two different prescribers. If those prescriptions are written for different brand names, then the two bottles the patient receives will be labeled with different names. Consequently, although both bottles contain the same drug, the patient may be unaware of this fact. If both medications are taken as prescribed, excessive dosing will result. However, if generic names had been used, both labels would bear the same name, thereby informing the patient that both bottles contain the same drug. Given this information, the patient is likely to consult the prescribers to determine if both prescriptions should be honored.

3.3.2.2.2

Products with the Same Trade Name May Have Different Active Ingredients.

As indicated in [Table 3-5](#), products that have very similar trade names can actually contain very different drugs. For example, although the two Monistat products have nearly identical trade names, they actually contain two different drugs. Confusion would be avoided by simply labeling these products *miconazole* and *tioconazole*, rather than *Monistat* and *Monistat 1*.

The problem becomes even more complex for products that contain two or more drugs. When such combination products are referred to by trade name, the name is unlikely to indicate either

the number of drugs present or their identity. Referring to [Table 3-5](#), there is nothing about the trade name *Excedrin Tablets* to suggest that the product consists of three different drugs: acetaminophen, aspirin, and caffeine. Moreover, there is nothing in the trade names *Excedrin Tablets* and *Excedrin P.M.* to tell us that these two products have different compositions. By discarding the trade names and labeling one product *acetaminophen plus aspirin plus caffeine* and the other *acetaminophen plus diphenhydramine*, we could eliminate any confusion.

The two 4-Way products listed in [Table 3-5](#) further illustrate the potential for confusion. If nothing else, the name *4-Way* suggests that the product contains more than one drug. In fact, the name seems to imply the presence of *four* drugs. However, this implication is not correct.

Neither 4-Way preparation is composed of four drugs; rather, they both contain only one drug. Furthermore, note that these similarly named products are, in fact, completely different; they have no ingredients in common. Hence, in the case of these 4-Way products, we can see that the trade name cannot be taken to mean either (1) the presence of four different drugs or (2) that these preparations that bear similar names have the same composition. Had generic names been employed to label these products, there could be no confusion about their makeup.

TABLE 3-6 Products from the United States and Abroad That Have the Same Trade Name but Different Active Ingredients

Trade Name	Country	Active Drug	Therapeutic Use
Norpramin	United States	Desipramine	Depression
	Spain	Omeprazole	Peptic ulcer disease
Flomax	United States	Tamsulosin	Enlarged prostate
	Italy	Morniflumate	Inflammation
Allegra	United States	Fexofenadine	Allergies
	Germany	Frovatriptan	Migraine
Urex	United States	Methenamine	Urinary tract infection
	Australia	Furosemide	Diuresis
Dilacor	United States	Diltiazem	Angina, hypertension, dysrhythmias
	Serbia	Digoxin	Heart failure, dysrhythmias

Perhaps the most disturbing aspect of trade names is illustrated by the reformulation of *Kaopectate*, a well-known antidiarrheal product. In 2003, the manufacturer switched the active ingredient in *Kaopectate* from attapulgite (which had replaced kaolin and pectate some years earlier) to bismuth subsalicylate. However, although the active ingredient changed, the brand

name did not. As a result, new bottles of Kaopectate contain a drug that is completely different from the one found in bottles of Kaopectate produced in 2002—posing a risk for patients who should not take salicylates, but may be unaware of their presence in the new product. This example illustrates an important point: Manufacturers can reformulate brand-name products whenever they want—without changing the name at all. Hence, there is no guarantee that the brand-name product you buy today contains the same drug as the brand-name product you bought last week, last month, or last year.

In the spring of 1999, the FDA issued a ruling that will help reduce the confusion created by trade names—but only for over-the-counter (OTC) drugs. Under the ruling, generic names for the drugs in OTC products are now clearly and prominently listed on the label, using a standardized format.

3.3.2.2.3 Products with the Same Trade Name in the United States and Abroad May Have Different Active Ingredients.

Along with the problems discussed above, trade names present an additional problem for travelers. Why? Because products with the *identical* trade name may have different active ingredients, depending on where the products were made ([Table 3-6](#)). As a result, when a prescription for a trade-name product is filled abroad, the patient may receive the wrong drug. For example, Americans in Australia with a prescription for Urex will receive furosemide (a powerful diuretic) rather than the methenamine (a urinary tract antiseptic) that they were expecting. Not only will this lead to inconvenience (frequent urination) and potential danger (dehydration, hypokalemia), but the urinary tract infection will continue unabated. Hence, the patient is exposed to all the risks of medication without getting any of the benefits. Accordingly, to ensure that travelers get the drugs they need, prescriptions should bear generic names of drugs, not trade names.

3.3.2.3 What If Peas Were Marketed Like Drugs?

Given the problems that trade names create, why do we use trade names at all? We use trade names because the pharmaceutical industry wants them. Why? Because trade names give this industry a unique and powerful tool for marketing. As we shall see, the extent to which trade names are exploited to promote drug sales is without parallel in the marketing of any other product.

To understand the immense marketing value that trade names have, it will be helpful to consider the marketing of a product that is not a drug. Take peas, for example. All companies that sell

peas use the same name—*peas*—to identify their product. When we buy peas, no matter whose, all pea packages say “PEAS” in big letters on the label. Pea packages even have a picture of peas to help us identify what's inside. Consequently, when we choose a package of peas, we know with certainty what we're buying.

When we want to compare different *brands* of peas, the task is easy. Company A's peas are easily distinguished from those of company B or company C by the presence of a company name and logo on the label. Consequently, thanks to the way peas are marketed, we have no trouble understanding (1) just what we are buying and (2) who made it. As a result, we can easily select the product we want from the manufacturer we like best.

Now let's consider what we could expect if peas were marketed like drugs. Under the new system, pea packages would have no pictures of peas on them. Nor would pea packages proclaim “PEAS” in big letters to help us identify their contents. Instead, pea packages would be emblazoned with trade names like *Vegi-P* or *Producin* or *NuPod-500's*. If peas were marketed using trade names, when we went shopping for peas we'd be obliged to read a lot of fine print to find the product we wanted. And, once we finally did turn up a package with peas in it—for example, the one labeled *NuPod-500's*—we'd probably buy *NuPod-500's* for life, it being too much trouble to figure out which of the other packages with meaningless names also contain

21

22

peas. From the point of view of the people who sell *NuPod-500's*, this technique of marketing by trade names is a terrific arrangement. Consumers will be loyal to their product not because that product is better or cheaper than someone else's, but because product labeling with trade names makes it very difficult to identify the competition so that comparisons can be made. Fortunately, we don't allow this kind of marketing for peas. When we shop for peas, we demand that all pea packages bear the word *peas*—not *Vegi-P* or *NuPod-500's* or any other trade name. Why we permit medicines to be marketed in any less informative a manner is a disturbing question.

When we consider that drugs, unlike peas, cannot be identified by simple observation, the use of trade names for marketing becomes especially unsettling. With peas, once we open the package, we no longer need the label to identify the contents. We know what peas look like. Hence, even if peas were marketed like drugs, we would not be completely dependent upon labeling to identify the product. With drugs we have no options: Since we cannot identify a drug by looking at it, we cannot escape reliance on package labeling to inform us about the medicine inside. It is ironic that a product whose label is so essential for identification can be marketed under a system that employs multiple trade names, thereby making product identification needlessly and dangerously difficult.

3.3.2.4 Generic Products Versus Brand-Name Products

To complete our discussion of drug names, we need to address two questions: (1) Do significant differences exist between different brands of the same drug? and (2) If such differences do exist, do they justify the use of trade names? The answer to both questions is NO!

3.3.2.4.1 Are Generic Products and Brand-Name Products Therapeutically Equivalent?

When a new drug comes to market, it is sold under a trade name by the company that developed it. When that company's patent expires, other companies can produce the drug and market it under its generic name. Our question, then, is, “Are the generic formulations equivalent to the brand-name formulation produced by the original manufacturer?”

Because all equivalent products—generic or brand name—contain the same dose of the same drug, the only real concern with generic formulations is their rate and extent of absorption. For a few drugs (eg, phenytoin, warfarin), a slight increase in absorption can result in toxicity, and a slight decrease can result in therapeutic failure. Hence, for these agents, a small difference in absorption can be important. In the past, there was concern that generic formulation of these drugs were not as safe or reliable as the brand-name formulation. However, there is no well-documented evidence to support this concern. Hence, it is reasonable to conclude that *all FDA-approved generic products are therapeutically equivalent to their brand-name counterparts*. A list of FDA-approved generic equivalents is available online at www.fda.gov/cder/ob/default.htm.

3.3.2.4.2 Would a Difference Between Brand-Name and Generic Products Justify the Use of Trade Names?

Even if generic formulations *were* significantly different from brand-name formulations, this would not justify using trade names to identify preferred products. If clinicians want to prescribe a drug made by a particular company, they needn't resort to trade names to do so; their preference can be indicated simply by including the manufacturer's name on the prescription. As with peas, if we prefer a particular brand (eg, BIRDS EYE), that's what we ask for. We haven't found it necessary to create a complicated system of alternative names for peas in order to distinguish one brand from another. On the contrary, common sense tells us that such a system of trade names would make it more difficult—not easier—for us to clearly

communicate our needs. Perhaps some day we will market medicines with as much common sense as we use for vegetables.

3.3.2.5 Conclusion Regarding Generic Names and Trade Names

In the preceding discussion, we considered the advantages and disadvantages associated with trade names and generic names. We noted that, although generic names may be long, this disadvantage is more than offset by the fact that each drug has only one generic name. In contrast, the sole virtue of trade names—ease of recall and pronunciation—is far outweighed by the problems that stem from the existence of multiple trade names for a single drug. Multiple trade names can impede name recognition and can thereby promote medication errors and miscommunication about drugs. With generic names, the opposite is achieved: facilitation of communication and promotion of safe and effective drug use. Clearly, generic names are preferable to trade names. Accordingly, until such time as trade names are outlawed, the least we can do is actively discourage their use. In this text, generic names are employed for routine discussion. Although trade names are presented, they are not emphasized. We may eventually see the day when trade names are abandoned and generic names are employed universally. On that day, efforts to achieve the therapeutic objective will receive a huge boost.

3.4 OVER-THE-COUNTER DRUGS

Over-the-counter (OTC) drugs are defined as drugs that can be purchased without a prescription. These agents are used for a wide variety of complaints, including mild pain, motion sickness, allergies, colds, constipation, and heartburn. Whether a drug is available by prescription or over the counter is ultimately determined by the FDA.

OTC drugs are an important part of health care. When used properly, these agents can provide relief from many ailments while saving consumers the expense and inconvenience of visiting a prescriber. The following facts underscore how important the OTC market is:

- Americans spend about \$20 billion annually on OTC drugs.
- OTC drugs account for 60% of all doses administered.
- Forty percent of Americans take at least one OTC drug every 2 days.
- Four times as many illnesses are treated by a consumer using an OTC drug as by a consumer visiting a prescriber.

- With most illnesses (60% to 95%), initial therapy consists of self-care, including self-medication with an OTC drug.
- The average home medicine cabinet contains 24 OTC preparations.

Some drugs that were originally sold only by prescription are now sold over the counter. Since the 1970s, over 60 prescription drugs have been switched to OTC status. About 50 more are under FDA consideration for the change. Because of this process, more and more highly effective drugs are becoming directly available to consumers. Unfortunately, most consumers lack the knowledge needed to choose the most appropriate drug from among the steadily increasing options.

22

23

In 2006, the FDA began phasing in new labeling requirements for OTC drugs. The goal is to standardize labels and to make them more informative and easy to understand. The labels, titled *Drug Facts*, are to be written in plain language, have a user-friendly format, and use type that is big enough to read. Active ingredients will be listed first, followed by uses, warnings, directions, and inactive ingredients. This information is designed to help consumers select drugs that can provide the most benefit with the least risk.

In contrast to some texts, which present all OTC drugs in a single chapter, this text presents OTC drugs throughout. Why? Because this format allows discussion of OTC drugs in their proper pharmacologic and therapeutic contexts. I believe this makes more sense than lumping these drugs together solely because they can be purchased without a prescription.

3.5 SOURCES OF DRUG INFORMATION

There is much more to pharmacology than we can address in this text. When you need additional information, the sources discussed below should help.

3.5.1 People

3.5.1.1 Clinicians and Pharmacists.

Nurses and other clinicians can be invaluable sources of information about medicines. Pharmacists know a great deal about drugs and are usually eager to share their insight.

3.5.1.2 Poison Control Centers.

Poison control centers are located throughout the country. These centers are accessible by telephone, permitting rapid access to information about poisoning with medicines and toxic

compounds. Calling the national emergency hotline (1-800-222-1222) will connect you with the certified poison center nearest you.

3.5.1.3 Pharmaceutical Sales Representatives.

Pharmaceutical sales representatives (drug representatives, detail persons) can be useful sources of drug information. These people know their own products very well, and they can provide detailed, authoritative information about them. Keep in mind, however, that the ultimate job of the drug representative is sales, not education. Because their objective is sales, drug representatives may fail to volunteer negative information about their product. Likewise, they are unlikely to point out superior qualities in a competing drug. (Is a Honda salesperson going to extol the virtues of a Ford?) Such a lack of complete candor does not mean that drug representatives are unethical; they are simply doing their job. However, since full disclosure may be inconsistent with successful sales, the drug representative may not be your best source of information—especially if you are trying to establish an unbiased comparison between the representative's product and a drug from a competing manufacturer.

3.5.2 Published Information

The publications described below are general references. These works cover a broad range of topics but in limited depth. Accordingly, these references are most useful as initial sources of information. If more detail is needed, specialty publications should be consulted. Some important drug references, including the ones described below, are listed in [Table 3-7](#).

TABLE 3-7 Some Important Drug References

General Information on Drug Actions, Pharmacokinetics, Therapeutics, Adverse Effects, and Drug Interactions

Goodman and Gilman's The Pharmacological Basis of Therapeutics, 11th ed. (Brunton LL, Lazo JS, Parker KL, eds.). New York: McGraw-Hill, 2006

Pharmacotherapy: A Pathophysiologic Approach, 6th ed. (DiPiro JT, et al., eds.). New York: McGraw-Hill, 2005

Applied Therapeutics: The Clinical Use of Drugs, 8th ed. (Koda-Kimble MA, Young LY, Kradjan WA, Guglielmo BJ, Alldredge BK, Corelli RL, eds.). Philadelphia: Lippincott Williams & Wilkins, 2005

Detailed Information on Specific Drugs and Drug Families

AHFS Drug Information. (McEvoy GK, ed.). Bethesda, MD: American Society of Hospital Pharmacists [updated annually]

Drug Facts and Comparisons, Loose-leaf ed. St. Louis: Facts and Comparisons [updated monthly]

Physicians' Desk Reference. Montvale, NJ: Medical Economics Data Production Co. [updated annually]

United States Pharmacopeia Drug Information (USP DI): Drug Information for the Health Care Professional. Rockville, MD: The United States Pharmacopeial Convention, Inc. [updated bimonthly]

Very Current Information

The Medical Letter. New Rochelle, NY: The Medical Letter, Inc. [published bimonthly]

Prescriber's Letter. Stockton, CA: Therapeutic Research Center [published monthly]

3.5.2.1

Text-like Books

Goodman & Gilman's The Pharmacological Basis of Therapeutics is the classic text/reference on pharmacology used by generations of medical students and practicing physicians. As its name implies, this book focuses on the basic science information that underlies drug use—and not on therapeutics per se. New editions are released every 4 to 5 years.

Pharmacotherapy: A Pathophysiologic Approach is a comprehensive text on drug therapy. Each chapter focuses on the treatment of a specific disorder. To facilitate understanding of drug therapy, the book presents thorough reviews of pathophysiology.

Applied Therapeutics: The Clinical Use of Drugs is another comprehensive text on drug therapy, with each chapter focusing on a specific disorder. However, this book is different from the others in that it employs a case-study approach to present content on pharmacology and therapeutics.

3.5.2.2 Newsletters

The Medical Letter on Drugs and Therapeutics is a bimonthly publication that gives current information on drugs. A typical issue addresses two or three agents. Discussions consist of a summary of data from clinical trials plus a conclusion regarding the drug's therapeutic utility. The conclusions can be a valuable guide when deciding whether or not to use a new drug.

Prescriber's Letter is a monthly publication with very current information. Unlike *The Medical Letter*, which usually focuses on just two or three drugs, this newsletter addresses (briefly) most major drug-related developments—from new drugs to FDA warnings to new uses of older agents. In addition, subscribers can access an Internet site that provides expanded information on all topics addressed in the monthly letter.

23

24

3.5.2.3 Reference Books

The *Physicians' Desk Reference*, also known as the PDR, is a reference work financed by the pharmaceutical industry. The information on each drug is identical to the information on its package insert. In addition to textual content, the PDR has a pictorial section for product identification. The PDR is updated annually.

Drug Facts and Comparisons is a comprehensive reference that contains monographs on virtually every drug marketed in the United States. Information is provided on drug actions, indications, warnings, precautions, adverse reactions, dosage, and administration. In addition to describing the properties of single medications, the book lists the contents of most combination products sold in this country. Indexing is by generic name and trade name. *Drug Facts and Comparisons* is available in a loose-leaf format (updated monthly) and a hard-cover format (published annually).

A number of drug references have been compiled expressly for nurses. All address topics of special interest to the nurse, including information on administration, assessment, evaluation, and patient education. Representative nursing drug references include *Nurse's Drug Handbook* and *Mosby's Drug Guide for Nurses*, both published annually.

3.5.2.4 The Internet

The Internet can be a valuable source of drug information. However, since anyone, regardless of qualifications, can post information, not everything you find will be accurate. Accordingly, you need to exercise discretion when searching for information. A list of reliable drug-related information is available online at evolve.elsevier.com/Lehne/.

3.5.2.4.1

KEY POINTS

- The Food, Drug and Cosmetic Act of 1938 was the first legislation to regulate drug safety.
- The Harris-Kefauver Amendments, passed in 1962, were the first legislation to demand that drugs actually be of some benefit.
- The Controlled Substances Act, passed in 1970, set rules for the manufacture and distribution of drugs considered to have potential for abuse.
- The FDA Amendments Act, passed in 2007, expanded the mission of the FDA to include rigorous oversight of drug safety *after* a drug has been released for marketing.
- Development of a new drug is an extremely expensive process that takes years to complete.
- The randomized controlled trial is the most reliable way to objectively assess drug therapy.
- Drug testing in Phase II and Phase III clinical trials is limited to a relatively small number of patients, most of whom take the drug for a relatively short time.
- Since women and children have been excluded from drug trials in the past, our understanding of drug effectiveness and safety in these groups is limited.
- When a new drug is released for general use, it may well have adverse effects that have not yet been detected. Consequently, when working with a new drug, you should be especially watchful for previously unreported adverse events.
- Drugs have three types of names: a chemical name, a generic or nonproprietary name, and a trade or proprietary name.
- Each drug has only one generic name but can have many trade names.
- Generic names facilitate communication and therefore are good. Trade names confuse communication and should be outlawed. (Even science writers are allowed to voice an opinion now and then.)
- Over-the-counter (OTC) drugs are defined as drugs that can be purchased without a prescription.

- Since the job of the drug representative is sales and not education, this person may not be your best source of drug information—especially if you are trying to establish an unbiased comparison between the representative's product and a drug from a competing manufacturer.
- As pharmacology students, you should know that *Goodman & Gilman's The Pharmacological Basis of Therapeutics* (aka *G & G*) is the classic text/reference on pharmacology.

⁴ CHAPTER 4 Pharmacokinetics

The term *pharmacokinetics* is derived from two Greek words: *pharmakon* (drug or poison) and *kinesis* (motion). As this derivation implies, pharmacokinetics is the study of drug movement throughout the body. Pharmacokinetics also includes drug metabolism and drug excretion.

There are four basic pharmacokinetic processes: *absorption*, *distribution*, *metabolism*, and *excretion* (Fig. 4-1). Absorption is defined as the movement of a drug from its site of administration into the blood. Distribution is defined as drug movement from the blood to the interstitial space of tissues and from there into cells. Metabolism (biotransformation) is defined as enzymatically mediated alteration of drug structure. Excretion is the movement of drugs and their metabolites out of the body. The combination of metabolism plus excretion is called *elimination*. The four pharmacokinetic processes, acting in concert, determine the concentration of a drug at its sites of action.

^{4.1} APPLICATION OF PHARMACOKINETICS IN THERAPEUTICS

By applying knowledge of pharmacokinetics to drug therapy, we can help maximize beneficial effects and minimize harm. Recall that the intensity of the response to a drug is directly related to the concentration of the drug at its site of action. To maximize beneficial effects, we must achieve concentrations that are high enough to elicit desired responses; to minimize harm, we must avoid concentrations that are too high. This balance is achieved by selecting the most appropriate route, dosage, and dosing schedule. The only way we can rationally choose the most effective route, dosage, and schedule is by considering pharmacokinetic factors.

As a nurse, you will have ample opportunity to apply knowledge of pharmacokinetics in clinical practice. For example, by understanding the reasons behind selection of route, dosage, and dosing schedule, you will be less likely to commit medication errors than will the nurse who, through lack of this knowledge, administers medications by blindly following prescribers' orders. Also, as noted in [Chapter 2](#), prescribers do make mistakes. Accordingly, you will have occasion to question or even challenge prescribers regarding their selection of dosage, route, or schedule of administration. In order to alter a prescriber's decision, you will need a rational argument to support your position. To present that argument, you will need to understand pharmacokinetics.

Knowledge of pharmacokinetics can increase job satisfaction. Working with medications is a significant component of nursing practice. If you lack knowledge of pharmacokinetics, drugs will always be somewhat mysterious and, as a result, will be a potential source of unease. By helping to demystify drug therapy, knowledge of pharmacokinetics can decrease some of the stress of nursing practice and can increase intellectual and professional satisfaction.

4.2 A NOTE TO CHEMOPHOBES

Before we proceed, some advance notice (and encouragement) are in order for chemophobes (students who fear chemistry). Because drugs are chemicals, we cannot discuss pharmacology meaningfully without occasionally talking about chemistry. This chapter has some chemistry in it. In fact, the chemistry

25

26

Figure 4-1 The four basic pharmacokinetic processes. Dotted lines represent membranes that must be crossed as drugs move throughout the body.

presented here is the most difficult in the book. Accordingly, once you've worked your way through this chapter, the chapters that follow will be a relative breeze. Because the concepts addressed here are fundamental, and because they reappear frequently, all students, including chemophobes, are encouraged to learn this material now, regardless of the effort required.

I also want to comment on the chemical structures that appear in the book. Structures are presented only to illustrate and emphasize concepts. They are not intended for memorization, and they are certainly not intended for exams. So, relax, look at the pictures, and focus on the concepts I am trying to help you grasp.

4.3 PASSAGE OF DRUGS ACROSS MEMBRANES

All four phases of pharmacokinetics—absorption, distribution, metabolism, and excretion—involve drug movement. To move throughout the body, drugs must cross membranes. Drugs must cross membranes to enter the blood from their site of administration. Once in the blood, drugs must cross membranes to leave the vascular system and reach their sites of action. In addition, drugs must cross membranes to undergo metabolism and excretion. Accordingly, the factors that determine the passage of drugs across biologic membranes have a profound influence on all aspects of pharmacokinetics.

4.3.1 Membrane Structure

Biologic membranes are composed of layers of individual cells. The cells composing most membranes are very close to one another—so close, in fact, that drugs must usually pass *through* cells, rather than between them, in order to cross the membrane. Hence, the ability of a drug to cross a biologic membrane is determined primarily by its ability to pass through single cells. The major barrier to passage through a cell is the cytoplasmic membrane (the membrane that surrounds every cell).

The basic structure of the cell membrane is depicted in [Figure 4-2](#). As indicated, the basic membrane structure consists of a double layer of molecules known as *phospholipids*. Phospholipids are simply lipids (fats) that contain an atom of phosphate.

In [Figure 4-2](#), the phospholipid molecules are depicted as having a round head (the phosphate-containing component) and two tails (long-chain hydrocarbons). The large objects embedded in the membrane represent protein molecules, which serve a variety of functions.

4.3.2 Three Ways to Cross a Cell Membrane

The three most important ways by which drugs cross cell membranes are (1) passage through channels or pores, (2) passage with the aid of a transport system, and (3) direct penetration of the membrane itself. Of the three, direct penetration of the membrane is most common.

4.3.2.1 Channels and Pores

Very few drugs cross membranes via channels or pores. The channels in membranes are extremely small (approximately 4 angstroms), and are specific for certain molecules. Consequently, only the smallest of compounds (molecular weight <200) can pass through these channels, and then only if the channel is the right one. Compounds with the ability to cross membranes via channels include small ions, such as potassium and sodium.

4.3.2.2 Transport Systems

Transport systems are carriers that can move drugs from one side of the cell membrane to the other. Some transport systems require the expenditure of energy; others do not. All

26

27

Figure 4-2 Structure of the cell membrane. The cell membrane consists primarily of a double layer of phospholipid molecules. The large globular structures represent protein molecules imbedded in the lipid bilayer.

(Modified from Singer SJ, Nicolson GL: The fluid mosaic model of the structure of cell membranes. Science 175:720, 1972.)

transport systems are selective: They will not carry just any drug. Whether a transporter will carry a particular drug depends on the drug's structure.

Transport systems are an important means of drug transit. For example, certain orally administered drugs could not be absorbed unless there were transport systems to move them across the membranes that separate the lumen of the intestine from the blood. A number of drugs could not reach intracellular sites of action without a transport system to move them across the

cell membrane. Renal excretion of many drugs would be extremely slow were it not for transport systems in the kidney that can pump drugs from the blood into the renal tubules.

4.3.2.2.1 P-Glycoprotein.

One transporter, known as *P-glycoprotein* or *multidrug transporter protein*, deserves special mention. P-glycoprotein is a transmembrane protein that transports a wide variety of drugs *out* of cells. This transporter is present in cells at many sites, including the liver, kidney, placenta, intestine, and capillaries of the brain. In the liver, P-glycoprotein transports drugs into the bile for elimination. In the kidney, it pumps drugs into the urine for excretion; in the placenta, it transports drugs back into the maternal blood, thereby reducing fetal drug exposure. In the intestine, it transports drugs into the intestinal lumen, and can thereby reduce drug absorption into the blood. And in brain capillaries, it pumps drugs into the blood, thereby limiting drug access to the brain.

4.3.2.3 Direct Penetration of the Membrane

For most drugs, movement throughout the body is dependent on the ability to penetrate membranes directly. Why? Because (1) most drugs are too large to pass through channels or pores and (2) most drugs lack transport systems to help them cross all of the membranes that separate them from their sites of action, metabolism, and excretion.

In order to directly penetrate membranes, a drug must be *lipid soluble* (lipophilic). Recall that membranes are composed primarily of lipids. Consequently, if a drug is to penetrate a membrane, it must be able to dissolve into the lipids the membrane is made of.

Certain kinds of molecules are *not* lipid soluble and therefore cannot penetrate membranes. This group consists of *polar molecules* and *ions*.

4.3.3 Polar Molecules

Polar molecules are molecules with uneven distribution of electrical charge. That is, positive and negative charges within the molecule tend to congregate separately from one another. Water is the classic example. As depicted in [Figure 4-3A](#), the electrons (negative charges) in the water molecule spend more time in the vicinity of the oxygen atom than in the vicinity of the two hydrogen atoms. As a result, the area around the oxygen atom tends to be negatively charged, whereas the area around the hydrogen atoms tends to be positively charged. Kanamycin ([Fig. 4-3B](#)), an antibiotic, is an example of a polar drug. The hydroxyl groups, which attract electrons, give kanamycin its polar nature.

Although polar molecules have an uneven *distribution* of charge, they have no *net* charge. Polar molecules have an equal number of protons (which bear a single positive charge) and electrons (which bear a single negative charge).

27

28

Figure 4-3 Polar molecules. **A**, Stippling shows the distribution of electrons within the water molecule. As indicated, water's electrons spend more time near the oxygen atom than near the hydrogen atoms, making the area near the oxygen atom somewhat negative and the area near the hydrogen atoms more positive. **B**, Kanamycin is a polar drug. The -OH groups of kanamycin attract electrons, thereby causing the area around these groups to be more negative than the rest of the molecule.

As a result, the positive and negative charges balance each other exactly, and the molecule as a whole has neither a net positive charge nor a net negative charge. Molecules that *do* bear a net charge are called *ions*. These are discussed below.

There is a general rule in chemistry that states: “like dissolves like.” In accord with this rule, polar molecules will dissolve in *polar* solvents (such as water) but not in *nonpolar* solvents (such as oil). Table sugar provides a common example. I'm sure you've observed that sugar, a polar compound, readily dissolves in water but not in salad oil, butter, and other lipids, which are nonpolar

Pharmacology for Nursing Care, 7th Edition

compounds. Just as sugar is unable to dissolve in lipids, polar drugs are unable to dissolve in the lipid bilayer of the cell membrane.

4.3.4 Ions

Ions are defined as molecules that have a *net electrical charge* (either positive or negative). Except for very small molecules, *ions are unable to cross membranes*.

4.3.4.1 Quaternary Ammonium Compounds

Quaternary ammonium compounds are molecules that contain at least one atom of nitrogen and *carry a positive charge at all times*. The constant charge on these compounds results from atypical bonding to the nitrogen. In most nitrogen-containing compounds, the nitrogen atom bears only three chemical bonds. In contrast, the nitrogen atoms of quaternary ammonium compounds have four chemical bonds ([Fig. 4-4A](#)). Because of the fourth bond, quaternary ammonium compounds always carry a positive charge. And because of the charge, these compounds are unable to cross most membranes.

Tubocurarine ([Fig. 4-4B](#)) is a representative quaternary ammonium compound. In purified form, tubocurarine can be employed as a muscle relaxant for surgery and other procedures. A crude preparation—curare—is used by South American

Figure 4-4 Quaternary ammonium compounds.**A**, The basic structure of quaternary ammonium compounds. Because the nitrogen atom has bonds to four organic radicals, quaternary ammonium compounds always carry a positive charge. Because of this charge, quaternary ammonium compounds are not lipid soluble and cannot cross most membranes. **B**, Tubocurarine is a representative quaternary ammonium compound. Note that tubocurarine contains two “quaternized” nitrogen atoms.

Indians as an arrow poison. When employed for hunting, tubocurarine (curare) produces paralysis of the diaphragm and other skeletal muscles, causing death by asphyxiation. Interestingly, even though meat from animals killed with curare is laden with poison, it can be eaten with no ill effect. Why? Because tubocurarine, being a quaternary ammonium compound, cannot cross membranes, and therefore cannot be absorbed from the intestine; as long as it remains in the lumen of the intestine, curare can do no harm. As you might gather, when tubocurarine is used clinically, it cannot be administered by mouth. Instead, it must be injected. Once in the bloodstream, tubocurarine has ready access to its sites of action on the surface of muscles.

28

4.3.4.2

pH-Dependent Ionization

29

Unlike quaternary ammonium compounds, which always carry a charge, certain drugs can exist in either a charged or uncharged form. Many drugs are either weak organic acids or weak organic bases, which can exist in charged and uncharged forms. Whether a weak acid or base carries a charge is determined by the pH of the surrounding medium.

A review of acid-base chemistry will be helpful. An acid is defined as a compound that can give up a hydrogen ion (proton). Put another way, *an acid is a proton donor*. A base is defined as a compound that can take on a hydrogen ion. That is, *a base is a proton acceptor*. When an acid gives up its proton, which is positively charged, the acid itself becomes negatively charged. Conversely, when a base accepts a proton, the base becomes positively charged. These reactions are depicted in [Figure 4-5](#), showing aspirin as an example of an acid and amphetamine as an example of a base. Because the process of an acid giving up a proton or a base accepting a proton converts the acid or base into a charged particle (ion), the process for either an acid or a base is termed *ionization*.

The extent to which a weak acid or weak base becomes ionized is determined in part by the pH of its environment. The following rules apply:

- *Acids tend to ionize in basic (alkaline) media.*
- *Bases tend to ionize in acidic media.*

To illustrate the importance of pH-dependent ionization, let's consider the ionization of aspirin. Being an acid, aspirin tends to give up its proton (become ionized) in basic media. Conversely, aspirin keeps its proton and remains nonionized in acidic media. Accordingly, when aspirin is in the stomach (an acidic environment), most of the aspirin molecules remain nonionized. Because aspirin molecules are nonionized in the stomach, they can be absorbed across the membranes that separate the stomach from the bloodstream. When aspirin molecules pass from the stomach

into the small intestine, where the environment is relatively alkaline, they change to their ionized form. As a result, absorption of aspirin from the intestine is impeded.

4.3.4.3 Ion Trapping (pH Partitioning)

Because the ionization of drugs is pH dependent, when the pH of the fluid on one side of a membrane differs from the pH of the fluid on the other side, drug molecules will tend to accumulate on the side where the pH most favors their ionization. Accordingly, since acidic drugs tend to ionize in basic media, and since basic drugs tend to ionize in acidic media, *when there is a pH gradient between two sides of a membrane,*

- *Acidic drugs will accumulate on the alkaline side.*
- *Basic drugs will accumulate on the acidic side.*

The process whereby a drug accumulates on the side of a membrane where the pH most favors its ionization is referred to as *ion trapping* or *pH partitioning*. [Figure 4-6](#) shows the steps of ion trapping using aspirin as an example.

Because ion trapping can influence the movement of drugs throughout the body, the process is not simply of academic interest. Rather, ion trapping has practical clinical implications. Knowledge of ion trapping helps us understand drug absorption as well as the movement of drugs to sites of action, metabolism, and excretion. Understanding of ion trapping can

Figure 4-5 Ionization of weak acids and weak bases. The extent of ionization of weak acids **(A)** and weak bases **(B)** depends on the pH of their surroundings. The ionized (charged) forms of acids and bases are not lipid soluble and hence do not readily cross membranes. Note that acids ionize by giving up a proton and that bases ionize by taking on a proton.

be put to practical use when we need to actively influence drug movement. Poisoning is the principal example: By manipulating urinary pH, we can employ ion trapping to draw toxic substances from the blood into the urine, thereby accelerating their removal.

4.4 ABSORPTION

Absorption is defined as *the movement of a drug from its site of administration into the blood*. The *rate* of absorption determines how *soon* effects will begin. The *amount* of absorption helps determine how *intense* effects will be.

4.4.1 Factors Affecting Drug Absorption

The rate at which a drug undergoes absorption is influenced by the physical and chemical properties of the drug itself and by physiologic and anatomic factors at the site of absorption.

4.4.1.1 Rate of Dissolution.

Before a drug can be absorbed, it must first dissolve. Hence, the rate of dissolution helps determine the rate of absorption. Drugs in formulations that allow rapid dissolution have a faster onset than drugs formulated for slow dissolution.

4.4.1.2 Surface Area.

The surface area available for absorption is a major determinant of the rate of absorption. The larger the surface area, the faster absorption will be. For this reason, orally administered drugs are usually absorbed from the small intestine rather than from the stomach. (Recall that the small intestine, because of its lining of microvilli, has an extremely large surface area, whereas the surface area of the stomach is relatively small.)

4.4.1.3 Blood Flow.

Drugs are absorbed most rapidly from sites where blood flow is high. Why? Because blood containing newly absorbed drug will be replaced rapidly by drug-free blood, thereby maintaining a large gradient between the

Figure 4-6 **Ion trapping of drugs.** This figure demonstrates ion trapping using aspirin as an example. Because aspirin is an acidic drug, it will be nonionized in acid media and ionized in alkaline media. As indicated, ion trapping causes molecules of orally administered aspirin to move from the acidic (pH 1) environment of the stomach to the more alkaline (pH 7.4) environment of the plasma, thereby causing aspirin to accumulate in the blood. In the figure, aspirin (acetylsalicylic acid) is depicted as ASA with its COOH (carboxylic acid) group attached. *Step 1:* Once ingested, ASA dissolves in the stomach contents, after which some ASA molecules give up a proton and become ionized. However, most of the ASA in the stomach remains nonionized. Why? Because the stomach is acidic, and acidic drugs don't ionize in acidic media. *Step 2:* Because most ASA molecules in the stomach are nonionized (and therefore lipid soluble), most ASA molecules in the stomach can readily cross the membranes that separate the stomach lumen from the plasma. Because of the concentration gradient that exists between the stomach and the plasma, nonionized ASA molecules will begin moving into the plasma. (Note that, because of their charge, ionized ASA molecules cannot leave the stomach.) *Step 3:* As the nonionized ASA molecules enter the relatively alkaline environment of the plasma, most give up a proton (H^+) and become negatively charged ions. ASA molecules that become ionized in the plasma cannot diffuse back into the stomach. *Step 4:* As the nonionized ASA molecules in the plasma become ionized, more nonionized molecules will pass from the stomach to the plasma to replace them.

This movement occurs because the laws of diffusion demand equal concentrations of diffusible substances on both sides of a membrane. Because only the nonionized form of ASA is able to diffuse across the membrane, it is this form that the laws of diffusion will attempt to equilibrate. Nonionized ASA will continue to move from the stomach to the plasma until the amount of ionized ASA in plasma has become large enough to prevent conversion of newly arrived nonionized molecules into the ionized form. Equilibrium will then be established between the plasma and the stomach. At equilibrium, there will be equal amounts of *nonionized* ASA in the stomach and plasma. However, on the plasma side, the amount of ionized ASA will be much larger than on the stomach side. Because there are equal concentrations of nonionized ASA on both sides of the membrane but a much higher concentration of ionized ASA in the plasma, the total concentration of ASA in plasma will be much higher than in the stomach.

concentration of drug outside the blood and the concentration of drug in the blood. The greater the concentration gradient, the more rapid absorption will be.

4.4.1.4 Lipid Solubility.

As a rule, highly lipid-soluble drugs are absorbed more rapidly than drugs whose lipid solubility is low. Why? Because lipid-soluble drugs can readily cross the membranes that separate them from the blood, whereas drugs of low lipid solubility cannot.

4.4.1.5 pH Partitioning.

pH partitioning can influence drug absorption. Absorption will be enhanced when the difference between the pH of plasma and the pH at the site of administration is such that drug molecules will have a greater tendency to be ionized in the plasma.

4.4.2 Characteristics of Commonly Used Routes of Administration

The routes of administration that are used most commonly fall into two major groups: *enteral* (via the gastrointestinal [GI] tract) and *parenteral*. The literal definition of *parenteral* is *outside the GI tract*. However, in common parlance, the term *parenteral* is used to mean *by injection*. The principal parenteral routes are *intravenous*, *subcutaneous*, and *intramuscular*. 30
31

For each of the major routes of administration—oral (PO), intravenous (IV), intramuscular (IM), and subcutaneous (subQ)—the pattern of drug absorption (ie, the rate and extent of absorption) is unique. Consequently, the route by which a drug is administered will significantly affect both the onset and the intensity of effects. Why do patterns of absorption differ between routes? Because the barriers to absorption associated with each route are different. In the discussion below, we examine these barriers and their influence on absorption pattern. In addition, as we discuss each major route, we consider its clinical advantages and disadvantages. The distinguishing characteristics of the four major routes are summarized in [Table 4-1](#).

4.4.2.1 Intravenous

4.4.2.1.1 Barriers to Absorption.

When a drug is administered IV, there are no barriers to absorption. Why? Because, with IV administration, absorption is bypassed. Recall that absorption is defined as the movement of a drug from its site of administration into the blood. Since IV administration puts a drug directly into the blood, all barriers are bypassed.

4.4.2.1.2 Absorption Pattern.

Intravenous administration results in “absorption” that is both instantaneous and complete. Intravenous “absorption” is instantaneous in that drug enters the blood directly. “Absorption” is complete in that virtually all of the administered dose reaches the blood.

4.4.2.1.3 Advantages

4.4.2.1.3.1 Rapid Onset.

Intravenous administration results in rapid onset of action. Although rapid onset is not always important, it is clearly beneficial in emergencies.

4.4.2.1.3.2 Control.

Because the entire dose is administered directly into the blood, we have precise control over levels of drug in the blood. This contrasts with the other major routes of administration, and especially with oral administration (see below), in which the amount absorbed is less predictable.

4.4.2.1.3.3 Use of Large Fluid Volumes.

The IV route is the only parenteral route that permits the use of large volumes of fluid. Some drugs that require parenteral administration are poorly soluble in water, and hence must be dissolved in a large volume. Because of the physical limitations presented by soft tissues (eg, muscle, subcutaneous tissue), injection of large volumes at these sites is not feasible. In contrast, the amount of fluid that can be infused into a vein, although limited, is nonetheless relatively big.

4.4.2.1.3.4 Use of Irritant Drugs.

Certain drugs, because of their irritant properties, can be administered only by the IV route. A number of anticancer drugs, for example, are very chemically reactive. If present in high concentrations, these agents can cause severe local injury. However, when administered through a freely flowing IV line, these drugs are rapidly diluted in the blood, thereby minimizing the risk of injury.

4.4.2.1.4 Disadvantages

4.4.2.1.4.1 High Cost, Difficulty, and Inconvenience.

Intravenous administration is expensive, difficult, and inconvenient. The cost of IV administration sets and their set-up charges can be substantial. Setting up an IV line takes time and special training. Because of the difficulty involved, most patients are unable to self-administer IV drugs, and therefore must depend on a healthcare professional. Because patients are tethered to lines and bottles, their mobility is limited. In contrast, oral administration is easy, convenient, and cheap.

4.4.2.1.4.2 Irreversibility.

More important than cost or convenience, IV administration can be *dangerous*. Once a drug has been injected, there is no turning back; the drug is in the body and cannot be retrieved. Hence, if the dose is excessive, avoiding harm may be impossible.

31

32

TABLE 4-1 Properties of Major Routes of Drug Administration

Route	Barriers to Absorption	Absorption Pattern	Advantages	Disadvantages
Parenteral				
Intravenous (IV)	None (absorption is bypassed)	Instantaneous	Rapid onset, and hence ideal for emergencies Precise control over drug levels Permits use of large fluid volumes Permits use of irritant drugs	Irreversible Expensive Inconvenient Difficult, and hence poorly suited for self-administration Risk of fluid overload, infection, and embolism Drug must be water soluble
Intramuscular (IM)	Capillary wall (easy to pass)	Rapid with water-soluble drugs Slow with poorly soluble drugs	Permits use of poorly soluble drugs Permits use of depot preparations	Possible discomfort Inconvenient Potential for injury
Subcutaneous (subQ)	Same as IM	Same as IM	Same as IM	Same as IM
Enteral				
Oral (PO)	Epithelial lining of GI tract; capillary wall	Slow and variable	Easy Convenient Inexpensive Ideal for self-medication Potentially reversible, and hence safer than parenteral routes	Variability Inactivation of some drugs by gastric acid and digestive enzymes Possible nausea and vomiting from local irritation Patient must be conscious and cooperative

To minimize risk, IV drugs should be injected slowly (over 1 minute or more). Because all of the blood in the body is circulated about once every minute, by injecting a drug over a 1-

minute interval, we cause it to be diluted in the largest volume of blood possible. By doing so, we can avoid drug concentrations that are unnecessarily high—or even dangerously high.

Performing IV injections slowly has the additional advantage of reducing the risk of toxicity to the central nervous system (CNS). When a drug is injected into the antecubital vein of the arm, it takes about 15 seconds for it to reach the brain. Consequently, if the dose is sufficient to cause CNS toxicity, signs of toxicity may become apparent 15 seconds after starting the injection. If the injection is being done slowly (eg, over a 1-minute interval), only 25% of the total dose will have been administered when signs of toxicity appear. If administration is discontinued immediately, adverse effects will be much less than they would have been had the entire dose been given.

4.4.2.1.4.3 **Fluid Overload.**

When drugs are administered in a large volume, fluid overload can occur. This can be a significant problem for patients with hypertension, kidney disease, or heart failure.

4.4.2.1.4.4 **Infection.**

Infection can occur from injecting a contaminated drug. Fortunately, the risk of infection is much lower today than it was before the development of modern techniques for sterilizing drugs intended for IV use.

4.4.2.1.4.5 **Embolism.**

Intravenous administration carries a risk of embolism (blood vessel blockage at a site distant from the point of administration). Embolism can be caused in several ways. First, insertion of an IV needle can injure the venous wall, leading to formation of a thrombus (clot); embolism can result if the clot breaks loose and becomes lodged in another vessel. Second, injection of hypotonic or hypertonic fluids can destroy red blood cells; the debris from these cells can produce embolism.

Lastly, injection of drugs that are not fully dissolved can cause embolism. Particles of undissolved drug are like small grains of sand, which can become embedded in blood vessels and cause blockage. Because of the risk of embolism, you should check IV solutions prior to administration to ensure that drugs are in solution. If the fluid is cloudy or contains particles, the drug is not dissolved and must not be administered.

4.4.2.1.4.6 The Importance of Reading Labels

Not all formulations of the same drug are appropriate for IV administration. Accordingly, it is essential to read the label before giving a drug IV. Two examples illustrate the importance of this admonition. The first is insulin. Only one preparation of insulin, labeled *insulin injection*, can be administered safely IV. Insulin injection is a clear solution formulated for IV use. With one exception, all other insulin preparations are *particulate suspensions*. These preparations are intended for subQ administration only. Because of their particulate nature, these preparations could prove fatal if given IV. By checking the label, inadvertent IV injection of particulate insulin can be avoided.

Epinephrine provides our second example of why you should read the label before giving a drug IV. Epinephrine, which stimulates the cardiovascular system, can be injected by several routes (IM, IV, subQ, intracardiac, intraspinal). It must be noted, however, that a solution prepared for use by one route will differ in concentration from a solution prepared for use by other routes. For example, whereas solutions intended for *subcutaneous* administration are *concentrated*, solutions intended for *intravenous* use are *dilute*. If a solution prepared for subQ use were to be inadvertently administered IV, the result could prove *fatal*. (Intravenous administration of concentrated epinephrine could overstimulate the heart and blood vessels, causing severe hypertension, cerebral hemorrhage, stroke, and death.) The take-home message is that simply giving the *right drug* is not sufficient; you must also be sure that the formulation and concentration are *appropriate for the intended route*.

4.4.2.2 Intramuscular

4.4.2.2.1 Barriers to Absorption.

When a drug is injected IM, the only barrier to absorption is the *capillary wall*. In capillary beds that serve muscles and most other tissues, there are “large” spaces between the cells that compose the capillary wall ([Fig. 4-7](#)). Drugs can pass through these spaces with ease, and need not cross cell membranes to enter the bloodstream. Accordingly, like IV administration, IM administration presents no significant barrier to absorption.

4.4.2.2.2 Absorption Pattern.

Drugs administered IM may be absorbed rapidly or slowly. The rate of absorption is determined largely by two factors: (1) water solubility of the drug and (2) blood flow to the site of injection. Drugs that are highly soluble in water will be absorbed rapidly (within 10 to 30 minutes), whereas drugs that are poorly soluble will be absorbed slowly. Similarly,

absorption will be rapid from sites where blood flow is high, and slow where blood flow is low.

4.4.2.2.3 Advantages.

The IM route can be used for parenteral administration of *poorly soluble drugs*. Recall that drugs must be dissolved if they are to be administered IV. Consequently, the IV route cannot be used for poorly soluble compounds. In contrast, since little harm will come from depositing a suspension of undissolved drug in the interstitial space of muscle tissue, the IM route is acceptable for drugs whose water solubility is poor.

A second advantage of the IM route is that we can use it to administer *depot preparations* (preparations from which the drug is absorbed slowly over an extended time). Depending on the depot formulation, the effects of a single injection may persist for days, weeks, or even months. For example, *benzathine penicillin G*, a depot preparation of penicillin, can release therapeutically effective amounts of penicillin for a month following a single IM injection. In contrast, a single IM injection of penicillin G itself would be absorbed and excreted in less than 1 day. The obvious advantage of depot preparations is that they can greatly reduce the number of injections required during long-term therapy.

4.4.2.2.4 Disadvantages.

The major drawbacks of IM administration are discomfort and inconvenience. Intramuscular injection of some preparations can be painful. Also, IM injections can cause local tissue injury and possibly nerve damage (if the injection is done improperly). Lastly, because of bleeding risk, IM injections cannot be used for patients receiving anticoagulant therapy. Like all other forms of parenteral administration, IM injections are less convenient than oral administration.

4.4.2.3 Subcutaneous

The pharmacokinetics of subQ administration are nearly identical to those of IM administration. As with IM administration, there are no significant barriers to absorption:

32

Figure 4-7 Drug movement at typical capillary beds. In most capillary beds, “large” gaps exist between the cells that compose the capillary wall. Drugs and other molecules can pass freely into and out of the bloodstream through these gaps. As illustrated, lipid-soluble compounds can also pass directly through the cells of the capillary wall.

Once a drug has been injected subQ, it readily enters the blood by passing through the spaces between cells of the capillary wall. As with IM administration, blood flow and drug solubility are the major determinants of how fast absorption takes place. Because of the similarities between subQ and IM administration, these routes have similar advantages (suitability for poorly soluble drugs and depot preparations) and similar drawbacks (discomfort, inconvenience, potential for injury).

4.4.2.4 Oral

In the discussion below, the abbreviation PO is used in reference to oral administration. This abbreviation stands for *per os*, a Latin phrase meaning *by way of the mouth*.

4.4.2.4.1 Barriers to Absorption.

Following oral administration, drugs may be absorbed from the stomach or intestine. In either case, there are two barriers to cross: (1) the layer of *epithelial cells* that lines the GI tract, and (2) the *capillary wall*. Because the walls of the capillaries that serve the GI tract offer no significant resistance to absorption, the major barrier to absorption is the GI epithelium. To cross this layer of tightly packed cells, drugs must pass *through* cells rather than between them. For some drugs, intestinal absorption may be reduced by *P-glycoprotein*, a transporter that can pump certain drugs *out* of epithelial cells back into the intestinal lumen.

4.4.2.4.2 Absorption Pattern.

Because of multiple factors, the rate and extent of drug absorption following oral administration can be *highly variable*. Factors that can influence absorption include (1) solubility and stability of the drug, (2) gastric and intestinal pH, (3) gastric emptying time, (4) food in the gut, (5) coadministration of other drugs, and (6) special coatings on the drug preparation.

4.4.2.4.3 Drug Movement Following Absorption.

Before proceeding, we need to quickly review what happens to drugs following their absorption from the GI tract. As depicted in [Figure 4-8](#), drugs absorbed from all sites along the GI tract (except the oral mucosa and the distal segment of the rectum) must pass through the liver (the major site of drug metabolism) before they can reach the general circulation. For many drugs, this passage is uneventful: they go through the liver, enter the inferior vena cava, and eventually reach the general circulation. Other drugs undergo extensive hepatic metabolism. And still others may undergo *enterohepatic recirculation*, a cycle in which drugs in the liver are taken up into bile, secreted back into the small intestine (via the bile duct), and then reabsorbed back into the portal blood (see [Fig. 4-8](#)).*

* Before a drug can be taken up into bile, it must first undergo *glucuronidation*, an enzymatic reaction in which a molecule of glucuronic acid is coupled with the drug. Once the glucuronide form of the drug has been secreted into the intestine, bacterial enzymes cleave off the glucuronic acid, converting the drug back into its original form, which can then be reabsorbed into the hepatic portal circulation.

4.4.2.4.4 Advantages.

Oral administration is easy, convenient, and inexpensive. (By inexpensive, we don't mean that oral drugs themselves are inexpensive, but rather that there is no cost for the process of

administration.) Because of its relative ease, oral administration is the preferred route for self-medication.

Although absorption of oral drugs can be highly variable, this route is still *safer than injection*. With oral administration, there is no risk of fluid overload, infection, or embolism.

Furthermore, since oral administration is potentially reversible, whereas injections are not, oral administration is safer. Recall that with parenteral administration there is no turning back:

Once a drug has been injected, there is little we can do to prevent absorption and subsequent effects. Therefore, when giving drugs parenterally, we must live with the consequences of our mistakes. In contrast, if need be, there are steps we can take to prevent absorption following inappropriate oral administration. For example, we can decrease absorption of oral drugs by giving activated charcoal, a compound that adsorbs (soaks up) drugs while they are still in the GI tract; once drugs are adsorbed onto the

33

34

Figure 4-8 Movement of drugs following GI absorption. All drugs absorbed from sites along the GI tract—stomach, small intestine, and large intestine (but not the oral mucosa or distal rectum)—must go through the liver, via the portal vein, on their way toward the heart and the general circulation. For some drugs, passage is uneventful. Others undergo extensive metabolism. Still others undergo excretion into the bile, after which they re-enter the small intestine (via the bile duct), and then either (1) undergo reabsorption into the portal blood, thereby creating a cycle known as *enterohepatic recirculation*, or (2) exit the body in the stool (not shown).

charcoal, they cannot be absorbed into the bloodstream. Our ability to prevent the absorption of orally administered drugs gives PO medications a safety factor that is unavailable with drugs given by injection.

4.4.2.4.5 Disadvantages.

Variability. The major disadvantage of PO therapy is that absorption can be highly variable. That is, a drug administered to patient A may be absorbed rapidly and completely, whereas the same drug given to patient B may be absorbed slowly and incompletely. This variability makes it difficult to control the concentration of a drug at its sites of action, and therefore makes it difficult to control the onset, intensity, and duration of responses.

4.4.2.4.5.1 Inactivation.

Oral administration can lead to inactivation of certain drugs. Penicillin G, for example, can't be taken orally because it would be destroyed by stomach acid. Similarly, insulin can't be taken orally because it would be destroyed by digestive enzymes. Other drugs (eg, nitroglycerin) undergo extensive inactivation as they pass through the liver, a phenomenon known as the “first-pass effect” (see below under *Special Considerations in Drug Metabolism*).

4.4.2.4.5.2 Patient Requirements

Oral drug administration requires a conscious, cooperative patient. Drugs cannot be administered PO to comatose individuals or to individuals who, for whatever reason (eg, psychosis, seizure, obstinacy, nausea), are unable or unwilling to swallow medication.

4.4.2.4.5.3 Local Irritation

Some oral preparations cause local irritation of the GI tract, which can result in discomfort, nausea, and vomiting.

4.4.2.5 Comparing Oral Administration with Parenteral Administration

Because of ease, convenience, and relative safety, *oral administration is generally preferred to parenteral administration*. However, there *are* situations in which parenteral administration may be superior. These are

- Emergencies that require rapid onset of drug action.
- Situations in which plasma drug levels must be tightly controlled. (Because of variable absorption, oral administration does not permit tight control of drug levels.)

- Treatment with drugs that would be destroyed by gastric acidity, digestive enzymes, or hepatic enzymes if given orally (eg, insulin, penicillin G, nitroglycerin).
- Treatment with drugs that would cause severe local injury if administered by mouth (eg, certain anticancer agents).
- Treating a systemic disorder with drugs that cannot cross membranes (eg, quaternary ammonium compounds).
- Treating conditions for which the prolonged effects of a depot preparation might be desirable.
- Treating patients who cannot or will not take drugs orally.

4.4.3 Pharmaceutical Preparations for Oral Administration

There are several kinds of “packages” (formulations) into which a drug can be put for oral administration. Three such formulations—*tablets*, *enteric-coated preparations*, and *sustained-release preparations*—are discussed below.

34

Before we discuss drug formulations, it will be helpful to define two terms: *chemical equivalence* and *bioavailability*. Drug preparations are considered *chemically equivalent* if they contain the same amount of the identical chemical compound (drug). Preparations are considered equal in *bioavailability* if the drug they contain is absorbed at the same rate and to the same extent. Please note that it is possible for two formulations of the same drug to be chemically equivalent while differing in bioavailability.

35

4.4.3.1 Tablets.

A tablet is a mixture of a drug plus binders and fillers, all of which have been compressed together. Tablets made by different manufacturers can differ in their rates of disintegration and dissolution, causing differences in bioavailability. As a result, two tablets that contain the same amount of the same drug can differ with respect to onset and intensity of effects.

4.4.3.2 Enteric-Coated Preparations.

Enteric-coated preparations consist of drugs that have been covered with a material designed to dissolve in the intestine but not the stomach. Materials used for enteric coatings include fatty acids, waxes, and shellac. Because enteric-coated preparations release their contents into the intestine and not the stomach, these preparations are employed for two general purposes: (1) to

protect drugs from acid and pepsin in the stomach and (2) to protect the stomach from drugs that can cause gastric discomfort.

The primary disadvantage of enteric-coated preparations is that absorption can be even more variable than with standard tablets. Because gastric emptying time can vary from minutes up to 12 hours, and because enteric-coated preparations cannot be absorbed until they leave the stomach, variations in gastric emptying time can alter time of onset. Furthermore, enteric coatings sometimes fail to dissolve, thereby allowing medication to pass through the GI tract without being absorbed at all.

4.4.3.3 Sustained-Release Preparations.

Sustained-release formulations are capsules filled with tiny spheres that contain the actual drug; the spheres have coatings that dissolve at variable rates. Because some spheres dissolve more slowly than others, drug is released steadily throughout the day. The primary advantage of sustained-release preparations is that they permit a reduction in the number of daily doses. These formulations have the additional advantage of producing relatively steady drug levels over an extended time (much like giving a drug by infusion). The major disadvantages of sustained-release formulations are high cost and the potential for variable absorption.

4.4.4 Additional Routes of Administration

Drugs can be administered by a number of routes in addition to those already discussed. Drugs can be applied *topically* for local therapy of the skin, eyes, ears, nose, mouth, and vagina. In a few cases, topical agents (eg, nitroglycerin, nicotine, testosterone, estrogen) are formulated for *transdermal* absorption into the systemic circulation. Some drugs are *inhaled* to elicit local effects in the lung, especially in the treatment of asthma. Other inhalational agents (eg, volatile anesthetics, oxygen) are used for their systemic effects. *Rectal suppositories* may be employed for local effects or for effects throughout the body. *Vaginal suppositories* may be employed to treat local disorders. For management of some conditions, drugs must be given by *direct injection into a specific site* (eg, heart, joints, nerves, CNS). The unique characteristics of these routes are addressed throughout the book as we discuss specific drugs that employ them.

4.5 DISTRIBUTION

Distribution is defined as *the movement of drugs throughout the body*. Drug distribution is determined by three major factors: blood flow to tissues, the ability of a drug to exit the vascular system, and, to a lesser extent, the ability of a drug to enter cells.

4.5.1 Blood Flow to Tissues

In the first phase of distribution, drugs are carried by the blood to the tissues and organs of the body. The rate at which drugs are delivered to a particular tissue is determined by blood flow to that tissue. Since most tissues are well perfused, regional blood flow is rarely a limiting factor in drug distribution.

There are two pathologic conditions—abscesses and tumors—in which low regional blood flow can affect drug therapy. An abscess is a pus-filled pocket of infection that has no internal blood vessels. Because abscesses lack a blood supply, antibiotics cannot reach the bacteria within. Accordingly, if drug therapy is to be effective, the abscess must first be surgically drained.

Solid tumors have a limited blood supply. Although blood flow to the outer regions of tumors is relatively high, blood flow becomes progressively lower toward the core. As a result, we cannot achieve high drug levels deep inside tumors. Limited blood flow is a major reason why solid tumors are resistant to drug therapy.

4.5.2 Exiting the Vascular System

After a drug has been delivered to an organ or tissue via the blood, the next step is to exit the vasculature. Since most drugs do not produce their effects within the blood, the ability to leave the vascular system is an important determinant of drug actions. Exiting the vascular system is also necessary for drugs to undergo metabolism and excretion. Drugs in the vascular system leave the blood at capillary beds.

4.5.2.1 Typical Capillary Beds

Most capillary beds offer no resistance to the departure of drugs. Why? Because, in most tissues, drugs can leave the vasculature simply by passing through pores in the capillary wall. Since drugs pass *between* capillary cells rather than *through* them, movement into the interstitial space is not impeded. The exit of drugs from a typical capillary bed is depicted in [Figure 4-7](#).

4.5.2.2 The Blood-Brain Barrier

The term *blood-brain barrier* (BBB) refers to the unique anatomy of capillaries in the CNS. As shown in [Figure 4-9](#), there are *tight junctions* between the cells that compose the walls of most capillaries in the CNS. These junctions are so tight that they prevent drug passage. Consequently, in order to leave the blood and reach sites of action within the brain, a

Figure 4-9 **Drug movement across the blood-brain barrier.** Tight junctions between cells that compose the walls of capillaries in the CNS prevent drugs from passing between cells to exit the vascular system. Consequently, in order to reach sites of action within the brain, a drug must pass directly through cells of the capillary wall. To do this, the drug must be lipid soluble or be able to use an existing transport system.

drug must be able to pass *through* cells of the capillary wall. Only drugs that are *lipid soluble* or have a *transport system* can cross the BBB to a significant degree.

Recent evidence indicates that, in addition to tight junctions, the BBB has another protective component: *P-glycoprotein*. As noted earlier, P-glycoprotein is a transport molecule that pumps a variety of drugs out of cells. In capillaries of the CNS, P-glycoprotein pumps drugs back into the blood, and thereby limits their access to the brain.

The presence of the blood-brain barrier is a mixed blessing. The good news is that the barrier protects the brain from injury by potentially toxic substances. The bad news is that the barrier

can be a significant obstacle to therapy of CNS disorders. The barrier can, for example, impede access of antibiotics to CNS infections.

The blood-brain barrier is not fully developed at birth. As a result, newborns are much more sensitive than older children or adults to medicines that act on the brain. Likewise, neonates are especially vulnerable to CNS poisons.

4.5.2.3 Placental Drug Transfer

The membranes of the placenta separate the maternal circulation from the fetal circulation ([Fig. 4-10](#)). *The membranes of the placenta do NOT constitute an absolute barrier to the passage of drugs.* The same factors that determine the movement of drugs across other membranes determine the movement of drugs across the placenta. Accordingly, lipid-soluble, nonionized compounds readily pass from the maternal bloodstream into the blood of the fetus. In contrast, compounds that are ionized, highly polar, or protein bound (see below) are largely excluded—as are drugs that are substrates for P-glycoprotein, a transport molecule that can pump a variety of drugs out of placental cells into the maternal blood.

Drugs that have the ability to cross the placenta can cause serious harm. Some compounds can cause birth defects, ranging from low birth weight to mental retardation to gross malformations. (Recall the thalidomide experience.) If a pregnant woman is a habitual user of opioids (eg, heroin), her child will be born drug dependent, and hence will need treatment with a heroin substitute to prevent withdrawal. The use of respiratory depressants (anesthetics and analgesics) during delivery can depress respiration in the neonate. Accordingly, infants exposed to respiratory depressants must be monitored until breathing has normalized.

4.5.2.4 Protein Binding

Drugs can form reversible bonds with various proteins in the body. Of all the proteins to which drugs can bind, *plasma albumin* is the most important, being the most abundant protein in plasma. Like other proteins, albumin is a large molecule, having a molecular weight of 69,000. Because of its size, *albumin always remains within the bloodstream*: Albumin is too large to squeeze through pores in the capillary wall, and no transport system exists by which it might leave.

[Figure 4-11A](#) depicts the binding of drug molecules to albumin. Note that the drug molecules are much smaller than albumin. (The molecular mass of the average drug is about 300 to 500 compared with 69,000 for albumin.) As indicated by the two-way arrows, binding between albumin and drugs is *reversible*. As a result, a drug may exist either *bound* or *unbound* (free).

For drugs with the ability to bind with plasma albumin, only some molecules will be bound at any moment. The percentage of drug molecules that are bound is determined by the strength of the attraction between albumin and the drug. For example, the attraction between albumin and warfarin (an anticoagulant) is strong, causing nearly all (99%) of the warfarin molecules in plasma to be bound, leaving only 1% free. For gentamicin (an antibiotic), the ratio of bound to free is quite different; since the attraction between

36

37

Figure 4-10 Placental drug transfer. To enter the fetal circulation, drugs must cross membranes of the maternal and fetal vascular systems. Lipid-soluble drugs can readily cross these membranes and enter the fetal blood, whereas ions and polar molecules are prevented from reaching the fetal blood.

Figure 4-11 **Protein binding of drugs.****A**, Albumin is the most prevalent protein in plasma and the most important of the proteins to which drugs bind. **B**, Only unbound (free) drug molecules can leave the vascular system. Bound molecules are too large to fit through the pores in the capillary wall.

A Reversible Binding of a Drug to Albumin

B Retention of Protein-Bound Drug Within the Vasculature

gentamicin and albumin is relatively weak, less than 10% of the gentamicin molecules in plasma are bound, leaving more than 90% free.

An important consequence of protein binding is restriction of drug distribution. Because albumin is too large to leave the bloodstream, drug molecules that are bound to albumin cannot leave

either ([Fig. 4-11B](#)). As a result, bound molecules cannot reach their sites of action, metabolism, or excretion.

In addition to restricting drug distribution, protein binding can be a source of drug interactions. As suggested by [Figure 4-11A](#), each molecule of albumin has only a few sites to which drug molecules can bind. Because the number of binding sites is limited, drugs with the ability to bind albumin will compete with one another for binding. As a result, one drug can displace another from albumin, causing the free concentration of the displaced drug to rise. By increasing levels of free drug, competition for binding can increase the intensity of drug responses. Toxicity can result.

4.5.3 Entering Cells

Some drugs must enter cells to reach their sites of action, and practically all drugs must enter cells to undergo metabolism and excretion. The factors that determine the ability of a drug to cross cell membranes are the same factors that determine the passage of drugs across all other membranes, namely, lipid solubility, the presence of a transport system, or both.

As discussed in [Chapter 5](#), many drugs produce their effects by binding with receptors located on the external surface of the cell membrane. Obviously, these drugs do not need to cross the cell membrane to act.

4.6 METABOLISM

Drug metabolism, also known as *biotransformation*, is defined as *the enzymatic alteration of drug structure*. Most drug metabolism takes place in the liver.

37

Figure 4-12 **Therapeutic consequences of drug metabolism.** (See text for details.)

4.6.1 Hepatic Drug-Metabolizing Enzymes

Most drug metabolism that takes place in the liver is performed by the *hepatic microsomal enzyme system*, also known as the *P450 system*. The term *P450* refers to *cytochrome P450*, a key component of this enzyme system.

It is important to appreciate that cytochrome P450 is not a single molecular entity, but rather a group of 12 closely related enzyme families. Three of the cytochrome P450 (CYP) families—designated CYP1, CYP2, and CYP3—metabolize drugs. The other nine families metabolize endogenous compounds (eg, steroids, fatty acids). Each of the three P450 families that metabolize drugs is itself composed of multiple forms, each of which metabolizes only certain drugs. To identify the individual forms of cytochrome P450, we use designations such as CYP1A2, CYP2D6, and CYP3A4, indicating specific members of the CYP1, CYP2, and CYP3 families, respectively. I mention this nomenclature only so that it will be familiar when you come across it in your reading. This information is not intended for memorization.

Hepatic microsomal enzymes are capable of catalyzing a wide variety of reactions using drugs as substrates. Some of these reactions are illustrated in [Figure 4-12](#). As these examples indicate, drug metabolism doesn't always result in the breakdown of drugs into smaller molecules; drug metabolism can also result in the synthesis of a molecule that is larger than the parent drug.

4.6.2 Therapeutic Consequences of Drug Metabolism

Drug metabolism has six possible consequences of therapeutic significance:

- Accelerated renal excretion of drugs
- Drug inactivation
- Increased therapeutic action
- Activation of “prodrugs”
- Increased toxicity
- Decreased toxicity

The reactions shown in [Figure 4-12](#) illustrate these consequences of metabolism.

4.6.2.1 Accelerated Renal Drug Excretion.

The most important consequence of drug metabolism is promotion of renal drug excretion. As discussed in the next section, the kidney, which is the major organ of drug excretion, is unable to excrete drugs that are highly lipid soluble. By converting lipid-soluble drugs into more polar (less lipid-soluble) compounds, drug metabolism makes it possible for the kidney to excrete many drugs. For certain highly lipid-soluble drugs (eg, thiopental), complete renal excretion would take years were it not for their conversion into more polar compounds by drug-metabolizing enzymes.

4.6.2.2 Drug Inactivation.

Drug metabolism can convert pharmacologically active compounds to inactive forms. This process is illustrated by the conversion of procaine (a local anesthetic) into *para*-aminobenzoic acid (PABA), an inactive metabolite (see [Fig. 4-12](#)).

4.6.2.3 Increased Therapeutic Action.

Metabolism can increase the effectiveness of some drugs. This concept is illustrated by the conversion of codeine into morphine (see [Fig. 4-12](#)). The analgesic activity of morphine is so much greater than that of codeine that formation of morphine may account for virtually all the pain relief that occurs following codeine administration.

38

39

4.6.2.4 Activation of Prodrugs.

A *prodrug* is a compound that is pharmacologically inactive as administered and then undergoes conversion to its active form within the body. Activation of a prodrug is illustrated by the metabolic conversion of prazepam into desmethyldiazepam (see [Fig. 4-12](#)). (Prazepam is a close relative of diazepam, a drug familiar to us under the trade name Valium.)

4.6.2.5 Increased or Decreased Toxicity.

By converting drugs into inactive forms, metabolism can decrease toxicity. Conversely, metabolism can increase the potential for harm by converting relatively safe compounds into forms that are toxic. Increased toxicity is illustrated by the conversion of acetaminophen [Tylenol, others] into a hepatotoxic metabolite (see [Fig. 4-12](#)). It is this product of metabolism, and not acetaminophen itself, that causes injury when acetaminophen is taken in overdose.

4.6.3 Special Considerations in Drug Metabolism

Several factors can influence the rate at which drugs are metabolized. These must be accounted for in drug therapy.

4.6.3.1 Age.

The drug-metabolizing capacity of infants is limited. The liver does not develop its full capacity to metabolize drugs until about 1 year after birth. During the time prior to hepatic maturation, infants are especially sensitive to drugs, and care must be taken to avoid injury.

4.6.3.2 Induction of Drug-Metabolizing Enzymes.

Some drugs act on the liver to increase rates of drug metabolism. For example, when phenobarbital is administered for several days, it can cause the drug-metabolizing capacity of the liver to double. Phenobarbital increases metabolism by causing the liver to synthesize drug-metabolizing enzymes. This process of stimulating enzyme synthesis is known as *induction*.

Induction of drug-metabolizing enzymes can have two therapeutic consequences. First, by stimulating the liver to produce more drug-metabolizing enzymes, a drug can increase the rate of its own metabolism, thereby necessitating an increase in its dosage to maintain therapeutic effects. Second, induction of drug-metabolizing enzymes can accelerate the metabolism of other drugs used concurrently, necessitating an increase in their dosages.

4.6.3.3 First-Pass Effect.

The term *first-pass effect* refers to the rapid hepatic inactivation of certain oral drugs. As discussed earlier, when oral drugs are absorbed from the GI tract, they are carried directly to the liver via the hepatic portal vein. If the capacity of the liver to metabolize a drug is extremely high, that drug can be completely inactivated on its first pass through the liver. As a result, no therapeutic effects can occur. To circumvent the first-pass effect, a drug that undergoes rapid hepatic metabolism is often administered parenterally. This permits the drug to temporarily bypass the liver, thereby allowing it to reach therapeutic levels in the systemic blood.

Nitroglycerin is the classic example of a drug that undergoes such rapid hepatic metabolism that it is largely without effect following oral administration. However, when administered sublingually (under the tongue), nitroglycerin is very active. Sublingual administration is effective because it permits nitroglycerin to be absorbed directly into the systemic circulation. Once in the circulation, the drug is carried to its sites of action prior to passage through the liver. Hence, therapeutic action can be exerted before the drug is exposed to hepatic enzymes.

4.6.3.4 Nutritional Status.

Hepatic drug-metabolizing enzymes require a number of cofactors to function. In the malnourished patient, these cofactors may be deficient, causing drug metabolism to be compromised.

4.6.3.5 Competition Between Drugs.

When two drugs are metabolized by the same metabolic pathway, they may compete with each other for metabolism, and thereby decrease the rate at which one or both agents are metabolized. If metabolism is depressed enough, a drug can accumulate to dangerous levels.

4.7 EXCRETION

Drug excretion is defined as *the removal of drugs from the body*. Drugs and their metabolites can exit the body in urine, bile, sweat, saliva, breast milk, and expired air. The most important organ for drug excretion is the kidney.

4.7.1 Renal Drug Excretion

The kidneys account for the majority of drug excretion. When the kidneys are healthy, they serve to limit the duration of action of many drugs. Conversely, if renal failure occurs, both the duration and intensity of drug responses may increase.

4.7.1.1 Steps in Renal Drug Excretion

Urinary excretion is the net result of three processes: (1) glomerular filtration, (2) passive tubular reabsorption, and (3) active tubular secretion ([Fig. 4-13](#)).

4.7.1.1.1 Glomerular Filtration.

Renal excretion begins at the glomerulus of the kidney tubule. The glomerulus consists of a capillary network surrounded by Bowman's capsule; small pores perforate the capillary walls. As blood flows through the glomerular capillaries, fluids and small molecules—including drugs—are forced through the pores of the capillary wall. This process, called glomerular filtration, moves drugs from the blood into the tubular urine. Blood cells and large molecules (eg, proteins) are too big to pass through the capillary pores and therefore do not undergo filtration. Because large molecules are not filtered, drugs bound to albumin remain behind in the blood.

4.7.1.1.2 Passive Tubular Reabsorption.

As depicted in [Figure 4-13](#), the vessels that deliver blood to the glomerulus return to proximity with the renal tubule at a point distal to the glomerulus. At this distal site, drug concentrations in the blood are lower than drug concentrations in the tubule. This concentration gradient acts as a driving force to move drugs from the lumen of the tubule back into the blood. Because lipid-soluble drugs can readily cross the membranes that compose the tubular and vascular walls, *drugs that are lipid soluble undergo passive reabsorption from the tubule back into the blood*. In contrast, drugs that are not lipid soluble (ions and polar compounds) remain in the urine to be excreted. By converting lipid-soluble drugs into more polar forms, drug metabolism reduces passive reabsorption of drugs and thereby accelerates their excretion.

4.7.1.1.3 Active Tubular Secretion.

There are active transport systems in the kidney tubules that pump drugs from the blood to the tubular urine. The tubules have two primary classes of pumps, one for organic acids and one for organic bases. In addition, tubule cells contain P-glycoprotein, which can pump

39

40

Figure 4-13 Renal drug excretion. (MW = molecular weight.)

(Redrawn from Binns TB [ed]: Absorption and Distribution of Drugs. Edinburgh: Churchill Livingstone, 1964.)

a variety of drugs into the urine. These pumps have a relatively high capacity and play a significant role in excreting certain compounds.

4.7.1.2 Factors That Modify Renal Drug Excretion

4.7.1.2.1 pH-Dependent Ionization.

The phenomenon of pH-dependent ionization can be used to accelerate renal excretion of drugs. Recall that passive tubular reabsorption is limited to lipid-soluble compounds. Because ions are not lipid soluble, drugs that are ionized at the pH of tubular urine will remain in the tubule and be excreted. Consequently, by manipulating urinary pH in such a way as to promote the ionization of a drug, we can decrease passive reabsorption back into the blood and thereby hasten the drug's elimination. This principle has been employed to promote the excretion of poisons as well as medications that have been taken in toxic doses.

The treatment of aspirin poisoning provides an example of how manipulation of urinary pH can be put to therapeutic advantage. When children have been exposed to toxic doses of aspirin, they can be treated, in part, by giving an agent that elevates urinary pH (ie, makes the urine more basic). Since aspirin is an acidic drug, and since acids tend to ionize in basic media, elevation of urinary pH causes more of the aspirin molecules in urine to become ionized. As a result, less drug is passively reabsorbed and hence more is excreted.

4.7.1.2.2 Competition for Active Tubular Transport.

Competition between drugs for active tubular transport can delay renal excretion, thereby prolonging effects. The active transport systems of the renal tubules can be envisioned as motor-driven revolving doors that carry drugs from the plasma into the renal tubules. These “revolving doors” can carry only a limited number of drug molecules per unit of time. Accordingly, if there are too many molecules present, some must wait their turn. Because of competition, if we administer two drugs at the same time, and if both use the same transport system, excretion of each will be delayed by the presence of the other.

Competition for transport has been employed clinically to prolong the effects of drugs that normally undergo rapid renal excretion. For example, when administered alone, penicillin is rapidly cleared from the blood by active tubular transport. Excretion of penicillin can be delayed by concurrent administration of probenecid, an agent that is removed from the blood by the same tubular transport system that pumps penicillin. Hence, if a large dose of probenecid is administered, renal excretion of penicillin will be delayed while the transport system is occupied with moving the probenecid. By delaying penicillin excretion, probenecid prolongs antibacterial effects.

4.7.1.2.3 Age.

The kidneys of newborns are not fully developed. Until their kidneys reach full capacity (a few months after birth), infants have a limited capacity to excrete drugs. This must be accounted for when medicating an infant.

4.7.2 Nonrenal Routes of Drug Excretion

In most cases, excretion of drugs by nonrenal routes has minimal clinical significance. However, in certain situations, nonrenal excretion can have important therapeutic and toxicologic consequences.

4.7.2.1 Breast Milk

Drugs taken by breast-feeding women can undergo excretion into milk. As a result, breast-feeding can expose the nursing infant to drugs. The factors that influence the appearance of drugs in breast milk are the same factors that determine the passage of drugs across membranes. Accordingly, lipid-soluble drugs will have ready access to breast milk, whereas drugs that are polar, ionized, or protein bound will not enter in significant amounts. Because infants may be harmed by compounds excreted in breast milk, it is recommended that nursing mothers avoid all drugs. If a woman must take medication, she should consult with her prescriber to ensure that the drug will not reach concentrations in her milk that are high enough to harm her baby.

4.7.2.2 Other Nonrenal Routes of Excretion

The *bile* is an important route of excretion for certain drugs. Recall that bile is secreted into the small intestine and then leaves the body in the feces. In some cases, drugs entering the intestine in bile may undergo reabsorption back into the portal blood. This reabsorption, referred to as *enterohepatic recirculation*, can substantially prolong a drug's sojourn in the body (see [Fig. 4-8](#)).

The *lungs* are the major route by which volatile anesthetics are excreted.

Small amounts of drugs can appear in *sweat* and *saliva*. These routes have little therapeutic or toxicologic significance.

4.8 TIME COURSE OF DRUG RESPONSES

To achieve the therapeutic objective, we must control the time course of drug responses. We need to regulate the time at which drug responses start, the time they are most intense, and the time they cease. Because the four pharmacokinetic processes—absorption, distribution, metabolism, and excretion—determine how much drug will be at its sites of action at any given time, these processes are the major determinants of the time course over which drug responses take place. Having

Pharmacology for Nursing Care, 7th Edition

discussed the individual processes that contribute to determining the time course of drug action, we can now discuss the time course itself.

4.8.1 Plasma Drug Levels

In most cases, the time course of drug action bears a direct relationship to the concentration of a drug in the blood. Hence, before discussing the time course per se, we need to review several important concepts related to plasma drug levels.

4.8.1.1 Clinical Significance of Plasma Drug Levels

Clinicians frequently monitor plasma drug levels in efforts to regulate drug responses. When measurements indicate that drug levels are inappropriate, these levels can be adjusted up or down by changing the dosage, administration timing, or both.

The practice of regulating plasma drug levels in order to control drug responses should seem a bit odd, given that (1) drug responses are related to drug concentrations at sites of action and that (2) the site of action of most drugs is not in the blood. The question arises, “Why adjust plasma levels of a drug when what really matters is the concentration of that drug at its sites of action?” The answer begins with the following observation: More often than not, it is a practical impossibility to measure drug concentrations at sites of action. For example, when a patient with epilepsy takes phenytoin (an antiseizure agent), we cannot routinely draw samples from inside the skull to see if brain levels of the medication are adequate for seizure control. Fortunately, in the case of phenytoin and most other drugs, it is not necessary to measure drug concentrations at actual sites of action in order to have an objective basis for adjusting dosage. Experience has shown that, for most drugs, *there is a direct correlation between therapeutic and toxic responses and the amount of drug present in plasma*. Therefore, although we can't usually measure drug concentrations at sites of action, we *can* determine plasma drug concentrations that, in turn, are highly predictive of therapeutic and toxic responses. Accordingly, the dosing objective is commonly spoken of in terms of achieving a specific plasma level of a drug.

Figure 4-14 Single-dose time course.

4.8.1.2 Two Plasma Drug Levels Defined

Two plasma drug levels are of special importance: (1) the minimum effective concentration and (2) the toxic concentration. These levels are depicted in [Figure 4-14](#) and defined below.

4.8.1.3 Minimum Effective Concentration.

The minimum effective concentration (MEC) is defined as *the plasma drug level below which therapeutic effects will not occur*. Hence, to be of benefit, a drug must be present in concentrations at or above the MEC.

4.8.1.4 Toxic Concentration.

Toxicity occurs when plasma drug levels climb too high. The plasma level at which toxic effects begin is termed the *toxic concentration*. Doses must be kept small enough so that the toxic concentration is not reached.

4.8.1.5 Therapeutic Range

As indicated in [Figure 4-14](#), there is a range of plasma drug levels, falling between the MEC and the toxic concentration, that is termed the *therapeutic range*. When plasma levels are within the therapeutic range, there is enough drug present to produce therapeutic responses but not so much that toxicity results. *The objective of drug dosing is to maintain plasma drug levels within the therapeutic range.*

The width of the therapeutic range is a major determinant of the ease with which a drug can be used safely. Drugs that have a narrow therapeutic range are difficult to administer safely. Conversely, drugs that have a wide therapeutic range can be administered safely with relative ease. Acetaminophen, for example, has a relatively wide therapeutic range: The toxic concentration is about 30 times greater than the MEC. Because of this wide therapeutic range, dosage does not need to be highly precise; a broad range of doses can be employed to produce plasma levels that will be above the MEC and below the toxic concentration. In contrast, lithium (used for bipolar disorder [manic-depressive illness]) has a very narrow therapeutic range: The toxic concentration is only 3 times greater than the MEC. Because toxicity can result from lithium levels that are not much greater than those needed for therapeutic effects, lithium dosing must be done carefully. If lithium had a wider therapeutic range, the drug would be much easier to use.

Understanding the concept of therapeutic range can facilitate patient care. Because drugs with a narrow therapeutic range are more dangerous than drugs with a wide therapeutic range, patients

41

42

taking drugs with a narrow therapeutic range are the most likely to require intervention for drug-related complications. The nurse who is aware of this fact can focus attention on these patients. In contrast, the nurse who has no basis for predicting which drugs are most likely to produce toxicity has no basis for allocating attention, and therefore is obliged to monitor all patients with equal diligence—a process that is both stressful and inefficient.

However, lest you get the wrong impression, the above advice should not be construed as a license to be lax about patients taking drugs that have a wide therapeutic range. Even these drugs can cause harm. Hence, although patients receiving drugs with a narrow therapeutic range should be monitored most closely, common sense dictates that patients receiving safer drugs must not be neglected.

4.8.2 Single-Dose Time Course

[Figure 4-14](#) shows how plasma drug levels change over time after a single dose of an oral medication. Drug levels rise as the medicine undergoes absorption. Drug levels then decline as metabolism and excretion eliminate the drug from the body.

Because responses cannot occur until plasma drug levels have reached the MEC, there is a period of latency between drug administration and onset of effects. The extent of this delay is determined by the rate of absorption.

The duration of effects is determined largely by the combination of metabolism and excretion. As long as drug levels remain above the MEC, therapeutic responses will be maintained; when levels fall below the MEC, responses will cease. Since metabolism and excretion are the processes most responsible for causing plasma drug levels to fall, these processes are the primary determinants of how long drug effects will persist.

4.8.3 Drug Half-Life

Before proceeding to the topic of multiple dosing, we need to discuss the concept of half-life. When a patient ceases drug use, the combination of metabolism and excretion will cause the amount of drug in the body to decline. The half-life of a drug is an index of just how rapidly that decline occurs.

Drug half-life is defined as *the time required for the amount of drug in the body to decrease by 50%*. A few drugs have half-lives that are extremely short—on the order of minutes. In contrast, the half-lives of some drugs exceed 1 week. Drugs with short half-lives leave the body quickly. Drugs with long half-lives leave slowly.

Note that, in our definition of half-life, a *percentage*—not a specific *amount*—of drug is lost during one half-life. That is, the half-life does not specify, for example, that 2 gm or 18 mg will leave the body in a given time. Rather, the half-life tells us that, no matter what the amount of drug in the body may be, half (50%) will leave during a specified period of time (the half-life). The actual amount of drug that is lost during one half-life depends on just how much drug is present: The more drug that is in the body, the larger the amount lost during one half-life.

The concept of half-life is best understood through an example. Morphine provides a good illustration. The half-life of morphine is approximately 3 hours. By definition, this means that body stores of morphine will decrease by 50% every 3 hours—regardless of how much morphine is in the body. If there is 50 mg of morphine in the body, 25 mg (50%) will be lost in 3 hours; if there is only 2 mg of morphine in the body, only 1 mg (50% of 2 mg) will be lost in 3 hours. Note that, in both cases, morphine levels drop by 50% during an interval of one half-life. However, the actual *amount* lost is larger when total body stores of the drug are higher.

The half-life of a drug determines the dosing interval (ie, how much time separates each dose). For drugs with a short half-life, the dosing interval must be correspondingly short. If a long dosing interval were used, drug levels would fall below the MEC between doses, and therapeutic effects would be lost. Conversely, if a drug has a long half-life, a long time can separate doses without loss of effect.

4.8.4 Drug Levels Produced with Repeated Doses

Multiple dosing leads to drug accumulation. When a patient takes a single dose of a drug, plasma levels simply go up and then come back down. In contrast, when a patient takes repeated doses of a drug, the process is more complex and results in drug accumulation. The factors that determine the rate and extent of accumulation are considered below.

4.8.4.1 The Process by Which Plateau Drug Levels Are Achieved

Administering repeated doses will cause a drug to build up in the body until a *plateau* (steady level) has been achieved. What causes drug levels to reach plateau? To begin with, common sense tells us that, if a second dose of a drug is administered before all of the prior dose has been eliminated, total body stores of that drug will be higher after the second dose than after the initial dose. As succeeding doses are administered, drug levels will climb even higher. The drug will continue to accumulate until a state has been achieved in which the amount of drug eliminated between doses equals the amount administered. *When the amount of drug eliminated between doses equals the dose administered, average drug levels will remain constant and plateau will have been reached.*

The process by which multiple dosing produces a plateau is illustrated in [Figure 4-15](#). The drug in this figure is a hypothetical agent with a half-life of exactly 1 day. The regimen consists of a 2-gm dose administered once daily. For the purpose of illustration, we will assume that absorption takes place instantly. Upon administration of the first 2-gm dose (day 1 in the figure), total body stores go from zero to 2 gm. Within one half-life (1 day), body stores drop by 50%—from 2 gm down to 1 gm. At the beginning of day 2, the second 2-gm dose is given, causing body stores to rise from 1 gm up to 3 gm. Over the next day (one half-life), body stores again drop by 50%, this time from 3 gm down to 1.5 gm. When the third dose is given, body stores go from 1.5 gm up to 3.5 gm. Over the next half-life, stores drop by 50% down to 1.75 gm. When the fourth dose is given, drug levels climb to 3.75 gm and, between doses, levels again drop by 50%, this time to approximately 1.9 gm. When the fifth dose is given (at the beginning of day 5), drug levels go up to about 3.9 gm. This process of accumulation continues until body stores reach 4 gm. When total body stores of this drug are 4 gm, 2 gm will be lost each day (ie, over one half-life). Since a 2-gm dose is being administered each

42

43

Figure 4-15 Drug accumulation with repeated administration.

This figure illustrates the accumulation of a hypothetical drug during repeated administration. The drug has a half-life of 1 day. The dosing schedule is 2 gm given once a day on days 1 through 9. Note that plateau is reached at about the beginning of day 5 (ie, after four half-lives). Note also that, when administration is discontinued, it takes about 4 days (four half-lives) for most (94%) of the drug to leave the body.

day, when body stores reach 4 gm, the amount lost between doses will equal the dose administered. At this point, body stores will simply alternate between 4 gm and 2 gm; average body stores will be stable, and plateau will have been reached. Note that the reason that plateau is finally reached is that the actual amount of drug lost between doses gets larger each day. That is, although 50% of total body stores is lost each day, the *amount* in grams grows progressively larger because total body stores are getting larger day by day. Plateau is reached when the amount lost between doses grows to be as large as the amount administered.

4.8.4.2 Time to Plateau

When a drug is administered repeatedly in the same dose, *plateau will be reached in approximately four half-lives*. For the hypothetical agent illustrated in [Figure 4-15](#), total body stores approached their peak near the beginning of day 5, or approximately 4 full days after treatment began. Because the half-life of this drug is 1 day, reaching plateau in 4 days is equivalent to reaching plateau in four half-lives.

As long as dosage remains constant, the time required to reach plateau is independent of dosage size. Put another way, the time required to reach plateau when giving repeated large doses of a particular drug is identical to the time required to reach plateau when giving repeated small doses of that drug. Referring to the drug in [Figure 4-15](#), just as it took four half-lives (4 days) to reach plateau when a dose of 2 gm was administered daily, it would also take four half-lives to reach plateau if a dose of 4 gm were administered daily. It is true that the *height* of the plateau would be greater if a 4-gm dose were given, but the time required to reach plateau would not be altered by the increase in dosage. To confirm this statement, substitute a dose of 4 gm in the exercise we just went through and see when plateau is reached.

4.8.4.3 Techniques for Reducing Fluctuations in Drug Levels

As we can see in [Figure 4-15](#), when a drug is administered repeatedly, its level will fluctuate between doses. The highest level is referred to as the *peak concentration*, and the lowest level is referred to as the *trough concentration*. How high the peaks and how low the troughs can be will depend upon the drug's therapeutic range: The peaks must be kept below the toxic concentration, and the troughs must be kept above the MEC. If there is not much difference between the toxic concentration and the MEC, then fluctuations must be kept to a minimum.

Three techniques can be employed to reduce fluctuations in drug levels. One technique is to *administer drugs by continuous infusion*. With this procedure, plasma levels can be kept nearly constant. Another is to *administer a depot preparation*, which releases the drug slowly and steadily. The third is to *reduce both the size of each dose and the dosing interval* (keeping the total daily dose constant). For example, rather than giving the drug from [Figure 4-15](#) in 2-gm

doses once every 24 hours, we could give this drug in 1-gm doses every 12 hours. With this altered dosing schedule, the total daily dose would remain unchanged, as would total body stores at plateau. However, instead of fluctuating over a range of 2 gm between doses, levels would fluctuate over a range of 1 gm.

4.8.4.4 Loading Doses Versus Maintenance Doses

As discussed above, if we administer a drug in repeated doses of *equal size*, an interval equivalent to about four half-lives is required to achieve plateau. For drugs whose half-lives are long, achieving plateau could take days or even weeks. When plateau must be achieved more quickly, a large initial dose can be administered. This large initial dose is called a *loading dose*. After high drug levels have been established with a loading dose, plateau can be maintained by giving smaller doses. These smaller doses are referred to as *maintenance doses*.

The claim that use of a loading dose will shorten the time to plateau may appear to contradict an earlier statement, which said that the time to plateau is not affected by dosage size. However, there is no contradiction. For any *specified dosage*, it will always take about four half-lives to reach plateau. When a loading dose is administered followed by maintenance doses, we have not reached plateau *for the loading dose*. Rather, we have simply used the loading dose to rapidly produce a drug level equivalent to the plateau level for a smaller dose. If we wished to achieve plateau level for the loading dose, we would be obliged to either administer repeated doses equivalent to the loading dose for a period of four half-lives or administer a dose even larger than the original loading dose. Think about it.

4.8.4.5 Decline from Plateau

When drug administration is discontinued, most (94%) of the drug in the body will be eliminated over an interval equal to about four half-lives. This statement can be validated with simple arithmetic. Let's consider a patient who has been taking morphine. In addition, let's assume that, at the time dosing ceased, the total body store of morphine was 40 mg. Within one half-life after drug withdrawal, morphine stores will decline by 50%—down to 20 mg. During the second half-life, stores will again decline by 50%, dropping from 20 mg to 10 mg. During the third half-life, the level will decline once more by 50%—from 10 mg down to 5 mg. During the fourth half-life, the level will again decline by 50%—from 5 mg down to 2.5 mg. Hence, over a period of four half-lives, total body stores of morphine will drop from an initial level of 40 mg down to 2.5 mg, an overall decline of 94%. Most of the drug in the body will be cleared within four half-lives.

The time required for drugs to leave the body is important when toxicity develops. Let's consider the elimination of digitoxin (a drug once used for heart failure). Digitoxin, true to its name, is a potentially dangerous drug with a narrow therapeutic range. In addition, the half-life of digitoxin

is prolonged—about 7 days. What will be the consequence of digitoxin overdose? Toxic levels of the drug will remain in the body for a long time: Since digitoxin has a half-life of 7 days, and since four half-lives are required for most of the drug to be cleared from the body, it could take weeks for digitoxin stores to fall to a safe level. During the time that excess drug remains in the body, significant effort will be required to keep the patient alive. If digitoxin had a shorter half-life, body stores would decline more rapidly, thereby making management of overdose less difficult. (Because of its long half-life and potential for toxicity, digitoxin has been replaced by digoxin, a drug with identical actions but a much shorter half-life.)

It is important to note that the concept of half-life does not apply to the elimination of all drugs. A few agents, most notably ethanol (alcohol), leave the body at a *constant rate*, regardless of how much is present. The implications of this kind of decline for ethanol are discussed in [Chapter 38](#).

4.8.4.5.1

KEY POINTS

- Pharmacokinetics consists of four basic processes: absorption, distribution, metabolism, and excretion.
- Pharmacokinetic processes determine the concentration of a drug at its sites of action, and thereby determine the intensity and time course of responses.
- To move around the body, drugs must cross membranes, either by (1) passing through pores, (2) undergoing transport, or (3) penetrating the membrane directly.
- P-glycoprotein—found in the liver, kidney, placenta, intestine, and brain capillaries—can transport a variety of drugs *out* of cells.
- To cross membranes, most drugs must dissolve directly into the lipid bilayer of the membrane. Accordingly, lipid-soluble drugs can cross membranes easily, whereas drugs that are polar or ionized cannot.
- Acidic drugs ionize in basic (alkaline) media, whereas basic drugs ionize in acidic media.
- Absorption is defined as the movement of a drug from its site of administration into the blood.
- Absorption is enhanced by rapid drug dissolution, high lipid solubility of the drug, a large surface area for absorption, and high blood flow at the site of administration.

- Intravenous administration has several advantages: rapid onset, precise control over the amount of drug entering the blood, suitability for use with large volumes of fluid, and suitability for irritant drugs.
- Intravenous administration has several disadvantages: high cost; difficulty; inconvenience; danger because of irreversibility; and the potential for fluid overload, infection, and embolism.
- Intramuscular administration has two advantages: suitability for insoluble drugs and suitability for depot preparations.
- Intramuscular administration has two disadvantages: inconvenience and the potential for discomfort.
- Subcutaneous administration has the same advantages and disadvantages as IM administration.
- Oral administration has the advantages of ease, convenience, economy, and safety.
- The principal disadvantages of oral administration are high variability and possible inactivation by stomach acid, digestive enzymes, and liver enzymes (because oral drugs must pass through the liver before reaching the general circulation).
- Enteric-coated oral formulations are designed to release their contents in the small intestine—not in the stomach.
- Sustained-release oral formulations are designed to release their contents slowly, thereby permitting a longer interval between doses.
- Distribution is defined as the movement of drugs throughout the body.
- In most tissues, drugs can easily leave the vasculature through spaces between the cells that compose the capillary wall.
- The term *blood-brain barrier* refers to the presence of tight junctions between the cells that compose capillary walls in the CNS. Because of this barrier, drugs must pass through the cells of the capillary wall (rather than between them) in order to reach the CNS.
- The membranes of the placenta do not constitute an absolute barrier to the passage of drugs. The same factors that determine drug movements across all other membranes determine the movement of drugs across the placenta.

- Many drugs bind reversibly to plasma albumin. While bound to albumin, drug molecules cannot leave the vascular system.
- Drug metabolism (biotransformation) is defined as the enzymatic alteration of drug structure.
- Most drug metabolism takes place in the liver and is catalyzed by the cytochrome P450 system of enzymes.
- The most important consequence of drug metabolism is promotion of renal drug excretion (by converting lipid-soluble drugs into more polar forms).
- Other consequences of drug metabolism are conversion of drugs to less active (or inactive) forms, conversion of drugs to more active forms, conversion of prodrugs to their active forms, and conversion of drugs to more toxic or less toxic forms.
- Some drugs can induce (stimulate) synthesis of hepatic drug-metabolizing enzymes, and can thereby accelerate their own metabolism and the metabolism of other drugs.
- The term *first-pass effect* refers to the rapid inactivation of some oral drugs as they pass through the liver after being absorbed.
- Most drugs are excreted by the kidneys.
- Renal drug excretion has three steps: glomerular filtration, passive tubular reabsorption, and active tubular secretion.

44

- Drugs that are highly lipid soluble undergo extensive passive reabsorption back into the blood, and therefore cannot be excreted by the kidney (until they are converted to more polar forms by the liver).
- Drugs can be excreted into breast milk, thereby posing a threat to the nursing infant.
- For most drugs, there is a direct correlation between the level of drug in plasma and the intensity of therapeutic and toxic effects.
- The minimum effective concentration (MEC) is defined as the plasma drug level below which therapeutic effects will not occur.
- The therapeutic range of a drug lies between the MEC and the toxic concentration.
- Drugs with a wide therapeutic range are relatively easy to use safely, whereas drugs with a narrow therapeutic range are difficult to use safely.

45

- The half-life of a drug is defined as the time required for the amount of drug in the body to decline by 50%.
- Drugs that have a short half-life must be administered more frequently than drugs that have a long half-life.
- When drugs are administered repeatedly, their levels will gradually rise and then reach a steady plateau.
- The time required to reach plateau is equivalent to about four half-lives.
- The time required to reach plateau is independent of dosage size, although the height of the plateau will be higher with larger doses.
- If plasma drug levels fluctuate too much between doses, the fluctuations could be reduced by (1) giving smaller doses at shorter intervals (keeping the total daily dose the same), (2) using a continuous infusion, or (3) using a depot preparation.
- For a drug with a long half-life, it may be necessary to use a loading dose to achieve plateau quickly.
- When drug administration is discontinued, most (94%) of the drug in the body will be eliminated over four half-lives.

⁵ CHAPTER 5 Pharmacodynamics

Pharmacodynamics is defined as the study of the biochemical and physiologic effects of drugs and the molecular mechanisms by which those effects are produced. In short, pharmacodynamics is the study of what drugs do to the body and how they do it.

In order to participate rationally in achieving the therapeutic objective, nurses need a basic understanding of pharmacodynamics. You must know about drug actions in order to educate patients about their medication, make PRN decisions, and evaluate patients for drug responses, both beneficial and harmful. You also need to understand drug actions when conferring with prescribers about drug therapy: If you believe that a patient is receiving inappropriate medication or is being denied a required drug, you will need to support that conviction with arguments based at least in part on knowledge of pharmacodynamics.

5.1 DOSE-RESPONSE RELATIONSHIPS

The dose-response relationship (ie, the relationship between the size of an administered dose and the intensity of the response produced) is a fundamental concern in therapeutics. Dose-response relationships determine the minimum amount of drug we can use, the maximum response a drug can elicit, and how much we need to increase the dosage in order to produce the desired increase in response.

5.1.1 Basic Features of the Dose-Response Relationship

The basic characteristics of dose-response relationships are illustrated in [Figure 5-1](#). Part *A* shows dose-response data plotted on *linear* coordinates. Part *B* shows the same data plotted on *semilogarithmic* coordinates (ie, the scale on which dosage is plotted is logarithmic rather than linear). The most obvious and important characteristic revealed by these curves is that the dose-response relationship is *graded*. That is, as the dosage increases, the response becomes progressively larger. Because drug responses are graded, therapeutic effects can be adjusted to fit the needs of each patient. To tailor treatment to a particular patient, all we need do is raise or lower the dosage until a response of the desired intensity is achieved. If drug responses were *all-or-nothing* instead of graded, drugs could produce only one intensity of response. If that response were too strong or too weak for a particular patient, there would be nothing we could do to adjust the intensity to better suit the patient. Clearly, the graded nature of the dose-response relationship is essential for successful drug therapy.

As indicated in [Figure 5-1](#), the dose-response relationship can be viewed as having three phases. Phase 1 (see [Fig. 5-1B](#)) occurs at low doses. The curve is flat during this phase because doses are

too low to elicit a measurable response. During phase 2, an increase in dose elicits a corresponding increase in the response. This is the phase during which the dose-response relationship is graded. As the dose goes higher, we eventually reach a point where an increase in dose is unable to elicit a further increase in response. At this point, the curve flattens out into phase 3.

5.1.2 Maximal Efficacy and Relative Potency

Dose-response curves reveal two characteristic properties of drugs: *maximal efficacy* and *relative potency*. Curves that reflect these properties are shown in [Figure 5-2](#).

5.1.2.1 Maximal Efficacy

Maximal efficacy is defined as *the largest effect that a drug can produce*. Maximal efficacy is indicated by the *height* of the dose-response curve.

The concept of maximal efficacy is illustrated by the dose-response curves for meperidine [Demerol] and pentazocine [Talwin], two morphine-like pain relievers ([Fig. 5-2A](#)). As you can see, the curve for pentazocine levels off at a maximum height below that of the curve for meperidine. This tells us that the maximum degree of pain

46

47

Figure 5-1 Basic components of the dose-response curve.**A**, A dose-response curve with dose plotted on a linear scale. **B**, The same dose-response relationship shown in **A** but with the dose plotted on a logarithmic scale. Note the three phases of the dose-response curve: *Phase 1*, The curve is relatively flat; doses are too low to elicit a significant response. *Phase 2*, The curve climbs upward as bigger doses elicit a corresponding increase in response. *Phase 3*, The curve levels off; bigger doses are unable to elicit a further increase in response. (Phase 1 is not indicated in **A** because very low doses cannot be shown on a linear scale.)

Figure 5-2 **Dose-response curves demonstrating efficacy and potency.** **A**, Efficacy, or “maximal efficacy,” is an index of the maximal response a drug can produce. The efficacy of a drug is indicated by the height of its dose-response curve. In this example, meperidine has greater efficacy than pentazocine. Efficacy is an important quality in a drug. **B**, Potency is an index of how much drug must be administered to elicit a desired response. In this example, achieving pain relief with meperidine requires higher doses than with morphine. We would say that morphine is more potent than meperidine. Note that, if administered in sufficiently high doses, meperidine can produce just as much pain relief as morphine. Potency is usually not an important quality in a drug.

relief we can achieve with pentazocine is less than the maximum degree of pain relief we can achieve with meperidine. Put another way, no matter how much pentazocine we administer, we can never produce the degree of pain relief that we can with meperidine. Accordingly, we would say that meperidine has greater maximal efficacy than pentazocine.

Despite what intuition might tell us, a drug with very high maximal efficacy is not always more desirable than a drug with lower efficacy. Recall that we want to match the intensity of the response to the patient's needs. This may be difficult to do with a drug that produces extremely intense responses. For example, certain diuretics (eg, furosemide) have such high maximal efficacy that they can cause dehydration. If we only want to mobilize a modest volume of water, a diuretic with lower maximal efficacy (eg, hydrochlorothiazide) would be preferred. Similarly,

if a patient has a headache, we would not select a powerful analgesic (eg, morphine) for relief; rather, we would select an analgesic with lower maximal efficacy, such as aspirin. Put another way, it is neither appropriate nor desirable to hunt squirrels with a cannon.

47

48

5.1.2.2 Relative Potency

The term *potency* refers to the amount of drug we must give to elicit an effect. Potency is indicated by the relative position of the dose-response curve along the x (dose) axis.

The concept of potency is illustrated by the curves in [Figure 5-2B](#). These curves plot doses for two analgesics—morphine and meperidine—versus the degree of pain relief achieved. As you can see, for any particular degree of pain relief, the required dose of meperidine is larger than the required dose of morphine. Because morphine produces pain relief at lower doses than meperidine, we would say that morphine is more potent than meperidine. That is, a potent drug is one that produces its effects at low doses.

Potency is rarely an important characteristic of a drug. The fact that morphine is more potent than meperidine does not mean that morphine is a superior medicine. In fact, the only consequence of morphine's greater potency is that morphine can be given in smaller doses. The difference between providing pain relief with morphine versus meperidine is much like the difference between purchasing candy with a dime instead of two nickels; although the dime is smaller (more potent) than the two nickels, the purchasing power of the dime and the two nickels is identical.

Although potency is usually of no clinical concern, it can be important if a drug is so lacking in potency that doses become inconveniently large. For example, if a drug were of extremely low potency, we might need to administer that drug in huge doses multiple times a day to achieve beneficial effects. In this case, an alternative drug with higher potency would be desirable. Fortunately, it is rare for a drug to be so lacking in potency that doses of inconvenient magnitude need be given.

It is important to note that the potency of a drug implies nothing about its maximal efficacy!

Potency and efficacy are completely independent qualities. Drug A can be more effective than drug B even though drug B may be more potent. Also, drugs A and B can be equally effective even though one may be more potent. As we saw in [Figure 5-2B](#), although meperidine happens to be less potent than morphine, the maximal degree of pain relief that we can achieve with these drugs is identical.

A final comment on the word *potency* is in order. In everyday parlance, we tend to use the word *potent* to express the pharmacologic concept of effectiveness. That is, when most people say,

“This drug is very potent,” what they mean is, “This drug produces powerful effects.” They do not mean, “This drug produces its effects at low doses.” In pharmacology, we use the words *potent* and *potency* with the specific meanings given above. Accordingly, whenever you see those words in this book, they will refer only to the dosage needed to produce effects—never to the maximal effects a drug can produce.

5.2 DRUG-RECEPTOR INTERACTIONS

5.2.1 Introduction to Drug Receptors

Drugs are not “magic bullets”—they are simply chemicals. Being chemicals, the only way drugs can produce their effects is by interacting with other chemicals. Receptors are the special “chemicals” in the body that most drugs interact with to produce effects.

We can define a receptor as *any functional macromolecule in a cell to which a drug binds to produce its effects*. Under this broad definition, many cellular components could be considered drug receptors, since drugs bind to many cellular components (eg, enzymes, ribosomes, tubulin) to produce their effects. However, although the formal definition of a receptor encompasses all functional macromolecules, *the term receptor is generally reserved for what is arguably the most important group of macromolecules through which drugs act: the body's own receptors for hormones, neurotransmitters, and other regulatory molecules*. The other macromolecules to which drugs bind, such as enzymes and ribosomes, can be thought of simply as target molecules, rather than as true receptors.

The general equation for the interaction between drugs and their receptors is as follows (where D = drug and R = receptor):

$D + R \rightleftharpoons D - R \text{ COMPLEX} \rightarrow \text{RESPONSE}$ As suggested by the equation, binding of a drug to its receptor is usually *reversible*.

A receptor is analogous to a light switch, in that it has two configurations: “ON” and “OFF.” Like the switch, a receptor must be in the “ON” configuration to influence cellular function. Receptors are activated (“turned on”) by interaction with other molecules. Under physiologic conditions, receptor activity is regulated by endogenous compounds (neurotransmitters, hormones, other regulatory molecules). When a drug binds to a receptor, all that it can do is mimic or block the actions of endogenous regulatory molecules. By doing so, the drug will either increase or decrease the rate of the physiologic activity normally controlled by that receptor.

An illustration will help clarify the receptor concept. Let's consider receptors for norepinephrine (NE) in the heart. Cardiac output is controlled in part by NE acting at specific receptors in the

heart. Norepinephrine is supplied to those receptors by neurons of the autonomic nervous system (Fig. 5-3). When

Figure 5-3 Interaction of drugs with receptors for norepinephrine.

Under physiologic conditions, cardiac output can be increased by the binding of norepinephrine (NE) to receptors (R) on the heart. Norepinephrine is supplied to these receptors by nerves. These same receptors can be acted on by drugs, which can either mimic the actions of endogenous NE (and thereby increase cardiac output) or block the actions of endogenous NE (and thereby reduce cardiac output).

the need to increase cardiac output arises, the following events take place: (1) the firing rate of autonomic neurons to the heart increases, causing increased release of NE; (2) NE then binds to receptors on the heart; and (3) as a consequence of the interaction between NE and its receptors, both the rate and force of cardiac contractions increase, thereby increasing cardiac output. When

Pharmacology for Nursing Care, 7th Edition

the demand for cardiac output subsides, the autonomic neurons reduce their firing rate, binding of NE to its receptors diminishes, and cardiac output returns to resting levels.

The same cardiac receptors whose function is regulated by endogenous NE can also serve as receptors for drugs. That is, just as endogenous molecules can bind to these receptors, so can compounds that enter the body as drugs. The binding of drugs to these receptors can have one of two effects: (1) drugs can *mimic* the action of endogenous NE (and thereby increase cardiac output), or (2) drugs can *block* the action of endogenous NE (and thereby prevent stimulation of the heart by autonomic neurons).

Several important properties of receptors and drug-receptor interactions are illustrated by this example:

- The receptors through which drugs act are normal points of control of physiologic processes.
- Under physiologic conditions, receptor function is regulated by molecules supplied by the body.
- All that drugs can do at receptors is mimic or block the action of the body's own regulatory molecules.
- Because drug action is limited to mimicking or blocking the body's own regulatory molecules, drugs cannot give cells new functions. Rather, drugs can only alter the rate of pre-existing processes. In other words, drugs cannot make the body do anything that it is not already capable of doing.*
- Drugs produce their therapeutic effects by helping the body use its pre-existing capabilities to the patient's best advantage. Put another way, medications simply help the body help itself.
- In theory, it should be possible to synthesize drugs that can alter the rate of any biologic process for which receptors exist.

* The only exception to this rule is gene therapy. By inserting genes into cells, we actually can make them do something they were previously incapable of.

5.2.2 The Four Primary Receptor Families

Although the body has many different receptors, they comprise only four primary families: cell membrane-embedded enzymes, ligand-gated ion channels, G protein-coupled receptor systems, and transcription factors. These families are depicted in [Figure 5-4](#). In the discussion below, the

term *ligand-binding domain* refers to the specific region of the receptor where binding of drugs and endogenous regulatory molecules takes place.

5.2.2.1 Cell Membrane–Embedded Enzymes.

As shown in [Figure 5-4](#), receptors of this type span the cell membrane. The ligand-binding domain is located on the cell surface, and the enzyme's catalytic site is inside. Binding of an endogenous regulatory molecule or agonist drug (one that mimics the action of the endogenous regulatory molecule) activates the enzyme, thereby increasing its catalytic activity. Responses to activation of these receptors occur in seconds. Insulin is a good example of an endogenous ligand that acts through this type of receptor.

5.2.2.2 Ligand-Gated Ion Channels.

Like membrane-embedded enzymes, ligand-gated ion channels span the cell membrane. The function of these receptors is to regulate flow of ions into and out of cells. Each ligand-gated channel is specific for a particular ion (eg, Na^+ , Ca^{++}). As shown in [Figure 5-4](#), the ligand-binding domain is on the cell surface. When an endogenous ligand or agonist drug binds the receptor, the channel opens, allowing ions to flow inward or outward. (The direction of flow is determined by the concentration gradient of the ion

Figure 5-4 The four primary receptor families. 1, Cell membrane–embedded enzyme. 2, Ligand-gated ion channel. 3, G protein–coupled receptor system (G = G protein). 4, Transcription factor. (See text for details.)

across the membrane.) Responses to activation of a ligand-gated ion channel are extremely fast, usually occurring in milliseconds. Several neurotransmitters, including acetylcholine and gamma-aminobutyric acid (GABA), act through this type of receptor.

5.2.2.3 G Protein–Coupled Receptor Systems.

G protein–coupled receptor systems have three components: the receptor itself, G protein (so named because it binds GTP), and an effector (typically an ion channel or an enzyme). These systems work as follows: binding of an endogenous ligand or agonist drug activates the receptor, which in turn activates G protein, which in turn activates the effector. Responses to activation of this type of system develop rapidly. Numerous endogenous ligands, including NE, serotonin, histamine, and many peptide hormones, act through G protein–coupled receptor systems.

As shown in [Figure 5-4](#), the receptors that couple to G proteins are serpentine structures that traverse the cell membrane 7 times. For some of these receptors, the ligand-binding domain is on the cell surface. For others, the ligand-binding domain is located in a pocket accessible from the cell surface.

5.2.2.4 Transcription Factors.

Transcription factors differ from other receptors in two ways: (1) transcription factors are found *within* the cell rather than on the surface, and (2) responses to activation of these receptors are *delayed*. Transcription factors are situated on DNA in the cell nucleus. Their function is to regulate protein synthesis. Activation of these receptors by endogenous ligands or by agonist drugs stimulates transcription of messenger RNA molecules, which then act as templates for synthesis of specific proteins. The entire process—from activation of the transcription factor through completion of protein synthesis—may take hours or even days. Because transcription factors are intracellular, they can be activated only by ligands that are sufficiently lipid soluble to cross the cell membrane. Endogenous ligands that act through transcription factors include thyroid hormone and all of the steroid hormones (eg, progesterone, testosterone, cortisol).

5.2.3 Receptors and Selectivity of Drug Action

In [Chapter 1](#) we noted that selectivity is a highly desirable characteristic of a drug, in that the more selective a drug is, the fewer side effects it will produce. Selective drug action is possible, in large part, because drugs act through specific receptors.

The body employs many different kinds of receptors to regulate its sundry physiologic activities. There are receptors for each neurotransmitter (eg, NE, acetylcholine, dopamine); there are receptors for each hormone (eg, progesterone, insulin, thyrotropin); and there are receptors for all

of the other molecules the body uses to regulate physiologic processes (eg, histamine, prostaglandins, leukotrienes). As a rule, each type of receptor participates in the regulation of just a few processes.

Selective drug action is made possible by the existence of many types of receptors, each regulating just a few processes. Common sense tells us that, if a drug interacts with only one type of receptor, and if that receptor type regulates just a few processes, then the effects of the drug will be limited. Conversely, intuition also tells us that, if a drug interacts with several different receptor types, then that drug is likely to elicit a wide variety of responses.

How can a drug interact with one receptor type and not with others? In some important ways, a receptor is analogous to a lock and a drug is analogous to a key for that lock: Just as only keys with the proper profile can fit a particular lock, only those drugs with the proper size, shape, and physical properties can bind to a particular receptor.

The binding of acetylcholine (a neurotransmitter) to its receptor illustrates the lock-and-key analogy ([Fig. 5-5](#)). To bind with its receptor, acetylcholine must have a shape that is complementary to the shape of the receptor. In addition, acetylcholine must possess positive charges that are positioned so as to permit their interaction with corresponding negative sites on the receptor. If acetylcholine lacked these properties, it would be unable to interact with the receptor.

Like the acetylcholine receptor, all other receptors impose specific requirements on the molecules with which they will interact. Because receptors have such specific requirements, it is possible to synthesize drugs that interact with just one receptor type to the exclusion of all others. Such medications tend to elicit selective responses.

Even though a drug is selective for only one type of receptor, is it possible for that drug to produce nonselective effects? Yes: If a single receptor type is responsible for regulating several physiologic processes, then drugs that interact

Figure 5-5 **Interaction of acetylcholine with its receptor.** **A**, Three-dimensional model of the acetylcholine molecule. **B**, Binding of acetylcholine to its receptor. Note how the shape of acetylcholine closely matches the shape of the receptor. Note also how the positive charges on acetylcholine align with the negative sites on the receptor.

(Modified from Goldstein A, Aronow L, Sumner MK: Principles of Drug Action: The Basis of Pharmacology, 2nd ed. New York: John Wiley & Sons, 1974.)

with that receptor will also influence a variety of processes. For example, in addition to modulating perception of pain, morphine receptors help regulate other processes, including respiration and motility of the bowel. Consequently, although morphine is selective for one class of receptor, the drug can still produce a variety of effects. In clinical practice, it is common for morphine to cause respiratory depression and constipation along with reduction of pain. Note that morphine produces these varied effects not because it lacks receptor selectivity, but because the receptor for which morphine is selective helps regulate a variety of physiologic processes.

One final comment on selectivity: *Selectivity does not guarantee safety*. A compound can be highly selective for a particular receptor and still be dangerous. For example, although botulinum toxin is highly selective for one type of receptor, the compound is anything but safe: Botulinum toxin can cause paralysis of the muscles of respiration, resulting in death from respiratory arrest.

5.2.4 Theories of Drug-Receptor Interaction

In the discussion below, we consider two theories of drug-receptor interaction: (1) the simple occupancy theory and (2) the modified occupancy theory. These theories help explain dose-

response relationships and the ability of drugs to mimic or block the actions of endogenous regulatory molecules.

5.2.4.1 Simple Occupancy Theory

The simple occupancy theory of drug-receptor interaction states that (1) the intensity of the response to a drug is proportional to the number of receptors occupied by that drug and that (2) a maximal response will occur when *all* available receptors have been occupied. This relationship between receptor occupancy and the intensity of the response is depicted in [Figure 5-6](#).

Although certain aspects of dose-response relationships can be explained by the simple occupancy theory, other important phenomena cannot. Specifically, there is nothing in this theory to explain why one drug should be more potent than another. In addition, this theory cannot explain how one drug can have higher maximal efficacy than another. That is, according to this theory, two drugs acting at the same receptor should produce the same maximal effect, providing that their dosages were high enough to produce 100% receptor occupancy. However, we have already seen this is not true. As illustrated in [Figure 5-2A](#), there is a dose of pentazocine above which no further increase in response can be elicited. Presumably, all receptors are occupied when the dose-response curve levels off. However, at 100% receptor occupancy, the response elicited by pentazocine is less than that elicited by morphine. Simple occupancy theory cannot account for this difference.

5.2.4.2 Modified Occupancy Theory

The modified occupancy theory of drug-receptor interaction explains certain observations that cannot be accounted for with the simple occupancy theory. The simple occupancy theory assumes that all drugs acting at a particular receptor are identical with respect to (1) the ability to bind to the receptor and (2) the ability to influence receptor function once binding has taken place. The modified occupancy theory is based on different assumptions.

Figure 5-6 **Model of simple occupancy theory.** The simple occupancy theory states that the intensity of response to a drug is proportional to the number of receptors occupied; maximal response is reached with 100% receptor occupancy. Because the hypothetical cell in this figure has only four receptors, maximal response is achieved when all four receptors are occupied. (*Please note: Real cells have thousands of receptors.*)

The modified theory ascribes two qualities to drugs: *affinity* and *intrinsic activity*. The term *affinity* refers to the strength of the attraction between a drug and its receptor. *Intrinsic activity*

refers to the ability of a drug to activate the receptor following binding. *Affinity and intrinsic activity are independent properties.*

5.2.4.2.1 Affinity.

As noted, the term *affinity* refers to the strength of the attraction between a drug and its receptor. Drugs with high affinity are strongly attracted to their receptors. Conversely, drugs with low affinity are weakly attracted.

The affinity of a drug for its receptors is reflected in its *potency*. Because they are strongly attracted to their receptors, drugs with high affinity can bind to their receptors when present in low concentrations. Because they bind to receptors at low concentrations, drugs with high affinity are effective in low doses. That is, *drugs with high affinity are very potent*. Conversely, drugs with low affinity must be present in high concentrations to bind to their receptors. Accordingly, these drugs are less potent.

5.2.4.2.2 Intrinsic Activity.

The term *intrinsic activity* refers to the ability of a drug to activate a receptor upon binding. Drugs with high intrinsic activity cause intense receptor activation. Conversely, drugs with low intrinsic activity cause only slight activation.

The intrinsic activity of a drug is reflected in its *maximal efficacy*. Drugs with high intrinsic activity have high maximal efficacy. That is, by causing intense receptor activation, they are able to cause intense responses. Conversely, if intrinsic activity is low, maximal efficacy will be low as well.

It should be noted that, under the modified occupancy theory, the intensity of the response to a drug is still related to the number of receptors occupied. The wrinkle added by the modified theory is that intensity is also related to the ability of the drug to activate receptors once binding has occurred. Under the modified theory, two drugs can occupy the same number of receptors but produce effects of different intensity; the drug with greater intrinsic activity will produce the more intense response.

51

52

5.2.5 Agonists, Antagonists, and Partial Agonists

As noted, when drugs bind to receptors they can do one of two things: they can either *mimic* the action of endogenous regulatory molecules or they can *block* the action of endogenous regulatory molecules. Drugs that mimic the body's own regulatory molecules are called *agonists*. Drugs that block the actions of endogenous regulators are called *antagonists*. Like agonists, *partial agonists*

also mimic the actions of endogenous regulatory molecules, but they produce responses of intermediate intensity.

5.2.5.1 Agonists

Agonists are molecules that activate receptors. Because neurotransmitters, hormones, and all other endogenous regulators of receptor function activate the receptors to which they bind, all of these compounds are considered agonists. When drugs act as agonists, they simply bind to receptors and mimic the actions of the body's own regulatory molecules.

In terms of the modified occupancy theory, an agonist is a drug that has both *affinity* and *high intrinsic activity*. Affinity allows the agonist to bind to receptors, while intrinsic activity allows the bound agonist to “activate” or “turn on” receptor function.

Many therapeutic agents produce their effects by functioning as agonists. Dobutamine, for example, is a drug that mimics the action of NE at receptors on the heart, thereby causing heart rate and force of contraction to increase. The insulin that we administer as a drug mimics the actions of endogenous insulin at receptors. Norethindrone, a component of many oral contraceptives, acts by “turning on” receptors for progesterone.

It is important to note that agonists do not necessarily make physiologic processes go faster; receptor activation by these compounds can also make a process go slower. For example, there are receptors on the heart that, when *activated* by acetylcholine (the body's own agonist for these receptors), will cause heart rate to *decrease*. Drugs that mimic the action of acetylcholine at these receptors will also decrease heart rate. Because such drugs produce their effects by causing receptor activation, they would be called agonists—even though they cause heart rate to decline.

5.2.5.2 Antagonists

Antagonists produce their effects by preventing receptor activation by endogenous regulatory molecules and drugs. Antagonists have virtually no effects of their own on receptor function.

In terms of the modified occupancy theory, an antagonist is a drug with affinity for a receptor but with no intrinsic activity. Affinity allows the antagonist to bind to receptors, but lack of intrinsic activity prevents the bound antagonist from causing receptor activation.

Although antagonists do not cause receptor activation, they most certainly *do* produce pharmacologic effects. Antagonists produce their effects by *preventing the activation of receptors by agonists*. Antagonists can produce beneficial effects by blocking the actions of endogenous regulatory molecules or by blocking the actions of drugs. (The ability of antagonists to block the actions of drugs is employed most commonly in the treatment of overdose.)

It is important to note that the response to an antagonist is determined by how much *agonist* is present. Because antagonists act by preventing receptor activation, *if there is no agonist present, administration of an antagonist will have no observable effect*; the drug will bind to its receptors but nothing will happen. On the other hand, if receptors are undergoing activation by agonists, administration of an antagonist will shut the process down, resulting in an observable response. This is an important concept, so please think about it.

Many therapeutic agents produce their effects by acting as receptor antagonists. Antihistamines, for example, suppress allergy symptoms by binding to receptors for histamine, thereby preventing activation of these receptors by histamine released in response to allergens. The use of antagonists to treat drug toxicity is illustrated by naloxone, an agent that blocks receptors for morphine and related opioids; by preventing activation of opioid receptors, naloxone can completely reverse all symptoms of opioid overdose.

5.2.5.2.1 Noncompetitive Versus Competitive Antagonists.

Antagonists can be subdivided into two major classes: (1) noncompetitive antagonists and (2) competitive antagonists. Most antagonists are competitive.

5.2.5.2.1.1 Noncompetitive (Insurmountable) Antagonists.

Noncompetitive antagonists bind *irreversibly* to receptors. The effect of irreversible binding is equivalent to reducing the total number of receptors available for activation by an agonist. Because the intensity of the response to an agonist is proportional to the total number of receptors occupied, and because noncompetitive antagonists decrease the number of receptors available for activation, noncompetitive antagonists *reduce the maximal response* that an agonist can elicit. If sufficient antagonist is present, agonist effects will be blocked completely. Dose-response curves illustrating inhibition by a noncompetitive antagonist are shown in [Figure 5-7A](#).

Because the binding of noncompetitive antagonists is irreversible, inhibition by these agents cannot be overcome, no matter how much agonist may be available. Because inhibition by noncompetitive antagonists cannot be reversed, these agents are rarely used therapeutically. (Recall from [Chapter 1](#) that reversibility is one of the properties of an ideal drug.)

Although noncompetitive antagonists bind irreversibly, this does not mean that their effects last forever. Cells are constantly breaking down “old” receptors and synthesizing new ones. Consequently, the effects of noncompetitive antagonists wear off as the receptors to which

they are bound are replaced. Since the life cycle of a receptor can be relatively short, the effects of noncompetitive antagonists may subside in a few days.

5.2.5.2.1.2

Competitive (Surmountable) Antagonists.

Competitive antagonists bind *reversibly* to receptors. As their name implies, competitive antagonists produce receptor blockade by competing with agonists for receptor binding. If an agonist and a competitive antagonist have equal affinity for a particular receptor, then the receptor will be occupied by whichever agent—agonist or antagonist—is present in the

52

53

Figure 5-7 Dose-response curves in the presence of competitive and noncompetitive antagonists.**A,** Effect of a noncompetitive antagonist on the dose-response curve of an agonist. Note that noncompetitive antagonists decrease the maximal response achievable with an agonist. **B,** Effect of a competitive antagonist on the dose-response curve of an agonist. Note that the maximal response achievable with the agonist is not reduced. Competitive antagonists simply increase the amount of agonist required to produce any given intensity of response.

highest concentration. If there are more antagonist molecules present than agonist molecules, antagonist molecules will occupy the receptors and receptor activation will be blocked. Conversely, if agonist molecules outnumber the antagonists, receptors will be occupied mainly by the agonist and little inhibition will occur.

Because competitive antagonists bind reversibly to receptors, the inhibition they cause is *surmountable*. In the presence of sufficiently high amounts of agonist, agonist molecules will occupy all receptors and inhibition will be completely overcome. The dose-response curves shown in [Figure 5-7B](#) illustrate the process of overcoming the effects of a competitive antagonist with large doses of an agonist.

5.2.5.3 Partial Agonists

A partial agonist is an agonist that has only moderate intrinsic activity. As a result, *the maximal effect that a partial agonist can produce is lower than that of a full agonist*. Pentazocine is an example of a partial agonist. As the curves in [Figure 5-2A](#) indicate, the degree of pain relief that can be achieved with pentazocine is much lower than the relief that can be achieved with meperidine (a full agonist).

Partial agonists are interesting in that they can act as *antagonists* as well as *agonists*. For example, when pentazocine is administered by itself, it occupies opioid receptors and produces moderate relief of pain. In this situation, the drug is acting as an agonist. However, if a patient is already taking meperidine (a full agonist at opioid receptors) and is then given a large dose of pentazocine, pentazocine will occupy the opioid receptors and prevent their activation by meperidine. As a result, rather than experiencing the high degree of pain relief that meperidine can produce, the patient will experience only the limited relief that pentazocine can produce. In this situation, pentazocine is acting as both an agonist (producing moderate pain relief) and an antagonist (blocking the higher degree of relief that could have been achieved with meperidine by itself).

5.2.6 Regulation of Receptor Sensitivity

Receptors are dynamic components of the cell. In response to continuous activation or continuous inhibition, the number of receptors on the cell surface can change, as can their sensitivity to agonist molecules (drugs and endogenous ligands). For example, when the receptors of a cell are continually exposed to an *agonist*, the cell usually becomes less responsive. When this occurs, the cell is said to be *desensitized* or *refractory*, or to have undergone *down-regulation*. Several mechanisms may be responsible, including destruction of receptors by the cell and modification of receptors such that they respond less fully. Continuous exposure to antagonists has the opposite effect, causing the cell to become *hypersensitive* (also referred to as *supersensitive*). One mechanism that can cause hypersensitivity is synthesis of more receptors.

5.3 DRUG RESPONSES THAT DO NOT INVOLVE RECEPTORS

Although the effects of most drugs result from drug-receptor interactions, some drugs do not act through receptors. Rather, they act through simple physical or chemical interactions with other small molecules.

Common examples of “receptorless drugs” include antacids, antiseptics, saline laxatives, and chelating agents. Antacids reduce gastric acidity by direct chemical interaction with stomach acid. The antiseptic action of ethyl alcohol results from precipitating bacterial proteins. Magnesium sulfate, a powerful laxative, acts by retaining water in the intestinal lumen through an osmotic effect. Dimercaprol, a chelating agent, prevents toxicity from heavy metals (eg, arsenic, mercury) by forming complexes with these compounds. All of these pharmacologic effects are the result of simple physical or chemical interactions, and not interactions with cellular receptors.

53

5.4 INTERPATIENT VARIABILITY IN DRUG RESPONSES

54

The dose required to produce a therapeutic response can vary substantially among patients. Why? Because people differ from one another. In this section we consider interpatient variation as a general issue. The specific kinds of differences that underlie variability in drug responses are discussed in [Chapter 8](#).

In order to promote the therapeutic objective, you must be alert to interpatient variation in drug responses. Because of interpatient variation, it is not possible to predict exactly how an individual patient will respond to medication. Hence, each patient must be evaluated to determine his or her actual response to treatment. The nurse who appreciates the reality of interpatient variability will be better prepared to anticipate, evaluate, and respond appropriately to each patient's therapeutic needs.

5.4.1 Measurement of Interpatient Variability

An example of how interpatient variability is measured will facilitate discussion. Let's assume we've just developed a drug that suppresses production of stomach acid, and now want to evaluate variability in patient responses. To make this evaluation, we must first define a specific *therapeutic objective* or *endpoint*. Because our drug reduces gastric acidity, an appropriate endpoint is elevation of gastric pH to a value of 5.

Having defined a therapeutic endpoint, we can now perform our study. Subjects for the study are 100 people with gastric hyperacidity. We begin our experiment by giving each subject a low initial dose (100 mg) of our drug. Next we measure gastric pH to determine how many individuals achieved the therapeutic goal of pH 5. Let's assume that only two people responded to the initial dose. To the remaining 98 subjects, we give an additional 20-mg dose and again determine whose

gastric pH rose to 5. Let's assume that six more responded to this dose (120 mg total). We continue the experiment, administering doses in 20-mg increments, until all 100 subjects have responded with the desired elevation in pH.

The data from our hypothetical experiment are plotted in [Figure 5-8](#). The plot is called a *frequency distribution curve*. We can see from the curve that a wide range of doses is required to produce the desired response in all subjects. For some subjects, a dose of only 100 mg was sufficient to produce the target response. For other subjects, the therapeutic endpoint was not achieved until the dose totaled 240 mg.

5.4.2 The ED_{50}

The dose at the middle of the frequency distribution curve is termed the ED_{50} (see [Fig. 5-8B](#)). (ED_{50} is an abbreviation for *average effective dose*.) The ED_{50} is defined as *the dose that is required to produce a defined therapeutic response in 50% of the population*. In the case of our new drug, the ED_{50} was 170 mg—the dose needed to elevate gastric pH to a value of 5 in 50 of the 100 people tested.

The ED_{50} can be considered a “standard” dose and, as such, is frequently the dose selected for initial treatment. After evaluating a patient's response to this “standard” dose, we can then adjust subsequent doses up or down to meet the patient's needs.

5.4.3 Clinical Implications of Interpatient Variability

Interpatient variation has four important clinical consequences. As a nurse you should be aware of these implications:

- *The initial dose of a drug is necessarily an approximation. Subsequent doses must be “fine tuned” based on the patient's response.* Because initial doses are approximations, it would be wise not to challenge the prescriber if the initial dose differs by a small amount (eg, 10% to 20%) from

Figure 5-8 **Interpatient variation in drug responses.****A**, Data from tests of a hypothetical acid suppressant in 100 patients. The goal of the study is to determine the dosage required by each patient to elevate gastric pH to 5. Note the wide variability in doses needed to produce the target response for the 100 subjects. **B**, Frequency distribution curve for the data in A. The dose at the middle of the curve is termed the ED₅₀—the dose that will produce a predefined intensity of response in 50% of the population.

recommended doses in a published drug reference. Rather, you should administer the medication as prescribed and evaluate the response. Dosage adjustments can then be made as needed. Of course, if the prescriber's order calls for a dose that differs from the recommended dose by a large amount, that order should be challenged.

- *When given an average effective dose (ED₅₀), some patients will be undertreated, whereas others will have received more drug than they need.* Accordingly, when therapy is initiated with a dose equivalent to the ED₅₀, it is especially important to evaluate the response. Patients who fail to respond may need an increase in dosage. Conversely, patients who show signs of toxicity will need a dosage reduction.
- *Because drug responses are not completely predictable, you must look at the patient (and not the Physicians' Desk Reference) to determine if too much or too little medication has been administered.* In other words, doses should be adjusted on the basis of the patient's response and not just on the basis of what some reference says is supposed to work. For example,

although many postoperative patients receive adequate pain relief with an “average” dose of morphine, this dose is not appropriate for everyone: An average dose may be effective for some patients, ineffective for others, and toxic for still others. Clearly, dosage must be adjusted on the basis of the patient's response, and must not be given in blind compliance with the dosage recommended in a book.

- *Because of variability in responses, nurses, patients, and other concerned individuals must evaluate actual responses and be prepared to inform the prescriber about these responses so that proper adjustments in dosage can be made.*

5.5 THE THERAPEUTIC INDEX

The therapeutic index is a measure of a drug's safety. The therapeutic index, determined using laboratory animals, is defined as *the ratio of a drug's LD_{50} to its ED_{50}* . (The LD_{50} , or average lethal dose, is the dose that is lethal to 50% of the animals treated.) A large (or high) therapeutic index indicates that a drug is relatively safe. Conversely, a small (or low) therapeutic index indicates that a drug is relatively unsafe.

The concept of therapeutic index is illustrated by the frequency distribution curves in [Figure 5-9](#). Part A of the figure shows curves for therapeutic and lethal responses to drug “X.” Part B shows equivalent curves for drug “Y.” We can see in [Figure 5-9A](#) that the average lethal dose (100 mg) for drug X is much larger than the average therapeutic dose (10 mg). Because this drug's lethal dose is much larger than its therapeutic dose, common sense tells us that the drug should be relatively safe. The safety of this drug is reflected in its high therapeutic index, which is 10. In contrast, drug Y is unsafe. As shown in [Figure 5-9B](#), the average lethal dose for drug Y (20 mg) is only twice the average therapeutic dose (10 mg). Hence, for drug Y, a dose only twice the ED_{50} could be lethal to 50% of those treated. Clearly, drug Y is not safe. This lack of safety is reflected in its low therapeutic index.

The curves for drug Y illustrate a phenomenon that is even more important than the therapeutic index. As we can see, there is *overlap* between the curve for therapeutic effects and the curve for lethal effects. This overlap tells us that the high doses needed to produce therapeutic effects in some people may be large enough to cause death. The message here is that, if a drug is to be truly safe, the highest dose required to produce therapeutic effects must be substantially lower than the lowest dose required to produce death.

Figure 5-9 **The therapeutic index.** **A**, Frequency distribution curves indicating the ED₅₀ and LD₅₀ for drug “X.” Because its LD₅₀ is much greater than its ED₅₀, drug X is relatively safe. **B**, Frequency distribution curves indicating the ED₅₀ and LD₅₀ for drug “Y.” Because its LD₅₀ is very close to its ED₅₀, drug Y is not very safe. Also note the overlap between the effective-dose curve and the lethal-dose curve.

55

56

5.5.1

KEY POINTS

- Pharmacodynamics is the study of the biochemical and physiologic effects of drugs and the molecular mechanisms by which those effects are produced.
- For most drugs, the dose-response relationship is graded. That is, the response gets more intense with increasing dosage.

- Maximal efficacy is defined as the biggest effect a drug can produce.
- Although efficacy is important, there are many situations in which a drug with relatively low efficacy is preferable to a drug with very high efficacy.
- A potent drug is simply a drug that produces its effects at low doses. As a rule, potency is not important.
- Potency and efficacy are independent qualities. Drug A can be more effective than drug B even though drug B may be more potent. Also, drugs A and B can be equally effective, although one may be more potent than the other.
- A receptor can be defined as any functional macromolecule in a cell to which a drug binds to produce its effects.
- Binding of drugs to their receptors is almost always reversible.
- The receptors through which drugs act are normal points of control for physiologic processes.
- Under physiologic conditions, receptor function is regulated by molecules supplied by the body.
- All that drugs can do at receptors is mimic or block the action of the body's own regulatory molecules.
- Because drug action is limited to mimicking or blocking the body's own regulatory molecules, drugs cannot give cells new functions. Rather, drugs can only alter the rate of pre-existing processes.
- Receptors make selective drug action possible.
- There are four primary families of receptors: cell membrane–embedded enzymes, ligand-gated ion channels, G protein–coupled receptor systems, and transcription factors.
- If a drug interacts with only one type of receptor, and if that receptor type regulates just a few processes, then the effects of the drug will be relatively selective.
- If a drug interacts with only one type of receptor, but that receptor type regulates multiple processes, then the effects of the drug will be nonselective.
- If a drug interacts with multiple receptors, its effects will be nonselective.

- Selectivity does not guarantee safety.
- The term *affinity* refers to the strength of the attraction between a drug and its receptor.
- Drugs with high affinity have high relative potency.
- The term *intrinsic activity* refers to the ability of a drug to activate receptors.
- Drugs with high intrinsic activity have high maximal efficacy.
- Agonists are molecules that activate receptors.
- In terms of the modified occupancy theory, agonists have both affinity and high intrinsic activity. Affinity allows them to bind to receptors, while intrinsic activity allows them to activate the receptor after binding.
- Antagonists are drugs that prevent receptor activation by endogenous regulatory molecules and by other drugs.
- In terms of the modified occupancy theory, antagonists have affinity for receptors but no intrinsic activity. Affinity allows the antagonist to bind to receptors, but lack of intrinsic activity prevents the bound antagonist from causing receptor activation.
- Antagonists have no observable effects in the absence of agonists.
- Partial agonists have only moderate intrinsic activity. Hence their maximal efficacy is lower than that of full agonists.
- Partial agonists can act as agonists (if there is no full agonist present) and as antagonists (if a full agonist is present).
- Continuous exposure of cells to agonists can result in receptor desensitization (aka refractoriness or downregulation), whereas continuous exposure to antagonists can result in hypersensitivity (aka supersensitivity).
- Some drugs act through simple physical or chemical interactions with other small molecules rather than through receptors.
- The ED₅₀ is defined as the dose required to produce a defined therapeutic response in 50% of the population.
- The initial dose of a drug is necessarily an approximation. Subsequent doses must be “fine tuned” based on the patient's response.

- An average effective dose (ED_{50}) is perfect for some people, insufficient for others, and excessive for still others.
- Because drug responses are not completely predictable, you must look at the patient (and not some drug reference book) to determine if dosage is appropriate.
- The therapeutic index—defined as the $LD_{50}:ED_{50}$ ratio—is a measure of a drug's safety. Drugs with a high therapeutic index are safe. Drugs with a low therapeutic index are not safe.

⁶ CHAPTER 6 Drug Interactions

In this chapter we consider the interactions of drugs with other drugs, with foods, and with dietary supplements. Our principal focus is on the mechanisms and clinical consequences of drug-drug interactions and drug-food interactions. Drug-supplement interactions are discussed briefly here and at greater length in [Chapter 107](#).

^{6.1} DRUG-DRUG INTERACTIONS

Drug-drug interactions can occur whenever a patient takes two or more drugs. Some interactions are both intended and desired, as when we combine drugs to treat hypertension. In contrast, some interactions are both unintended and undesired, as when we precipitate malignant hyperthermia in a patient receiving halothane and succinylcholine. Some adverse interactions are well known, and hence generally avoidable. Many others are yet to be documented.

Drug interactions occur because patients frequently take more than one drug. They may take multiple drugs to treat a single disorder. They may have multiple disorders that require treatment with different drugs. They may take over-the-counter drugs in addition to prescription medicines. And they may take caffeine, nicotine, alcohol, and other drugs that have nothing to do with illness.

Our objective in this chapter is to establish an overview of drug interactions, emphasizing the basic mechanisms by which drugs can interact. We will not attempt to catalog the huge number of specific interactions that are known. For information on interactions of specific drugs, you can refer to the chapters in which those drugs are discussed.

^{6.1.1} Consequences of Drug-Drug Interactions

When two drugs interact, there are three possible outcomes: (1) one drug may intensify the effects of the other; (2) one drug may reduce the effects of the other; or (3) the combination may produce a new response not seen with either drug alone.

^{6.1.1.1} Intensification of Effects

When a patient is taking two medications, one drug may intensify the effects of the other. This type of interaction is often termed *potentiation*. Potentiation interactions may be beneficial or detrimental. A potentiation interaction that enhances therapeutic effects is clearly beneficial. Conversely, a potentiation interaction that intensifies adverse effects is clearly detrimental. Examples of beneficial and detrimental potentiation interactions follow.

6.1.1.1.1 Increased Therapeutic Effects.

The interaction between sulbactam and ampicillin represents a beneficial potentiative interaction. When administered alone, ampicillin undergoes rapid inactivation by bacterial enzymes. Sulbactam inhibits those enzymes, and thereby prolongs and intensifies ampicillin's therapeutic effects.

6.1.1.1.2 Increased Adverse Effects.

The interaction between aspirin and warfarin represents a potentially detrimental potentiative interaction. Warfarin is an anticoagulant used to suppress formation of blood clots. Unfortunately, if the dosage of warfarin is too high, the patient is at risk of spontaneous bleeding. Accordingly, for therapy to be safe and effective, the dosage must be high enough to suppress clot formation but not so high that spontaneous bleeding occurs. Like warfarin, aspirin also suppresses clotting. As a result, if aspirin and warfarin are taken concurrently, the risk of spontaneous bleeding is significantly increased. Clearly, potentiative interactions such as this are undesirable.

6.1.1.2 Reduction of Effects

Interactions that result in reduced drug effects are often termed *inhibitory*. As with potentiative interactions, inhibitory interactions can be beneficial or detrimental. Inhibitory interactions that reduce toxicity are beneficial. Conversely, inhibitory interactions that reduce therapeutic effects are detrimental. Examples follow.

6.1.1.2.1 Reduced Therapeutic Effects.

The interaction between propranolol and albuterol represents a detrimental inhibitory interaction. Albuterol is taken by people with asthma to dilate the bronchi. Propranolol, a drug for cardiovascular disorders, can act in the lung to block the effects of albuterol. Hence, if propranolol and albuterol are taken together, propranolol can reduce albuterol's therapeutic effects. Inhibitory actions such as this, which can result in therapeutic failure, are clearly detrimental.

57

6.1.1.2.2 Reduced Adverse Effects.

The use of naloxone to treat morphine overdose is an excellent example of a beneficial inhibitory interaction. When administered in excessive dosage, morphine can produce coma and profound respiratory depression; death can result. Naloxone, a drug that blocks morphine's

58

actions, can completely reverse all symptoms of toxicity. The benefits of such an inhibitory interaction are obvious.

6.1.1.3 Creation of a Unique Response

Rarely, the combination of two drugs produces a new response not seen with either agent alone. To illustrate, let's consider the combination of alcohol with disulfiram [Antabuse], a drug used to treat alcoholism. When alcohol and disulfiram are combined, a host of unpleasant and dangerous responses can result. These effects do not occur when disulfiram or alcohol is used alone.

6.1.2 Basic Mechanisms of Drug-Drug Interactions

Drugs can interact through four basic mechanisms: (1) direct chemical or physical interaction, (2) pharmacokinetic interaction, (3) pharmacodynamic interaction, and (4) combined toxicity.

6.1.2.1 Direct Chemical or Physical Interactions

Some drugs, because of their physical or chemical properties, can undergo direct interaction with other drugs. Direct physical and chemical interactions usually render both drugs inactive.

Direct interactions occur most commonly when drugs are combined in IV solutions. Frequently, but not always, the interaction produces a precipitate. If a precipitate appears when drugs are mixed together, that solution should be discarded. Keep in mind, however, that direct drug interactions may not always leave visible evidence. Hence you cannot rely on simple inspection to reveal all direct interactions. Because drugs can interact in solution, *never combine two or more drugs in the same container unless it has been established that a direct interaction will not occur.*

The same kinds of interactions that can take place when drugs are mixed together in a bottle can also occur when drugs are mixed together in the patient. However, since drugs are diluted in body water following administration, and since dilution decreases chemical interactions, significant interactions within the patient are much less likely than in a bottle.

6.1.2.2 Pharmacokinetic Interactions

Drug interactions can affect all four of the basic pharmacokinetic processes. That is, when two drugs are taken together, one may alter the absorption, distribution, metabolism, or excretion of the other.

6.1.2.2.1 Altered Absorption.

Drug absorption may be enhanced or reduced by drug interactions. In some cases, these interactions have great clinical significance. There are several mechanisms by which one drug can alter the absorption of another:

- By elevating gastric pH, antacids can decrease the ionization of basic drugs in the stomach, thereby increasing the ability of basic drugs to cross membranes and be absorbed. Antacids have the opposite effect on acidic drugs.
- Laxatives can reduce absorption of other drugs by accelerating their passage through the intestine.
- Drugs that depress peristalsis (eg, morphine, atropine) prolong drug transit time in the intestine, thereby increasing the time for absorption.
- Drugs that induce vomiting can decrease absorption of oral drugs.
- Cholestyramine and certain other adsorbent drugs, which are administered orally but do not undergo absorption, can adsorb other drugs onto themselves, thereby preventing absorption of the other drugs into the blood.
- Drugs that reduce regional blood flow can reduce absorption of other drugs from that region. For example, when epinephrine is injected together with a local anesthetic (as is often done), the epinephrine causes local vasoconstriction, thereby reducing regional blood flow and delaying absorption of the anesthetic.

6.1.2.2.2 Altered Distribution.

There are two principal mechanisms by which one drug can alter the distribution of another: (1) competition for protein binding and (2) alteration of extracellular pH.

6.1.2.2.3 Competition for Protein Binding.

When two drugs bind to the same site on plasma albumin, coadministration of those drugs produces competition for binding. As a result, binding of one or both agents is reduced, causing plasma levels of free drug to rise. In theory, the increase in free drug can intensify effects. However, since the newly freed drug usually undergoes rapid elimination, the increase in plasma levels of free drug is rarely sustained or significant.

6.1.2.2.4 Alteration of Extracellular pH.

Because of the pH partitioning effect (see [Chapter 4](#)), a drug with the ability to change extracellular pH can alter the distribution of other drugs. For example, if a drug were to increase extracellular pH, that drug would increase the ionization of acidic drugs in extracellular fluids (ie, plasma and interstitial fluid). As a result, acidic drugs would be drawn from within cells (where the pH was below that of the extracellular fluid) into the extracellular space. Hence, the alteration in pH would change drug distribution.

The ability of drugs to alter pH and thereby alter the distribution of other drugs can be put to practical use in the management of poisoning. For example, symptoms of aspirin toxicity can be reduced with sodium bicarbonate, a drug that elevates extracellular pH. By increasing the pH outside cells, bicarbonate causes aspirin to move from intracellular sites into the interstitial fluid and plasma, thereby minimizing injury to cells.

6.1.2.2.5 Altered Metabolism.

Altered metabolism is one of the most important—and most complex—mechanisms by which drugs interact. Some drugs *increase* the metabolism of other drugs, and some drugs *decrease* the metabolism of other drugs. Drugs that increase the metabolism of other drugs do so by inducing synthesis of hepatic drugmetabolizing enzymes. Drugs that decrease the metabolism of other drugs do so by inhibiting those enzymes.

As we discussed in [Chapter 4](#), the majority of drug metabolism is catalyzed by the cytochrome P450 (CYP) group of enzymes, which is composed of a large number of isozymes (closely related enzymes). Of all the isozymes in the P450 group, five are responsible for the metabolism of most drugs. These five isozymes of CYP are designated CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. [Table 6-1](#) lists major drugs that are metabolized by each isozyme, and indicates drugs that can inhibit or induce those isozymes.

6.1.2.2.5.1 Induction of CYP Isozymes.

Drugs that stimulate the synthesis of CYP isozymes are referred to as *inducing agents*. The classic example of an inducing agent is phenobarbital, a member of the barbiturate family.

By increasing the synthesis of specific CYP isozymes, phenobarbital and other inducing agents can stimulate their own metabolism as well as that of other drugs.

58

59

TABLE 6-1 Drugs That Are Important Substrates, Inhibitors, or Inducers of Specific CYP Isozymes

CYP	Substrates	Inhibitors	Inducers
CYP1A2	Caffeine, clomipramine, clozapine, sertraline, theophylline	Cimetidine	Omeprazole
		Fluoroquinolones	Tobacco
		Fluvoxamine	
		Ticlopidine	
CYP2C9	Diclofenac, ibuprofen, irbesartan, losartan, piroxicam, tamoxifen, tolbutamide, warfarin	Azole antifungals	Rifampin
		Fluvastatin	
		Imatinib	
		Zafirlukast	
CYP2C19	Diazepam, lansoprazole, nelfinavir, omeprazole, pantoprazole, voriconazole	Cimetidine	Rifampin
		Fluvoxamine	
		Isoniazid	
CYP2D6	<i>CNS Drugs:</i> amitriptyline, atomoxetine, desipramine, haloperidol, imipramine, paroxetine, risperidone, thioridazine	Amiodarone	
		Cimetidine	
	<i>Antidysrhythmic Drugs:</i> mexiletine, propafenone	Fluoxetine	
	<i>Beta Blockers:</i> metoprolol, propranolol, timolol	Haloperidol	
	<i>Opioids:</i> codeine, dextromethorphan, hydrocodone	Imatinib	
		Paroxetine	
		Quinidine	
		Ritonavir	

Pharmacology for Nursing Care, 7th Edition

CYP3A4	<i>Calcium Channel Blockers:</i> diltiazem, felodipine, nifedipine, nimodipine, nisoldipine, nitrendipine, verapamil	Amiodarone	Barbiturates
		Azole antifungals	Carbamazepine
	<i>Immunosuppressants:</i> cyclosporine, tacrolimus	Clarithromycin	Isoniazid
	<i>Steroids:</i> 17-beta-estradiol, budesonide, cortisol, progesterone, testosterone	Efavirenz	Phenytoin
	<i>Macrolide Antibiotics:</i> clarithromycin, erythromycin, troleandomycin	Erythromycin	Rifampin
	<i>Anticancer Drugs:</i> cyclophosphamide, gefitinib, ifosfamide, tamoxifen, vinblastine, vincristine	Grapefruit juice	St. John's wort
	<i>Benzodiazepines:</i> alprazolam, midazolam, triazolam	Indinavir	
	<i>Opioids:</i> alfentanil, fentanyl, sufentanil	Mibefradil	
	<i>HMG-CoA Reductase Inhibitors:</i> atorvastatin, lovastatin, simvastatin	Imatinib	
	<i>HIV Protease Inhibitors:</i> amprenavir, indinavir, nelfinavir, ritonavir, saquinavir	Nefazodone	
	<i>Others:</i> eletriptan, quinidine, sildenafil, ziprasidone	Nevirapine	
		Ritonavir	
		Troleandomycin	
Adapted from The Medical Letter 45(1158):47, 2003.			
CNS = central nervous system, HIV = human immunodeficiency virus, HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A.			

Inducing agents can increase the rate of drug metabolism by as much as two- to threefold. This increase develops over 7 to 10 days. Rates of metabolism return to normal 7 to 10 days after the inducing agent has been withdrawn.

When an inducing agent is taken with another medicine, dosage of the other medicine may need adjustment. For example, if a woman taking oral contraceptives were to begin taking phenobarbital, induction of drug metabolism by phenobarbital would accelerate metabolism of the contraceptive, thereby lowering its level. If drug metabolism is increased enough, protection against pregnancy would be lost. To maintain contraceptive efficacy, dosage of the contraceptive should be increased. Conversely, when a patient *discontinues* an inducing agent, dosages of other drugs may need to be *lowered*. If dosage is not reduced, drug levels may climb dangerously high as rates of hepatic metabolism decline to their baseline (noninduced) values.

6.1.2.2.5.2 Inhibition of CYP Isozymes.

If drug A inhibits the metabolism of drug B, then levels of drug B will rise. The result may be beneficial or harmful. The interaction of ketoconazole (an antifungal drug) with cisapride* (a GI stimulant) and cyclosporine (an expensive immunosuppressant) provides an interesting case in point. Ketoconazole inhibits CYP3A4, the CYP isozyme that metabolizes cisapride and cyclosporine. If ketoconazole is combined with either drug, that drug's level will rise. In the case of cisapride, the result can be a fatal cardiac dysrhythmia—a clearly undesirable outcome. However, in the case of cyclosporine, inhibition of CYP3A4 allows us to achieve therapeutic drug levels at lower doses, thereby greatly reducing the cost of treatment—a clearly beneficial result.

Although inhibition of drug metabolism can be beneficial, as a rule inhibition has undesirable results. That is, in most cases, when an inhibitor increases the level of another drug, the outcome is toxicity. Accordingly, when a patient is taking an inhibitor along with his or her other medicines, you should be alert for possible adverse effects. Unfortunately, since the number of possible interactions of this type is large, keeping track is a challenge.

* In the United States, cisapride [Propulsid] availability is restricted.

6.1.2.2.6 Altered Renal Excretion.

Drugs can alter all three phases of renal excretion: filtration, reabsorption, and active secretion. By doing so, one drug can alter the renal excretion of another. Glomerular filtration can be decreased by drugs that reduce cardiac output: A reduction in cardiac output decreases renal blood flow, which decreases drug filtration at the glomerulus, which in turn decreases the rate of drug excretion. By altering urinary pH, one drug can alter the ionization of another, and thereby increase or decrease the extent to which that drug undergoes passive tubular reabsorption. Lastly, competition between two drugs for active tubular secretion can decrease the renal excretion of both agents.

6.1.2.2.7 Interactions That Involve P-Glycoprotein.

As discussed in [Chapter 4](#) (Pharmacokinetics), P-glycoprotein (PGP) is a transmembrane protein that transports a wide variety of drugs *out* of cells, including cells of the intestinal epithelium, placenta, blood-brain barrier, liver, and kidney tubules. Like P450 isozymes, PGP is subject to induction and inhibition by drugs. In fact (and curiously), most of the drugs that induce or inhibit P450 have the same impact on PGP. Drugs that *induce* PGP can have the following impact on other drugs:

- *Reduced absorption*—by increasing drug export from cells of the intestinal epithelium into the intestinal lumen
- *Reduced fetal drug exposure*—by increasing drug export from placental cells into the maternal blood
- *Reduced brain drug exposure*—by increasing drug export from cells of brain capillaries into the blood
- *Increased drug elimination*—by increasing drug export from liver into the bile and from renal tubular cells into the urine

Drugs that inhibit PGP will have opposite effects.

6.1.2.3 Pharmacodynamic Interactions

By influencing pharmacodynamic processes, one drug can alter the effects of another.

Pharmacodynamic interactions are of two basic types: (1) interactions in which the interacting drugs act at the *same* site and (2) interactions in which the interacting drugs act at *separate* sites.

Pharmacodynamic interactions may be potentiative or inhibitory, and can be of great clinical significance.

6.1.2.3.1 Interactions at the Same Receptor.

Interactions that occur at the same receptor are almost always *inhibitory*. Inhibition occurs when an antagonist drug blocks access of an agonist drug to its receptor. These agonist-antagonist interactions are described in [Chapter 5](#). There are many agonistantagonist interactions of clinical importance. Some reduce therapeutic effects and are therefore undesirable. Others reduce toxicity and are of obvious benefit. The interaction between naloxone and morphine noted above is an example of a beneficial inhibitory interaction: By blocking access of morphine to its receptors, naloxone can reverse all symptoms of morphine overdose.

6.1.2.3.2 Interactions Resulting from Actions at Separate Sites.

Even though two drugs have different mechanisms of action and act at separate sites, if both drugs influence the same physiologic process, then one drug can alter responses produced by the other. Interactions resulting from effects produced at different sites may be potentiative or inhibitory.

The interaction between morphine and diazepam [Valium] illustrates a potentiative interaction resulting from concurrent use of drugs that act at separate sites. Morphine and diazepam are central nervous system (CNS) depressants, but these drugs do not share the same mechanism of action. Hence, when these agents are administered together, the ability of each to depress CNS function reinforces the depressant effects of the other. This potentiative interaction can result in profound CNS depression.

The interaction between two diuretics—hydrochlorothiazide and spironolactone—illustrates how the effects of a drug acting at one site can *counteract* the effects of a second drug acting at a different site. Hydrochlorothiazide acts on the distal convoluted tubule of the nephron to *increase* excretion of potassium. Acting at a different site in the kidney, spironolactone works to *decrease* renal excretion of potassium. Consequently, when these two drugs are administered together, the potassium-sparing effects of spironolactone tend to balance the potassium-wasting effects of hydrochlorothiazide, leaving renal excretion of potassium at about the same level it would have been had no drugs been given at all.

6.1.2.4 Combined Toxicity

Common sense tells us that if drug A and drug B are both toxic to the same organ, then taking them together will cause more injury than if they were not combined. For example, when we treat tuberculosis with isoniazid and rifampin, both of which are hepatotoxic, we cause more liver injury than we would using just one of the drugs. As a rule, drugs with overlapping toxicity are not used together. Unfortunately, when treating tuberculosis, the combination is essential, and hence can't be avoided.

6.1.3 Clinical Significance of Drug-Drug Interactions

From the foregoing it should be clear that drug interactions have the potential to affect the outcome of therapy. As a result of drug-drug interactions, the intensity of responses may be increased or reduced. Interactions that increase therapeutic effects or reduce toxicity are desirable. Conversely, interactions that reduce therapeutic effects or increase toxicity are detrimental.

Common sense tells us that the risk of a serious drug interaction is proportional to the number of drugs that a patient is taking. That is, the more drugs the patient receives, the greater the risk of a detrimental interaction. Because the average hospitalized patient receives 6 to 10 drugs, interactions are common. Accordingly, you should always be alert for them.

Interactions are especially important for drugs that have a narrow therapeutic range. For these agents, an interaction that produces a modest increase in drug levels can cause toxicity.

Conversely, an interaction that produces a modest decrease in drug levels can cause therapeutic failure.

Although a large number of important interactions have been documented, many more are yet to be identified. Therefore, if a patient develops unusual symptoms, it is wise to suspect that a drug interaction may be the cause—especially since yet another drug might be given to control the new symptoms.

6.1.4 Minimizing Adverse Drug-Drug Interactions

We can minimize adverse interactions in several ways. The most obvious is to minimize the number of drugs a patient receives. Indiscriminate use of multiple-drug therapy does not constitute good treatment—and increases the risk of undesired interactions. A second and equally important way to avoid detrimental interactions is to take a thorough drug history. A history that identifies all drugs the patient is taking allows the prescriber to adjust the regimen accordingly. Please note, however, that patients taking illicit drugs or over-the-counter preparations may fail to report such drug use. You should be aware of this possibility and make a special effort to ensure that the patient's drug use profile is complete. Additional measures for reducing adverse interactions include adjusting the dosage when an inducer of metabolism is added to or deleted from the regimen, adjusting the timing of administration to minimize interference with absorption, monitoring for early signs of toxicity when combinations of toxic agents cannot be avoided, and being especially vigilant when the patient is taking a drug with a narrow therapeutic range.

60

61

6.2 DRUG-FOOD INTERACTIONS

Drug-food interactions are both important and poorly understood. They are important because they can result in toxicity or therapeutic failure. They are poorly understood because research has been sorely lacking.

6.2.1 Impact of Food on Drug Absorption

6.2.1.1 Decreased Absorption.

Food frequently decreases the *rate* of drug absorption, and occasionally decreases the *extent* of absorption. Reducing the rate of absorption merely delays the onset of effects; peak effects are not lowered. In contrast, reducing the extent of absorption reduces the intensity of peak responses.

The interaction between calcium-containing foods and tetracycline antibiotics is perhaps the classic example of food reducing drug absorption. Tetracyclines bind with calcium to form an

insoluble and nonabsorbable complex. Hence, if tetracyclines are administered with milk products or calcium supplements, absorption is reduced and antibacterial effects may be lost.

High-fiber foods can reduce absorption of some drugs. For example, absorption of digoxin [Lanoxin], a drug used for cardiac disorders, is reduced significantly by wheat bran, rolled oats, and sunflower seeds. Since digoxin has a narrow therapeutic range, reduced absorption can result in therapeutic failure.

6.2.1.2 Increased Absorption.

With some drugs, food increases the extent of absorption. When this occurs, peak effects are heightened. For example, a high-calorie meal more than doubles the absorption of saquinavir [Invirase], a drug for HIV infection. If saquinavir is taken without food, absorption may be insufficient for antiviral activity.

6.2.2 Impact of Food on Drug Metabolism: The Grapefruit Juice Effect

Grapefruit juice can inhibit the metabolism of certain drugs, thereby raising their blood levels. The effect is quite remarkable. In one study, coadministration of grapefruit juice produced a 406% increase in blood levels of felodipine [Plendil], a calcium channel blocker used for hypertension. In addition to felodipine and other calcium channel blockers, grapefruit juice can increase blood levels of lovastatin [Mevacor], cyclosporine [Sandimmune], midazolam [Versed], and many other drugs ([Table 6-2](#)). This effect is *not* seen with other citrus juices, including orange juice.

Grapefruit juice raises drug levels mainly by inhibiting metabolism. Specifically, grapefruit juice inhibits CYP3A4, an isozyme of cytochrome P450 found in the liver and the intestinal wall. Inhibition of the *intestinal* isozyme is much greater than inhibition of the liver isozyme. By inhibiting CYP3A4, grapefruit juice decreases the intestinal metabolism of many drugs (see [Table 6-2](#)), and thereby increases the amount available for absorption. As a result, blood levels of these drugs rise, causing peak effects to be more intense. Since inhibition of CYP3A4 in the liver is minimal, grapefruit juice does not usually affect metabolism of drugs after they have been absorbed. Importantly, grapefruit juice has little or no effect on drugs administered IV. Why? Because, with IV administration, intestinal metabolism is not involved. Inhibition of CYP3A4 is dose dependent: The more grapefruit juice the patient drinks, the greater the inhibition.

What's in grapefruit juice that can inhibit CYP3A4? Four compounds have been identified. Two of them—*bergapten* and *6',7'-dihydroxybergamottin*—are furanocoumarins. The other two—*naringin* and *naringenin*—are flavenoids.

Inhibition of CYP3A4 persists after grapefruit juice is consumed. Therefore, a drug needn't be administered concurrently with grapefruit juice for an interaction to occur. Put another way, metabolism can still be inhibited even if a patient drinks grapefruit juice in the morning but waits until later in the day to take his or her medicine. In fact, when grapefruit juice is consumed on a regular basis, inhibition can persist up to 3 days after the last glass.

The effects of grapefruit juice vary considerably among patients. Why? Because levels of CYP3A4 show great individual variation. In patients with very little CYP3A4, inhibition by grapefruit juice may be sufficient to stop metabolism completely. As a result, large increases in drug levels may occur. Conversely, in patients with lots of CYP3A4, metabolism may continue more or less normally, despite inhibition by grapefruit juice. Hence, drug levels will be largely unaffected.

The clinical consequences of inhibition may be good or bad. As indicated in [Table 6-2](#), by elevating levels of certain drugs, grapefruit juice can increase the risk of serious toxicity, an outcome that is obviously bad. On the other hand, by increasing levels of two other drugs—saquinavir and cyclosporine—grapefruit juice can intensify therapeutic effects, an outcome that is clearly good.

What should patients do if the drugs they are taking can be affected by grapefruit juice? Unless a predictable effect is known, prudence dictates avoiding grapefruit juice entirely.

6.2.3 Impact of Food on Drug Toxicity

Drug-food interactions sometimes increase toxicity. The most dramatic example is the interaction between monoamine oxidase (MAO) inhibitors (a family of antidepressants) and foods rich in tyramine (eg, aged cheeses, yeast extracts, Chianti wine). If an MAO inhibitor is combined with these foods, blood pressure can rise to a life-threatening level. To avoid disaster, patients taking MAO inhibitors must be warned about the consequences of consuming tyramine-rich foods, and must be given a list of foods to strictly avoid (see [Chapter 32](#)). Other drug-food combinations that can increase toxicity include the following:

- Theophylline (an asthma medicine) plus caffeine, which can result in excessive CNS excitation
- Potassium-sparing diuretics (eg, spironolactone) plus salt substitutes, which can result in dangerously high potassium levels

61

TABLE 6-2 Some Drugs Whose Levels Can Be Increased by Grapefruit Juice

Drug	Indications	Potential Consequences of Increased Drug Levels
<i>Dihydropyridine CCBs:</i> amlodipine, felodipine, nicardipine, nifedipine, nimodipine, nisoldipine	Hypertension; angina pectoris	Toxicity: flushing, headache, tachycardia, hypotension
<i>Nondihydropyridine CCBs:</i> diltiazem, verapamil	Hypertension; angina pectoris	Toxicity: bradycardia, AV heart block, hypotension, constipation
<i>HMG-CoA Reductase Inhibitors:</i> lovastatin, simvastatin (minimal effect on atorvastatin, fluvastatin, pravastatin, or rosuvastatin)	Lower cholesterol	Toxicity: headache, GI disturbances, liver and muscle toxicity
Amiodarone	Cardiac dysrhythmias	Toxicity
Caffeine	Prevents sleepiness	Toxicity: restlessness, insomnia, convulsions, tachycardia
Carbamazepine	Seizures; bipolar disorder	Toxicity: ataxia, drowsiness, nausea, vomiting, tremor
Buspirone	Anxiety	Drowsiness, dysphoria
Triazolam	Anxiety; insomnia	Increased sedation
Midazolam	Induction of anesthesia; conscious sedation	Increased sedation
Saquinavir	HIV infection	Increased therapeutic effect
Cyclosporine	Prevents rejection of organ transplants	Increased therapeutic effects; if levels rise too high, renal and hepatic toxicity will occur
Sirolimus and tacrolimus	Prevent rejection of organ transplants	Toxicity
<i>SSRIs:</i> fluoxetine, fluvoxamine, sertraline	Depression	Toxicity: serotonin syndrome
Pimozide	Tourette's syndrome	Toxicity: QT prolongation resulting in a life-threatening ventricular dysrhythmia
Praziquantel	Schistosomiasis	Toxicity
Dextromethorphan	Cough	Toxicity
Sildenafil	Erectile dysfunction	Toxicity

AV = atrioventricular, CCBs = calcium channel blockers, GI = gastrointestinal, HIV = human immunodeficiency virus, HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A, SSRIs = selective serotonin reuptake inhibitors.

- Aluminum-containing antacids (eg, Maalox) plus citrus beverages (eg, orange juice), which can result in excessive absorption of aluminum

6.2.4 Impact of Food on Drug Action

Although most drug-food interactions concern drug absorption or drug metabolism, food may also (rarely) have a direct impact on drug action. For example, foods rich in vitamin K (eg, broccoli, Brussels sprouts, cabbage) can reduce the effects of warfarin, an anticoagulant. How? As discussed in [Chapter 51](#), warfarin acts by inhibiting vitamin K–dependent clotting factors. Accordingly, when vitamin K is more abundant, warfarin is less able to inhibit the clotting factors, and therapeutic effects decline.

6.2.5 Timing of Drug Administration with Respect to Meals

Administration of drugs at the appropriate time with respect to meals is an important facet of drug therapy. As discussed, the absorption of some drugs can be significantly decreased by food, and hence these drugs should be administered on an empty stomach. Conversely, the absorption of other drugs can be increased by food, and hence these drugs should be administered with meals.

Many drugs cause stomach upset when taken without food. If food does not reduce their absorption, then these drugs should definitely be administered with meals. However, if food does reduce their absorption, then we have a difficult choice: we can administer them with food and thereby reduce stomach upset (good news), but also reduce absorption (bad news)—or, we can administer them without food and thereby improve absorption (good news), but also increase stomach upset (bad news). Unfortunately, the correct choice is not obvious. The best solution may be to select an alternative drug that doesn't upset the stomach.

When the medication order says to administer a drug “with food” or “on an empty stomach,” just what does this mean? To administer a drug with food means to administer it with or shortly after a meal. To administer a drug on an empty stomach means to administer it either 1 hour before a meal or 2 hours after.

Medication orders frequently fail to indicate when a drug should be administered with respect to meals. As a result, inappropriate administration may occur. If you are uncertain about when to give a drug, ask the prescriber if it should be taken on an empty stomach or with food, and if there are any foods or beverages to avoid.

62

63

6.3 DRUG-SUPPLEMENT INTERACTIONS

Dietary supplements (herbal medicines and other nontraditional remedies) are used widely in the United States, creating the potential for frequent and significant interactions with conventional drugs. Of greatest concern are interactions that reduce beneficial responses to conventional drugs and interactions that increase toxicity. How do these interactions occur? Through the same pharmacokinetic and pharmacodynamic mechanisms by which conventional drugs interact with each other. Unfortunately, reliable information about dietary supplements is largely lacking—including information on interactions with conventional agents. Interactions that *have* been well documented are discussed as appropriate throughout this text. Dietary supplements and their interactions are discussed at length in [Chapter 107](#).

6.3.1 KEY POINTS

- Some drug-drug interactions are intended and beneficial; others are unintended and detrimental.
- Drug-drug interactions may result in intensified effects, diminished effects, or an entirely new effect.
- Potentiative interactions are beneficial when they increase therapeutic effects and detrimental when they increase adverse effects.
- Inhibitory interactions are beneficial when they decrease adverse effects and detrimental when they decrease beneficial effects.
- Because drugs can interact in solution, never combine two or more drugs in the same container unless you are certain that a direct interaction will not occur.
- Drug interactions can result in increased or decreased absorption.
- Competition for protein binding rarely results in a sustained or significant increase in plasma levels of free drug.
- Drugs that induce hepatic drug-metabolizing enzymes can accelerate the metabolism of other drugs.
- When an inducing agent is added to the regimen, it may be necessary to increase the dosages of other drugs. Conversely, when an inducing agent is discontinued, dosages of other drugs may need to be reduced.

- A drug that inhibits the metabolism of other drugs will increase their levels. Sometimes the result is beneficial, but usually it's detrimental.
- Drugs that act as antagonists at a particular receptor will diminish the effects of drugs that act as agonists at that receptor. The result may be beneficial (if the antagonist prevents toxic effects of the agonist) or detrimental (if the antagonist prevents therapeutic effects of the agonist).
- Drugs that are toxic to the same organ should not be combined (if at all possible).
- We can help reduce the risk of adverse interactions by minimizing the number of drugs the patient is given and by taking a thorough drug history.
- Food may reduce the rate or extent of drug absorption. Reducing the extent of absorption reduces peak therapeutic responses; reducing the rate of absorption merely delays the onset of effects.
- For some drugs, food may increase the extent of absorption.
- Grapefruit juice can inhibit the intestinal metabolism of certain drugs, thereby increasing their absorption, which in turn increases their blood levels.
- Foods may increase drug toxicity. The combination of an MAO inhibitor with tyramine-rich food is the classic example.
- When the medication order says to administer a drug on an empty stomach, this means administer it either 1 hour before a meal or 2 hours after.
- Conventional drugs can interact with dietary supplements. The biggest concerns are increased toxicity and reduced therapeutic effects of the conventional agent.

⁷ CHAPTER 7 Adverse Drug Reactions and Medication Errors

In this chapter we discuss two related issues of drug safety: (1) adverse drug reactions (ADRs), also known as adverse drug events (ADEs) and (2) medication errors, a major cause of ADRs. We begin with ADRs and then discuss medication errors.

7.1 ADVERSE DRUG REACTIONS

An ADR, as defined by the World Health Organization, is any noxious, unintended, and undesired effect that occurs at normal drug doses. Note that this definition excludes undesired effects that occur when dosage is excessive (eg, because of accidental poisoning or medication error). Adverse reactions can range in intensity from annoying to life threatening. Fortunately, when drugs are used properly, many ADRs can be avoided, or at least minimized.

7.1.1 Scope of the Problem

Drugs can adversely affect all body systems in varying degrees of intensity. Among the more mild reactions are drowsiness, nausea, itching, and rash. Severe reactions include depression, neutropenia, hepatocellular injury, anaphylaxis, and hemorrhage—all of which can be fatal.

Although ADRs can occur in all patients, some patients are more vulnerable than others. Adverse events are most common in the elderly and the very young. (Patients over 60 account for nearly 50% of all ADR cases.) Severe illness also increases the risk of an ADR. Likewise, adverse events are more common in patients receiving multiple drugs than in patients taking just one.

Some data on ADRs will underscore their significance. Each year in the United States, about 700,000 people visit emergency departments because of ADRs. Among patients already in a hospital, over 770,000 experience a serious ADR, and about 110,000 die. If these numbers are correct, ADRs would be the fourth leading cause of death, exceeded only by heart disease, cancer, and stroke.

7.1.2 Definitions

7.1.2.1 Side Effect

A side effect is formally defined as *a nearly unavoidable secondary drug effect produced at therapeutic doses*. Common examples include drowsiness caused by traditional antihistamines and gastric irritation caused by aspirin. Side effects are generally predictable and their intensity

is dose dependent. Some side effects develop soon after drug use starts, whereas others may not appear until a drug has been taken for weeks or months.

7.1.2.2 Toxicity

The formal definition of toxicity is *an adverse drug reaction caused by excessive dosing*. Examples include coma from an overdose of morphine and severe hypoglycemia from an overdose of insulin. Although the formal definition of toxicity includes only those severe reactions that occur when dosage is excessive, in everyday parlance the term *toxicity* has come to mean any severe ADR, regardless of the dose that caused it. For example, when administered in therapeutic doses, many anticancer drugs cause neutropenia (profound loss of neutrophilic white blood cells), thereby putting the patient at high risk of infection. This neutropenia would be called a toxicity even though it was produced when dosage was therapeutic.

7.1.2.3 Allergic Reaction

An allergic reaction is an immune response. For an allergic reaction to occur, there must be prior sensitization of the immune system. Once the immune system has been sensitized to a drug, re-exposure to that drug can trigger an allergic response. The intensity of allergic reactions can range from mild itching to severe rash to anaphylaxis. (Anaphylaxis is a life-threatening response characterized by bronchospasm, laryngeal edema, and a precipitous drop in blood pressure.) Estimates suggest that less than 10% of ADRs are of the allergic type.

64

The intensity of an allergic reaction is determined primarily by the degree of sensitization of the immune system—not by drug dosage. Put another way, *the intensity of allergic reactions is largely independent of dosage*. As a result, a dose that elicits a very strong reaction in one allergic patient may elicit a very mild reaction in another. Furthermore, since a patient's sensitivity to a drug can change over time, a dose that elicits a mild reaction early in treatment may produce an intense reaction later on.

65

Very few medications cause severe allergic reactions. In fact, most serious reactions are caused by just one drug family—the *penicillins*. Other drugs noted for causing allergic reactions include the nonsteroidal anti-inflammatory drugs (eg, aspirin) and the sulfonamide group of compounds, which includes certain diuretics, antibiotics, and oral hypoglycemic agents.

7.1.2.4 Idiosyncratic Effect

An idiosyncratic effect is defined as *an uncommon drug response resulting from a genetic predisposition*. To illustrate this concept, let's consider responses to succinylcholine, a drug used

to produce flaccid paralysis of skeletal muscle. In most patients, succinylcholine-induced paralysis is brief, lasting only a few minutes. In contrast, genetically predisposed patients may become paralyzed for hours. Why the difference? Because in all patients the effects of succinylcholine are terminated through enzymatic inactivation of the drug. Since most people have very high levels of the inactivating enzyme, paralysis is short lived. However, in a small percentage of patients, the genes that code for succinylcholine-metabolizing enzymes are abnormal, producing enzymes that inactivate the drug very slowly. As a result, paralysis is greatly prolonged.

7.1.2.5 Iatrogenic Disease

The word *iatrogenic* is derived from two words: *iatros*, the Greek word for physician, and *-genic*, a combining form meaning *to produce*. Hence, an iatrogenic disease is *a disease produced by a physician*. The term *iatrogenic disease* is also used to denote *a disease produced by drugs*.

Iatrogenic diseases are nearly identical to idiopathic (naturally occurring) diseases. For example, patients taking certain antipsychotic drugs may develop a syndrome whose symptoms closely resemble those of Parkinson's disease. Because this syndrome is (1) drug induced and (2) essentially identical to a naturally occurring pathology, we would call the syndrome an iatrogenic disease.

7.1.2.6 Physical Dependence

Physical dependence develops during long-term use of certain drugs, such as opioids, alcohol, barbiturates, and amphetamines. We can define physical dependence as a state in which the body has adapted to drug exposure in such a way that an abstinence syndrome will result if drug use is discontinued. The precise nature of the abstinence syndrome is determined by the drug involved.

Although physical dependence is usually associated with “narcotics” (heroin, morphine, and other opioids), these are not the only dependence-inducing drugs. In addition to the opioids, a variety of other centrally acting drugs (eg, ethanol, barbiturates, amphetamines) can promote dependence. Furthermore, some drugs that work outside the central nervous system can cause physical dependence of a sort. Because a variety of drugs can cause physical dependence of one type or another, and because withdrawal reactions have the potential for harm, *patients should be warned against abrupt discontinuation of any medication without first consulting a knowledgeable health professional*.

7.1.2.7 Carcinogenic Effect

The term *carcinogenic effect* refers to the ability of certain medications and environmental chemicals to cause cancers. Fortunately, only a few therapeutic agents are carcinogenic. Ironically, several of the drugs used to *treat* cancer are among those with the greatest carcinogenic potential.

Evaluating drugs for the ability to cause cancer is extremely difficult. Evidence of neoplastic disease may not appear until 20 or more years after initial exposure to a cancer-causing compound. Consequently, it is nearly impossible to detect carcinogenic potential during preclinical and clinical trials. Accordingly, when a new drug is released for general marketing, we cannot know with certainty that it will not eventually prove carcinogenic.

Diethylstilbestrol (DES) illustrates the problem posed by the delayed appearance of cancer following exposure to a carcinogenic drug. DES is a synthetic hormone with actions similar to those of estrogen. At one time, DES was used to prevent spontaneous abortion during high-risk pregnancies. It was not until years later, when vaginal and uterine cancers developed in females who had been exposed to this drug *in utero*, that the carcinogenic actions of DES became known.

7.1.2.8 Teratogenic Effect

A *teratogenic effect* can be defined as a drug-induced birth defect. Medicines and other chemicals capable of causing birth defects are called teratogens. Teratogenesis is discussed at length in [Chapter 9](#).

7.1.3 Organ-Specific Toxicity

Many drugs are toxic to specific organs. Common examples include injury to the kidneys caused by amphotericin B (an antifungal drug), injury to the heart caused by doxorubicin (an anticancer drug), injury to the lungs caused by amiodarone (an antidysrhythmic drug), and injury to the inner ear caused by aminoglycoside antibiotics (eg, gentamicin). Patients using such drugs should be monitored for signs of developing injury. In addition, patients should be educated about these signs and advised to seek medical attention if they appear.

Two types of organ-specific toxicity deserve special comment. These are (1) injury to the liver and (2) altered cardiac function, as evidenced by a prolonged QT interval on the electrocardiogram. Both are discussed below.

7.1.3.1 Hepatotoxic Drugs

In the United States, drugs are the leading cause of acute liver failure, a rare condition that can rapidly prove fatal. Most cases end with a liver transplant or in death. The ability to cause severe liver damage is the most common reason for withdrawing an approved drug from the market.

Fortunately, liver failure from using known hepatotoxic drugs is rare, with an incidence of less than 1 in 50,000. (Drugs that cause liver failure more often than this are removed from the market—unless they are indicated for a life-threatening illness.) More than 50 drugs are known to be hepatotoxic. Some of these are listed in [Table 7-1](#).

65

TABLE 7-1 Some Hepatotoxic Drugs

Statins and Other Lipid-Lowering Drugs

Atorvastatin [Lipitor]

Fenofibrate [Tricor]

Fluvastatin [Lescol]

Gemfibrozil [Lopid]

Lovastatin [Mevacor]

Niacin [Niaspan, others]

Pravastatin [Pravachol]

Simvastatin [Zocor]

Oral Hypoglycemics

Acarbose [Precose]

Pioglitazone [Actos]

Rosiglitazone [Avandia]

Antiseizure Drugs

Carbamazepine [Tegretol]

Felbamate [Felbatol]

Valproic acid [Depakene, others]

Antifungal Drugs

Itraconazole [Sporanox]

Ketoconazole [Nizoral]

Terbinafine [Lamisil]

Drugs for Tuberculosis

Isoniazid

Pyrazinamide

Rifampin [Rifadin]

Immunosuppressants

Azathioprine [Imuran]

Methotrexate [Rheumatrex]

Antiretroviral Drugs

Nevirapine [Viramune]

Ritonavir [Norvir]

Other Drugs

Acetaminophen [Tylenol, others], but only when combined with alcohol, or taken in excessive dosage

Amiodarone [Cordarone]

Diclofenac [Voltaren]

Duloxetine [Cymbalta]

Halothane [Fluothane]

Leflunomide [Arava]

Methyldopa [Aldomet]

Nefazodone [Serzone]

Nitrofurantoin [Macrochantin]

Tacrine [Cognex]

Tamoxifen [Nolvadex]

Zileuton [Zyflo]

How do drugs damage the liver? Recall that the liver is the primary site of drug metabolism. As some drugs undergo metabolism, they are converted to toxic products that can injure liver cells.

Combining a hepatotoxic drug with certain other drugs may increase the risk of liver damage. A good example is the combination of acetaminophen [Tylenol] with alcohol. When taken in *therapeutic* doses* in the absence of alcohol, acetaminophen cannot harm the liver. However, if the drug is taken with just two or three drinks, severe liver injury can result.

Patients taking hepatotoxic drugs should undergo liver function tests (LFTs) at baseline and periodically thereafter. How do we assess liver function? By testing a blood sample for the presence of two liver enzymes: *aspartate aminotransferase* (AST, formerly known as SGOT) and *alanine aminotransferase* (ALT, formerly known as SGPT). Under normal conditions blood

levels of AST and ALT are low. However, when liver cells are injured, blood levels of these enzymes rise. LFTs are performed on a regular schedule (eg, every 3 months) in hopes of detecting injury early. Unfortunately, since drug-induced liver injury can develop very quickly, it may progress from undetectable to advanced between scheduled tests.

All patients receiving hepatotoxic drugs should be informed about signs of liver injury—jaundice (yellow skin and eyes), dark urine, light-colored stools, nausea, vomiting, malaise, abdominal discomfort, loss of appetite—and advised to seek medical attention if these develop.

* Excessive (toxic) doses of acetaminophen, by itself, can harm the liver.

7.1.3.2 QT Interval Drugs

The term *QT interval drugs*—or simply *QT drugs*—refers to the ability of some medications to prolong the QT interval on the electrocardiogram, thereby creating a risk of serious dysrhythmias. As discussed in [Chapter 48](#) (Antidysrhythmic Drugs), the QT interval is a measure of the time required for the ventricles to repolarize after each contraction. When the QT interval is prolonged, patients can develop a dysrhythmia known as *torsades de pointes*, which can progress to potentially fatal ventricular fibrillation.

More than 100 drugs are known to cause QT prolongation, torsades de pointes, or both. As shown in [Table 7-2](#), QT drugs are found in many drug families. Seven QT drugs—including astemizole [Hismanal], terfenadine [Seldane], and fenfluramine [Pondimin]—have been withdrawn because of deaths linked to their use, and use of another QT drug—cisapride [Propulsid]—is now restricted. To reduce the risks from QT drugs, the Food and Drug Administration (FDA) now requires that all new drugs be tested for the ability to cause QT prolongation.

When QT drugs are used, care should be taken to minimize the risk of dysrhythmias. These agents should be used with caution in patients predisposed to dysrhythmias. Among these are the elderly and patients with bradycardia, heart failure, congenital QT prolongation, and low levels of potassium or magnesium. Women are also at risk. Why? Because their normal QT interval is longer than the QT interval in men. Concurrent use of two or more QT drugs should be avoided, as should the concurrent use of a QT drug with another drug that can raise its blood level (eg, by inhibiting its metabolism). Obviously, excessive dosing should be avoided. Additional information on QT drugs, including a current list of these agents, is available online at www.QTdrugs.org.

7.1.4 Identifying Adverse Drug Reactions

It can be very difficult to determine whether a specific drug is responsible for an observed adverse event. Why? Because other factors—especially the underlying illness and other drugs being taken—could be the actual cause. To help determine if a particular drug is responsible, the following questions should be asked:

- Did symptoms appear shortly after the drug was first used?
- Did symptoms abate when the drug was discontinued?
- Did symptoms reappear when the drug was reinstituted?
- Is the illness itself sufficient to explain the event?
- Are other drugs in the regimen sufficient to explain the event?

TABLE 7-2 Drugs That Prolong the QT Interval, Induce Torsades de Pointes, or Both

Cardiovascular: Antidysrhythmics

Amiodarone [Cordarone]

Disopyramide [Norpace]

Dofetilide [Tikosyn]

Flecainide [Tambocor]

Ibutilide [Corvert]

Mexiletine [Mexitil]

Procainamide [Procan, Pronestyl]

Quinidine [Cardioquin, Quinaglute]

Sotalol [Betapace]

Cardiovascular: ACE Inhibitors/CCBs

Bepridil [Vascor]

Isradipine [DynaCirc]

Moexipril

Nicardipine [Cardene]

Cardiovascular: Others

Dobutamine [Dobutrex]

Dopamine

Norepinephrine [Levophed]

Ranolazine [Ranexa]

Antibiotics

Azithromycin [Zithromax]

Clarithromycin [Biaxin]

Erythromycin

Gatifloxacin [Tequin]

Gemifloxacin [Factive]

Levofloxacin [Levaquin]

Moxifloxacin [Avelox]

Ofloxacin [Floxin]

Sparfloxacin [Zagam]

Telithromycin [Ketek]

Antifungal Drugs

Fluconazole [Diflucan]

Itraconazole [Sporanox]

Ketoconazole [Nizoral]

Voriconazole [Vfend]

Antidepressants

Amitriptyline [Elavil]

Citalopram [Celexa]

Desipramine [Norpramin]

Doxepin [Sinequan]

Fluoxetine [Prozac]

Imipramine [Tofranil]

Protriptyline [Pamelor, Aventyl]

Sertraline [Zoloft]

Trimipramine [Surmontil]

Venlafaxine [Effexor]

Antipsychotics

Chlorpromazine [Thorazine]

Clozapine [Clozaril]

Haloperidol [Haldol]

Mesoridazine [Serentil]

Pimozide [Orap]

Quetiapine [Seroquel]

Risperidone [Risperdal]

Thioridazine [Mellaril]

Ziprasidone [Geodon]

Antiemetics/Antinausea Drugs

Dolasetron [Anzemet]

Domperidone [Motilium]

Droperidol [Inapsine]

Granisetron [Kytril]

Ondansetron [Zofran]

Bronchodilators

Albuterol [Proventil, Ventolin]

Ephedrine

Epinephrine [Bronkaid, Primatene]

Isoproterenol [Isuprel]

Levalbuterol [Xopenex]

Metaproterenol [Alupent]

Salmeterol [Serevent]

Terbutalin

Anticancer Drugs

Arsenic trioxide [Trisenox]

Sunitinib [Sutent]

Tamoxifen [Nolvadex]

Drugs for ADHD

Amphetamine/dextroamphetamine [Adderall]

Atomoxetine [Strattera]

Dexmethylphenidate [Focalin]

Dextroamphetamine [Dexedrine]

Methylphenidate [Ritalin, Concerta]

Nasal Decongestants

Phenylephrine [Neo-synephrine, Sudafed PE]

Pseudoephedrine [Sudafed]

Other Drugs

Alfuzosin [Uroxatral]

Amantadine [Symmetrel]

Chloroquine [Aralen]

Cisapride [Propulsid]^{*}

Cocaine

Felbamate [Felbatol]

Foscarnet [Foscavir]

Fosphenytoin [Cerebyx]

Galantamine [Razadyne]

Halofantrine [Halfan]

Indapamide [Lozol]

Lithium [Lithobid, Eskalith]

Methadone [Dolophine]

Midodrine [ProAmatine]

Octreotide [Sandostatin]

Pentamidine [Pentam, Nebupent]

Phentermine [Fastin]

Ritodrine [Yutopar]

Salmeterol [Serevent]

Sibutramine [Meridia]

Solifenacin [Vesicare]

Tacrolimus [Prograf]

Tizanidine [Zanaflex]

Tolterodine [Detrol]

Vardenafil [Levitra]

ACE = angiotensin-converting enzyme; ADHD = attention-deficit/hyperactivity disorder; CCB = calcium channel blocker.

* Restricted availability.

If the answers reveal a temporal relationship between the presence of the drug and the adverse event, and if the event cannot be explained by the illness itself or by other drugs in the regimen, then there is a high probability that the drug under suspicion is indeed the culprit. Unfortunately, this process is limited: It can only identify adverse effects that occur while the drug is being used; it cannot identify adverse events that develop years after drug withdrawal. Nor can it identify effects that develop slowly, that is, over the course of prolonged drug use.

7.1.5 Adverse Reactions to New Drugs

As we discussed in [Chapter 3](#), preclinical and clinical trials of new drugs cannot detect all of the ADRs that a drug may be able to cause. In fact, about 50% of all new drugs have serious ADRs that are not revealed during Phase II and Phase III trials.

Because newly released drugs may have as-yet unreported adverse effects, you should be alert for unusual responses when giving new drugs. If the patient develops new symptoms, it is wise to suspect that the drug may be responsible—even if the symptoms are not described in the literature. If the drug is especially new, you may be the first clinician to have observed this particular effect.

If you suspect a drug of causing a previously unknown adverse effect, you should report the effect to MEDWATCH, the FDA Medical Products Reporting Program. You can file your report online at www.fda.gov/medwatch. The form used for reporting is shown in [Figure 7-1](#). Because voluntary reporting by healthcare professionals is an important mechanism for bringing ADRs to light, you should report all suspected ADRs, even if absolute proof of the drug's complicity has not been established.

7.1.6 Ways to Minimize Adverse Drug Reactions

The responsibility for reducing ADRs lies with everyone associated with drug production and use. The pharmaceutical industry must strive to produce the safest medicines possible; the prescriber must select the least harmful medicine for a particular patient; the nurse must evaluate patients for ADRs and educate patients in ways to avoid or minimize harm; and patients and their families must watch for signs that an ADR may be developing, and should seek medical attention if one appears.

Anticipation of ADRs can help minimize them. Both the nurse and the patient should know the major ADRs that a drug can produce. This knowledge allows early identification of adverse effects, thereby permitting timely implementation of measures to minimize harm.

As noted, certain drugs are toxic to specific organs. When patients are using these drugs, function of the target organ should be monitored. The liver, kidneys, and bone marrow are important sites of drug toxicity. For drugs that are toxic to the liver, the patient should be monitored for signs and symptoms of liver damage (jaundice, dark urine, light-colored stools, nausea, vomiting, malaise, abdominal discomfort, loss of appetite), and periodic LFTs should be performed. For drugs that are toxic to the kidneys, the patient should undergo routine urinalysis and measurement of serum creatinine. In addition, periodic tests of creatinine clearance should be performed. For drugs that are toxic to bone marrow, periodic blood cell counts are required.

Adverse effects can be reduced by individualizing therapy. When choosing a drug for a particular patient, the prescriber must balance potential risks of that drug versus its probable benefits. Drugs that are likely to harm a specific patient should be avoided. For example, if a patient has a history of penicillin allergy, we can avoid a potentially severe reaction by withholding penicillin and administering a suitable substitute. Similarly, when treating pregnant patients, we must withhold drugs that can injure the fetus (see [Chapter 9](#)).

Lastly, we must be aware that patients with chronic disorders are especially vulnerable to ADRs. In this group are patients with hypertension, epilepsy, heart disease, and psychoses. When drugs must be used long term, the patient should be informed about the adverse effects that may develop over time and should be monitored for their appearance.

7.2 MEDICATION ERRORS

Medication errors are a major cause of morbidity and mortality, as documented in two landmark reports: *To Err is Human*, released in 1999, and *Preventing Medication Errors*, released in 2006.

Both were produced by special committees of the Institute of Medicine (IOM), a branch of the National Academies. According to the IOM reports, every year medication errors injure at least 1.5 million Americans, and kill an estimated 7000. The financial costs are staggering: Among hospitalized patients alone, treatment of drug-related injuries costs about \$3.5 billion a year. Some authorities argue that the IOM estimates exaggerate the problem; others argue that the estimates are too low. However, all agree that medication errors are a real problem—even if the IOM estimates *are* in dispute. In response to the IOM reports, healthcare organizations throughout the country have intensified efforts to reduce medical errors and thereby improve patient safety.

7.2.1 What's a Medication Error and Who Makes Them?

The National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP) defines a medication error as “any preventable event that may cause or lead to inappropriate medication use or patient harm, while the medication is in the control of the healthcare professional, patient, or consumer. Such events may be related to professional practice, healthcare products, procedures, and systems, including prescribing; order communication; product labeling, packaging and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use.” Note that, by this definition, medication errors can be made by many people—beginning with workers in the pharmaceutical industry, followed by people in the healthcare delivery system, and ending with patients and their family members.

In the hospital setting, a medication order must be processed by several people before it reaches the patient. All of these people can make a mistake. Fortunately, most are also in a position to catch mistakes made by others. The process typically begins with a physician or nurse practitioner writing a prescription; then someone transcribes the order; in the pharmacy, someone enters the order into a computer; then a pharmacy technician prepares the order, after which a pharmacist checks it; and finally a nurse checks the order again and then administers the drug. Each of these people is in a position to make an error. Except for the prescriber, each is also in a position to catch errors made by others as the order moves down the line. Because the nurse is the last person in the sequence, the nurse is the patient's last line of defense against mistakes—and also the last person with the opportunity to make one. Note also that the nurse is the only person whose actions are not routinely checked by anyone else. Because the nurse is the last person who can catch mistakes made by others, and because no one is there to catch mistakes the nurse might make, the nurse bears a heavy responsibility for ensuring patient safety. Can you think of a better reason to learn all you can about drugs?

7.2.2 Types of Medication Errors

Medication errors fall into 13 major categories ([Table 7-3](#)). Some types of errors cause harm directly, and some cause harm indirectly. For example, giving an excessive dose can cause direct harm (adverse effects or even death) from having too much drug in the body. Conversely, giving too little medication can lead to harm, not through direct effects of the drug, but through failure to adequately treat the patient's illness. According to the 1999 IOM report, among *fatal* medication errors, the most common types are giving an overdose (36.4%), giving the wrong drug (16.2%), and using the wrong route (9.5%).

7.2.3 Causes of Medication Errors

Medication errors can result from many causes ([Table 7-4](#)). Among fatal medication errors, the 1999 IOM report identified three categories—human factors, communication mistakes, and name confusion—that account for 90% of all errors. Of the human factors that can cause errors, performance deficits (eg, administering a drug IV instead of IM) are the most common (29.8%), followed by knowledge deficits (14.2%) and miscalculation of dosage (13%).

69

70

TABLE 7-3 Types of Medication Errors

Wrong patient
Wrong drug
Wrong route
Wrong time
Wrong dose
Overdose
Underdose
Extra dose
Omitted dose
Wrong dosage form
Wrong diluent
Wrong strength/concentration
Wrong infusion rate
Wrong technique (includes inappropriate crushing of tablets)
Deteriorated drug error (dispensing a drug after its expiration date)
Wrong duration of treatment (continuing too long or stopping too soon)

Miscommunication involving oral and written orders underlies 15.8% of fatal errors. Poor handwriting is an infamous cause of mistakes. In one example, an order for 2 mg of warfarin (an anticoagulant) was misread as 5 mg, and resulted in death from hemorrhage. In another case, a woman with arthritis died because her prescription to take 10 mg of methotrexate (an immunosuppressant) once a week was misread as 10 mg once a day. Because of illegible handwriting by prescribers, pharmacists make an estimated 150 million phone calls a year for clarification. When patients are admitted to the hospital, errors can result from poor communication regarding medications they were taking at home. For example, a child who was taking cisapride at home died because his prescription for one-fourth of a 10-mg tablet 4 times a day was incorrectly transcribed to read one 10-mg tablet 4 times a day. Other causes of communication errors include careless use of zeros and decimal points, and confusion between metric and apothecary units.

TABLE 7-4 Causes of Medication Errors

Cause	Examples
Human Factors	
Performance deficit	Administration by IV infusion when IM injection was intended
Knowledge deficit	Failure to know and follow reasonable practice standards
Miscalculation of dosage	
Drug preparation error	Using the wrong diluent; using the wrong amount of diluent; adding the wrong drug; adding the wrong amount of drug
Computer error	Incorrect selection from a list by computer operator; incorrect programming into the database; inadequate screening for allergies, interactions, etc.
Stocking error	Error in stocking or restocking; error in cart filling
Transcription error	Original to paper/carbon paper; original to computer; original to fax
Stress	High-volume workload, etc.
Fatigue or lack of sleep	
Communication	
Written miscommunication	Illegible handwriting; misreading or failure to read; confusion regarding decimal point placement in dosage
Oral miscommunication	
Name Confusion	
Trade name confusion	Name sounds or looks like another drug name
Generic name confusion	Name sounds or looks like another drug name
Packaging, Formulations, and Delivery Devices	
Inappropriate packaging	Topical product packaged in sterile IV multidose vial
Tablet or capsule confusion	Confusion because the tablet or capsule is similar in color, shape, or size to tablets or capsules that contain a different drug or a different strength of the same drug
Delivery device problems	Malfunction; infusion pump problems; selection of wrong device
Labeling and Reference Materials	
Manufacturer's carton	Carton looks similar to other cartons from the same manufacturer or cartons from a different manufacturer
Manufacturer's container label	Label looks similar to other labels from the same manufacturer or to labels from a different manufacturer
Label of dispensed product	Wrong patient name; wrong drug name; wrong strength; wrong or incomplete directions

Reference materials (package insert and other printed material, electronic material)	Inaccurate, incomplete, misleading, or outdated information
--	---

70

<i>Dioval</i>	<i>Diovan</i>
<i>Estratab</i>	<i>Estratest</i>
<i>Etidronate</i>	<i>Etretinate</i>
<i>Flomax</i>	<i>Volmax</i>
<i>Inderal</i>	<i>Adderall</i>
<i>Lamictal</i>	<i>Lamisil</i>
<i>Levoxine</i>	<i>Levoxyl</i>
<i>Lithobid</i>	<i>Lithostat</i>
<i>Lodine</i>	<i>Iodine</i>
<i>Lomotil</i>	<i>Lamictal</i>
<i>Naprelan</i>	<i>Naprosyn</i>
<i>Nasarel</i>	<i>Nizoral</i>
<i>Neoral</i>	<i>Neosar</i>
<i>Nephron</i>	<i>Nephrox</i>
<i>Nicoderm</i>	<i>Nitroderm</i>
<i>Plendil</i>	<i>Pletal</i>
<i>Preven</i>	<i>Preveon</i>
<i>Renagel</i>	<i>Remegel</i>
<i>Sarafem</i>	<i>Serophene</i>
<i>Serentil</i>	<i>Seroquel</i>

<i>Synagis</i>	<i>Synergis</i>
<i>Tamiflu</i>	<i>Theraflu</i>

* Trade names are italicized; generic names are not.

Confusion over drug names underlies 15% of all reports to the Medication Errors Reporting Program (see below). Why is there confusion? Because many drugs have names that sound like or look like the names of other drugs. [Table 7-5](#) lists some good examples, such as *Anaspaz/Antispas*, *Nasarel/Nizoral*, and *Renagel/Remegel*. Note that most of the examples in [Table 7-5](#) are trade names, not generic names. The potential for lethal confusion among trade names is a powerful reason for abandoning them in favor of universal use of generic names. (In case you skipped the discussion on trade names in [Chapter 3](#), your author feels very strongly that trade names should be outlawed.) To reduce name-related medication errors, all hospitals are now required to have a “read-back” system, in which verbal orders given to pharmacists or medical staff are transcribed and then read back to the prescriber.

7.2.4 Ways to Reduce Medication Errors

Healthcare organizations throughout the country are working to design and implement measures to reduce medication errors. A central theme in these efforts is to change institutional culture—from one that focuses on “naming, shaming, and blaming” those who make mistakes to one focused on designing institution-wide processes and systems that can prevent errors from happening. Measures stressed in the 2006 IOM report include (1) helping and encouraging patients and their families to be active, informed members of the healthcare team, and (2) giving healthcare providers the tools and information needed to prescribe, dispense, and administer drugs as safely as possible.

TABLE 7-6 Sixteen Ways to Cut Medication Errors*

Institutional Culture

- Establish an organizational commitment to a culture of safety.
- Provide medication safety education for all new and existing professional employees.
- Maintain ongoing recognition of safety innovation.
- Create a nonpunitive environment that encourages identification of errors and the development of new patient safety systems.

Infrastructure

- Designate a medication safety coordinator/officer and identify physician champions.
- Promote greater use of clinical pharmacists in high-risk areas.
- Establish area-specific guidelines for unit-stocked medications.
- Establish a mechanism to ensure availability of critical medication information to all members of the patient's care team.

Clinical Practice

- Eliminate dangerous abbreviations and dose designations.
- Implement safety checklists for high-alert medications.
- Implement safety checklists for infusion pumps.
- Develop limitations and safeguards regarding verbal orders.
- Perform failure-mode analysis during procurement process.
- Implement triggers and markers to indicate potential adverse medication events.

Technology

- Eliminate the use of infusion pumps that lack free-flow protection.
- Prepare for implementation of computerized prescriber order entry systems.

* These strategies are recommended in the Regional Medication Safety Program for Hospitals (RMSPH), developed by a consortium of hospitals in southeastern Pennsylvania.

In southeastern Pennsylvania, a consortium of hospitals has developed a unique system for reducing medication errors. This system, known as the Regional Medication Safety Program for

Hospitals (RMSPH), can be considered a model for other hospitals to follow. The RMSPH has a total of 16 action goals divided into four major categories: institutional culture, infrastructure, clinical practice, and technology ([Table 7-6](#)). Note that creating an institutional culture dedicated to safety tops the list, and that the institutional environment should be nonpunitive so as to encourage both the identification of errors and the development of new safety systems. This is a radical departure from the past, when organizations focused largely on identifying and punishing caregivers who made mistakes. As you read through [Table 7-6](#), the potential benefits of all 16 objectives should be apparent. To aid practitioners in achieving these 16 goals, the RMSPH contains a “tool kit” with detailed supporting information on how to meet each objective. For example, the kit includes safety checklists to follow when using high-alert drugs, such as anticoagulants, thrombolytics, and neuromuscular blocking agents. (About 20 such drugs cause 80% of medication error-related deaths.)

TABLE 7-7 Abbreviations, Symbols, and Dose Designations That Can Promote Medication Errors

Abbreviations, Symbols, or Dose Designations	Intended Meaning	Potential Misinterpretation	Preferred Alternative
Abbreviations and Notations for Which the Alternative MUST be Used (TJC Mandated)			
U or u	Unit	Misread as 0 or 4 (eg, 4U seen as 40; 4u seen as 44); mistaken to mean “cc” so dose given in volume instead of units (eg, 4u mistaken to mean 4cc)	Write “unit”
IU	International unit	Misread as IV (intravenous) or “10”	Write “international unit”
q.d./Q.D.	Every day	Misread as q.i.d. (four times a day)	Write “daily”
q.o.d./Q.O.D.	Every other day	Misread as q.d. (daily) or q.i.d. (four times a day)	Write “every other day”
MS or MSO ₄	Morphine sulfate	Mistaken as magnesium sulfate	Write “morphine sulfate”
MgSO ₄	Magnesium sulfate	Mistaken as morphine sulfate	Write “magnesium sulfate”
Trailing zero after final decimal point (eg, 1.0 mg)	1 mg	Mistaken as 10 mg if the decimal point is missed	Never write a zero by itself after a decimal point
Leading decimal point not preceded by a zero (eg, .5 mg)	0.5 mg	Mistaken as 5 mg if the decimal point is missed	Write “0” before a leading decimal point
Some Abbreviations and Notations for Which the Alternative is RECOMMENDED (but not yet TJC Mandated)			
μg	Microgram	Mistaken as “mg”	Write “mcg”
cc	Cubic centimeters	Mistaken as “u” (units)	Write “mL”
IN	Intranasal	Mistaken as “IM” or “IV”	Write “intranasal” or “NAS”
H.S., hs	Half-strength; at bedtime	Mistaken as opposite of what was intended	Write “half-strength” or “at bedtime”
qhs	At bedtime	Mistaken as qhr (every hour)	Write “at bedtime”
q1d	Daily	Mistaken as q.i.d. (four times daily)	Write “daily”

Pharmacology for Nursing Care, 7th Edition

q6PM, etc.	Nightly at 6 PM	Mistaken as every 6 hours	Write “nightly at 6 PM”
T.I.W.	Three times a week	Mistaken as three times a day or twice weekly	Write “three times weekly”
SC, SQ, sub q	Subcutaneous	SC mistaken as “SL” (sublingual); SQ mistaken as “5 every”; the “q” in “sub q” mistaken as “every” (eg, a heparin dose ordered “sub q 2 hours before surgery” mistaken as “every 2 hours before surgery”)	Write “subQ,” “sub-Q,” “every” “subcut,” or “subcutaneously”
D/C	Discharge or discontinue	Premature discontinuation of medications if D/C (intended to mean “discharge”) has been interpreted as “discontinued” when followed by a list of discharge medications	Write “discharge” or “discontinue”
AD, AS, AU	Right ear, left ear, each ear	Mistaken as OD, OS, OU (right eye, left eye, each eye)	Write “right ear,” “left ear,” or “each ear”
OD, OS, OU	Right eye, left eye, each eye	Mistaken as AD, AS, AU (right ear, left ear, each ear)	Write “right eye,” “left eye,” or “each eye”
Per os	By mouth, orally	The “os” can be mistaken as “left eye” (OS = oculus sinister)	Write “PO,” “by mouth,” or “orally”
> or <	Greater than or less than	Mistaken for the opposite	Write “greater than” or “less than”
AZT	Zidovudine [Retrovir]	Mistaken as azathioprine or aztreonam	Write complete drug name
CPZ	Prochlorperazine [Compazine]	Mistaken as chlorpromazine	Write complete drug name
ARA A	Vidarabine	Mistaken as cytarabine (ARA C)	Write complete drug name
HCT	Hydrocortisone	Mistaken as hydrochlorothiazide	Write complete drug name
HCTZ	Hydrochlorothiazide	Mistaken as hydrocortisone	Write complete drug name

Adapted from a list compiled by the Institute for Safe Medication Practices, as modified in 2005. The complete list is available online at www.ismp.org/PDF/ErrorProne.pdf.

TJC = The Joint Commission, formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO).

72

Some measures to reduce errors have had remarkable success. For example,

73

- Replacing handwritten medication orders with a computerized order entry system has reduced medication errors by 50%. (The 2006 IOM report recommends that all prescriptions be written electronically by the year 2010.)
- In ICUs, medication errors have been reduced by 66% by having a senior clinical pharmacist accompany physicians on rounds.
- Hospitals in the Department of Veterans Affairs (VA) system have reduced medication errors by up to 70% with a bar-code system. In this system, all nurses and patients wear bar-coded ID strips, and all medications have bar codes too. Before giving a medication, the nurse scans all three codes into a computer, which then either (1) verifies that the patient-drug match is correct and adverse interactions are unlikely or (2) flashes a warning if there is a potential problem. (In 2006, the FDA issued a rule requiring that all hospitals employ a bar-code system like the one used in VA hospitals.)

As noted above, many medication errors result from errors in communication. To help reduce such errors, the Institute for Safe Medication Practices (ISMP) has compiled a list of error-prone abbreviations, symbols, and dose designations ([Table 7-7](#)), and has recommended against their use. This list includes eight entries (at the top of [Table 7-7](#)) that have been *banned* by The Joint Commission (TJC), formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). These banned abbreviations can no longer be used by hospitals and other organizations that require TJC accreditation.

There is a wealth of information available on reducing medication errors. If you would like more, a good place to start is the 2006 IOM report: *Reducing Medication Errors*. You can purchase the full report or download free summaries from the National Academies Press at www.nap.edu/catalog.php?record_id=11623. Comprehensive information can also be found at www.nccmerp.org, the web site of the National Coordinating Council for Medication Error Reporting and Prevention. The NCC MERP was established to facilitate the reporting, understanding, and prevention of medication errors. Member organizations include the American Nurses Association, American Medical Association, American Hospital Association, FDA, and U.S. Pharmacopeia (USP). The NCC MERP web site has extensive recommendations for reducing medication errors related to drug administration, medication dispensing, and verbal medication orders and prescriptions. In addition, the site presents recommendations for promoting and standardizing bar coding on medication packaging. Even more information is available from the ISMP (at www.ismp.org/MSAarticles/AHA-ISMP.html) and the FDA (at www.fda.gov/cder/drug/mederrors).

7.2.5 How to Report a Medication Error

You can report a medication error via the *Medication Errors Reporting (MER) Program*, a nationwide program set up by the U.S. Pharmacopeia in cooperation with the ISMP. All reporting is confidential and can be done by phone or fax, or through the Internet. Details on submitting a report are available online at www.usp.org/hqi/patientSafety/mer/. The MER Program encourages participation by all healthcare providers, including pharmacists, nurses, physicians, and students. The objective is not to establish blame, but to improve patient safety by increasing our knowledge of medication errors. All information gathered by the MER Program is forwarded to the FDA, the ISMP, and the product manufacturer. The form for submitting a report is shown in [Figure 7-2](#).

7.2.5.1

KEY POINTS

- An adverse drug reaction can be defined as any noxious, unintended, and undesired effect that occurs at normal drug doses.
- Patients at increased risk of adverse drug events include the very young, the elderly, the very ill, and those taking multiple drugs.
- An iatrogenic disease is a drug- or physician-induced disease.
- An idiosyncratic effect is an adverse drug reaction based on a genetic predisposition.
- A carcinogenic effect is a drug-induced cancer.
- A teratogenic effect is a drug-induced birth defect.
- The intensity of an allergic drug reaction is based on the degree of immune system sensitization—not on drug dosage.
- Drugs are the most common cause of acute liver failure, and hepatotoxicity is the most common reason for removing drugs from the market.
- Drugs that prolong the QT interval pose a risk of torsades de pointes, a dysrhythmia that can progress to fatal ventricular fibrillation.
- At the time a new drug is released, it may well be able to cause adverse effects that are as yet unreported.

- Measures to minimize adverse drug events include avoiding drugs that are likely to harm a particular patient, monitoring the patient for signs and symptoms of likely adverse effects, educating the patient about possible adverse effects, and monitoring organs that are vulnerable to a particular drug.
- Medication errors are a major cause of morbidity and mortality.
- Medication errors can be made by many people, including pharmaceutical workers, pharmacists, prescribers, transcriptionists, nurses, and patients and their families.
- In a hospital, a medication order is processed by several people. Each is in a position to introduce errors, and, except for the prescriber, each is in a position to catch errors made by others.
- The nurse is the patient's last line of defense against medication errors made by others—and the last person with the opportunity to introduce an error.
- Because the nurse is the last person who can catch mistakes made by others, and because no one is there to catch mistakes the nurse might make, the nurse bears a unique responsibility for ensuring patient safety.

73

- The three most common *types* of fatal medication errors are giving an overdose, giving the wrong drug, and using the wrong route.
- The three most common *causes* of fatal medication errors are human factors (eg, performance or knowledge deficits), miscommunication (eg, because of illegible prescriber handwriting), and confusion caused by similarities in drug names.
- At the heart of efforts to reduce medication errors is a change in institutional culture—from a punitive system focused on “naming, blaming, and shaming” to a nonpunitive system in which medication errors can be discussed openly, thereby facilitating the identification of errors and the development of new safety procedures.
- Effective measures for reducing medication errors include (1) using a safety checklist for high-alert drugs; (2) replacing handwritten medication orders with a computerized order entry system; (3) having a clinical pharmacist accompany ICU physicians on rounds; (4) avoiding error-prone abbreviations; (5) helping and encouraging patients and their families to be active, informed participants in the healthcare team; and (6) using a

74

computerized bar-code system that (a) identifies the administering nurse and (b) ensures that the drug is going to the right patient and that adverse interactions are unlikely.

MEDICATION
ERRORS

REPORTING
PROGRAM

USP MEDICATION ERRORS REPORTING PROGRAM

Presented in cooperation with the Institute for Safe Medication Practices

USP is an FDA MEDWATCH partner

Reporters should not provide any individually identifiable health information, including names of practitioners, names of patients, names of healthcare facilities, or dates of birth (age is acceptable).

Date and time of event: _____

Please describe the error. Include description/sequence of events, type of staff involved, and work environment (e.g., code situation, change of shift, short staffing, no 24-hr. pharmacy, floor stock). If more space is needed, please attach a separate page.

Did the error reach the patient? ☐ Yes ☐ No

Was the incorrect medication, dose, or dosage form administered to or taken by the patient? ☐ Yes ☐ No

Circle the appropriate Error Outcome Category (select one—see back for details): A B C D E F G H I

Describe the direct result of the error on the patient (e.g., death, type of harm, additional patient monitoring). _____

Indicate the possible error cause(s) and contributing factor(s) (e.g., abbreviation, similar names, distractions, etc.). _____

Indicate the location of the error (e.g., hospital, outpatient or community pharmacy, clinic, nursing home, patient's home, etc.). _____

What type of staff or healthcare practitioner made the initial error? _____

Indicate if other practitioner(s) were also involved in the error (type of staff perpetuating error). _____

What type of staff or healthcare practitioner discovered the error or recognized the potential for error? _____

How was the error (or potential for error) discovered/intercepted? _____

If available, provide patient age, gender, diagnosis. Do not provide any patient identifiers. _____

Please complete the following for the product(s) involved. (If more space is needed for additional products, please attach a separate page.)

	Product #1	Product #2
Brand/Product Name (If Applicable)	_____	_____
Generic Name	_____	_____
Manufacturer	_____	_____
Labeler	_____	_____
Dosage Form	_____	_____
Strength/Concentration	_____	_____
Type and Size of Container	_____	_____

Reports are most useful when relevant materials such as product label, copy of prescription/order, etc., can be reviewed.
Can these materials be provided? ☐ Yes ☐ No Please specify: _____

Suggest any recommendations to prevent recurrence of this error, or describe policies or procedures you instituted or plan to institute to prevent future similar errors. _____

Name and Title/Profession _____ Telephone Number _____ Fax Number _____

Facility/Address and Zip _____ E-mail _____

Address/Zip (where correspondence should be sent) _____

Your name, contact information, and a copy of this report are routinely shared with the Institute for Safe Medication Practices (ISMP). Copies of reports will be sent to third parties such as the manufacturer/labeler, and to the Food and Drug Administration (FDA). You have the option of including your name on these copies.

In addition to releasing my name and contact information to ISMP, USP may release my identity to these third parties as follows (check boxes that apply):

☐ The manufacturer and/or labeler as listed above ☐ FDA ☐ Other persons requesting a copy of this report ☐ Anonymous to all third parties

National Coordinating Council for Medication Error Reporting and Prevention Definitions

Harm

Impairment of the physical, emotional, or psychological function or structure of the body and/or pain resulting therefrom.

Monitoring

To observe or record relevant physiological or psychological signs.

Intervention

May include change in therapy or active medical/surgical treatment.

Intervention Necessary to Sustain Life

Includes cardiovascular and respiratory support (e.g., CPR, defibrillation, intubation, etc.).

⁸ CHAPTER 8 Individual Variation in Drug Responses

Individual variation in drug responses has been a recurrent theme throughout the early chapters of this text. We noted that, because of individual variation, we must tailor drug therapy to each patient. In this chapter, we discuss the major factors that can cause one patient to respond to drugs differently than another. With this information, you will be better prepared to reduce individual variation in drug responses, thereby maximizing the benefits of treatment and reducing the potential for harm. Much of this chapter is a review of information presented in previous chapters.

8.1 BODY WEIGHT AND COMPOSITION

If we do not adjust dosage, body size can be a significant determinant of drug effects. Recall that the intensity of the response to a drug is determined in large part by the concentration of the drug at its sites of action—the higher the concentration, the more intense the response. Common sense tells us that, if we give the same dose to a small person and a large person, the drug will achieve a higher concentration in the small person, and therefore will produce more intense effects. To compensate for this potential source of individual variation, dosages must be adapted to the size of the patient.

When adjusting dosage to account for body weight, the clinician may base the adjustment on body surface area rather than on weight per se. Why? Because surface area determinations account not only for the patient's weight but also for how fat or lean he or she may be. Since percentage body fat can change drug distribution, and since altered distribution can change the concentration of a drug at its sites of action, dosage adjustments based on body surface area provide a more precise means of controlling drug responses than do adjustments based on weight alone.

8.2 AGE

Drug sensitivity varies with age. Infants are especially sensitive to drugs, as are the elderly. In the very young, heightened drug sensitivity is the result of organ immaturity. In the elderly, heightened sensitivity results largely from organ degeneration. Other factors that affect sensitivity in the elderly are increased severity of illness, the presence of multiple pathologies, and treatment with multiple drugs. The clinical challenge created by heightened drug sensitivity in the very young and in the elderly is discussed at length in [Chapters 10](#) and [11](#), respectively.

8.3 PATHOPHYSIOLOGY

Abnormal physiology can alter drug responses. In this section we examine the impact of four pathologic conditions: (1) kidney disease, (2) liver disease, (3) acid-base imbalance, and (4) altered electrolyte status.

8.3.1 Kidney Disease

Kidney disease can reduce drug excretion, causing drugs to accumulate in the body. If dosage is not lowered, drugs may accumulate to toxic levels. Accordingly, if a patient is taking a drug that is eliminated by the kidneys, and if renal function declines, dosage must be decreased.

The impact of kidney disease is illustrated in [Figure 8-1](#), which shows the decline in plasma levels of kanamycin (an antibiotic) following injection into two patients, one with healthy kidneys and one with renal failure. (Elimination of kanamycin is exclusively renal.) As indicated, kanamycin levels fall off rapidly in the patient with good kidney function. In this patient, the drug's half-life is brief—only 1.5 hours. In contrast, drug levels decline very slowly in the patient with renal failure. Because of kidney disease, the half-life of

77

78

Figure 8-1 Effect of renal failure on kanamycin half-life.

Kanamycin was administered at time “0” to two patients, one with healthy kidneys and one with renal failure. Note that drug levels declined very rapidly in the patient with healthy kidneys and extremely slowly in the patient with renal failure, indicating that renal failure greatly reduced the capacity to remove this drug from the body. ($T_{1/2}$ = half-life.)

kanamycin has increased by nearly 17-fold—from 1.5 hours to 25 hours. Under these conditions, if dosage is not reduced, kanamycin will quickly accumulate to dangerous levels.

8.3.2 Liver Disease

Like kidney disease, liver disease can cause drugs to accumulate. Recall that the liver is the major site of drug metabolism. Hence, if liver function declines, rates of metabolism will decline too, and drug levels will climb. Accordingly, to prevent accumulation to toxic levels, dosage must be reduced if liver disease develops. Of course, this guideline applies only to those drugs that are eliminated primarily by the liver, not to drugs that are eliminated by the kidneys and other nonhepatic routes.

8.3.3 Acid-Base Imbalance

By altering pH partitioning (see [Chapter 4](#)), changes in acid-base status can alter the absorption, distribution, metabolism, and excretion of drugs.

[Figure 8-2](#) illustrates the impact of altered acid-base status on drug distribution. Specifically, it shows the results of altered acid-base status on the distribution of phenobarbital (a weak acid) in a dog. The upper curve shows plasma levels of phenobarbital. The lower curve shows plasma pH. Acid-base status was altered by having the dog inhale a mixture of gas rich in carbon dioxide (CO_2), thereby causing respiratory acidosis. In the figure, acidosis is indicated by the drop in plasma pH. Note that the decline in pH is associated with a parallel drop in levels of phenobarbital. Upon discontinuation of CO_2 , plasma pH returned to normal and phenobarbital levels moved upward.

Why did acidosis alter plasma levels of phenobarbital? Recall that, because of pH partitioning, if there is a difference in pH on two sides of a membrane, a drug will accumulate on the side where the pH most favors its ionization. Hence, because acidic drugs ionize in alkaline media, acidic drugs will accumulate on the alkaline side of the membrane. Conversely, basic drugs will accumulate on the acidic side. Since phenobarbital is a weak acid, it tends to accumulate in alkaline environments. Accordingly, when the dog inhaled CO_2 , causing extracellular pH to decline, phenobarbital left the plasma and entered cells, where the environment was less acidic (more alkaline) than in plasma. When CO_2 administration ceased and plasma pH returned

Figure 8-2 **Altered drug distribution in response to altered plasma pH.** Lower curve, Plasma (extracellular) pH. Note the decline in pH in response to inhalation of CO₂. *Upper curve*, Plasma levels of phenobarbital. Note the decline in plasma drug levels during the period of extracellular acidosis. This decline results from the redistribution of phenobarbital into cells. (See text for details.)

(Redrawn from Waddell WJ, Butler TC: The distribution and excretion of phenobarbital. J Clin Invest 36:1217, 1957.)

to normal, the pH partitioning effect caused phenobarbital to leave cells and re-enter the blood, causing blood levels to rise.

8.3.4 Altered Electrolyte Status

Electrolytes (eg, potassium, sodium, calcium, magnesium) have important roles in cell physiology. Consequently, when electrolyte levels become disturbed, multiple cellular processes can be disrupted. Excitable tissues (nerves and muscles) are especially sensitive to alterations in electrolyte status. Given that disturbances in electrolyte balance can have widespread effects on

cell physiology, we might expect that electrolyte imbalances would cause profound and widespread effects on responses to drugs. However, this does not seem to be the case; examples in which electrolyte changes have a significant impact on drug responses are rare.

Perhaps the most important example of an altered drug effect occurring in response to electrolyte imbalance involves digoxin, a drug for heart disease. The most serious toxicity of digoxin is production of potentially fatal dysrhythmias. The tendency of digoxin to disturb cardiac rhythm is related to levels of potassium: When potassium levels are depressed, the ability of digoxin to induce dysrhythmias is greatly increased. Accordingly, all patients receiving digoxin must undergo regular measurement of serum potassium to ensure that levels remain within a safe range. Digoxin toxicity and its relationship to potassium levels are discussed at length in [Chapter 47](#).

8.4 TOLERANCE

Tolerance can be defined as *decreased responsiveness to a drug as a result of repeated drug administration*. Patients who are tolerant to a drug require higher doses to produce effects equivalent to those that could be achieved with lower doses before tolerance developed. There are three categories of drug tolerance: (1) pharmacodynamic tolerance, (2) metabolic tolerance, and (3) tachyphylaxis.

8.4.1 Pharmacodynamic Tolerance

The term *pharmacodynamic tolerance* refers to the familiar type of tolerance associated with long-term administration of drugs such as morphine and heroin. The person who is pharmacodynamically tolerant requires increased drug levels to produce effects that could formerly be elicited at lower drug levels. Put another way, in the presence of pharmacodynamic tolerance, the minimum effective concentration (MEC) of a drug is abnormally high. Pharmacodynamic tolerance is the result of adaptive processes that occur in response to chronic receptor occupation.

78

79

8.4.2 Metabolic Tolerance

Metabolic tolerance is defined as tolerance resulting from accelerated drug metabolism. This form of tolerance is brought about by the ability of certain drugs (eg, barbiturates) to induce synthesis of hepatic drug-metabolizing enzymes, thereby causing rates of drug metabolism to increase. Because of increased metabolism, dosage must be increased to maintain therapeutic drug levels. Unlike pharmacodynamic tolerance, which causes the MEC to increase, metabolic tolerance does not affect the MEC.

The experiment summarized in [Table 8-1](#) demonstrates the development of metabolic tolerance in response to repeated administration of pentobarbital, a central nervous system depressant. The

study employed two groups of rabbits, a control group and an experimental group. Rabbits in the experimental group were pretreated with pentobarbital for 3 days (60 mg/kg/day subQ) and then given an IV challenging dose (30 mg/kg) of the same drug. Drug effect (sleeping time) and plasma drug levels were then measured. The control rabbits received the challenging dose of pentobarbital but did not receive any pretreatment. As indicated in [Table 8-1](#), the challenging dose of pentobarbital had less effect on the pretreated rabbits than on the control animals. Specifically, whereas the control rabbits slept an average of 67 minutes, the pretreated rabbits slept only 30 minutes—less than half the sleeping time seen in controls.

Why was pentobarbital less effective in the pretreated animals? The data on half-life suggest an answer. As shown in the table, the half-life of pentobarbital was much shorter in the experimental group than in the control group. Since pentobarbital is eliminated primarily by hepatic metabolism, the reduced half-life indicates accelerated metabolism. This increase in metabolism, which was brought on by pentobarbital pretreatment, explains why the experimental rabbits were more tolerant than the controls.

You might ask, “How do we know that the experimental rabbits had not developed *pharmacodynamic* tolerance?” The answer lies in the plasma drug levels when the rabbits awoke. In the pretreated rabbits, the waking drug levels were slightly below the waking drug levels in the control group. Had the experimental animals developed pharmacodynamic tolerance, they would have required an *increase* in drug concentration to maintain sleep. Hence, if pharmacodynamic tolerance were present, drug levels would have been abnormally high at the time of awakening, rather than reduced.

8.4.3 Tachyphylaxis

Tachyphylaxis is a form of tolerance that can be defined as a reduction in drug responsiveness brought on by repeated dosing *over a short time*. Hence, unlike pharmacodynamic and metabolic tolerance, which take days to develop, tachyphylaxis occurs quickly. Tachyphylaxis is not a common mechanism of drug tolerance.

TABLE 8-1 Development of Metabolic Tolerance as a Result of Repeated Pentobarbital Administration

Results	Type of Pretreatment	
	None	Pentobarbital
Sleeping time (minutes)	67 ± 4	30 ± 7
Pentobarbital half-life in plasma (minutes)	79 ± 3	26 ± 2
Plasma level of pentobarbital upon awakening (mcg/mL)	9.9 ± 1.4	7.9 ± 0.6
Data from Remmer H: Drugs as activators of drug enzymes. <i>In</i> Brodie BB, Erdos EG (eds): Metabolic Factors Controlling Duration of Drug Action (Proceedings of First International Pharmacological Meeting, Vol 6). New York: Macmillan, 1962:235. (See text for details.)		

Transdermal nitroglycerin provides a good example of tachyphylaxis. When nitroglycerin is administered using a transdermal patch, effects are lost in less than 24 hours (if the patch is left in place around the clock). As discussed in [Chapter 50](#), the loss of effect results from depletion of a cofactor required for nitroglycerin to act. When nitroglycerin is administered on an intermittent schedule, rather than continuously, the cofactor can be replenished and no loss of effect occurs.

8.5 PLACEBO EFFECT

A *placebo* is a preparation that is devoid of intrinsic pharmacologic activity. Hence, any response that a patient may have to a placebo is based solely on his or her psychologic reaction to the idea of taking a medication and not to any direct physiologic or biochemical action of the placebo itself. The primary use of the placebo is as a control preparation during clinical trials.

In pharmacology, the *placebo effect* is defined as that component of a drug response that is caused by psychologic factors and not by the biochemical or physiologic properties of the drug. Although it is impossible to assess with precision the contribution that psychologic factors make to the overall response to any particular drug, it is widely believed that, with practically all medications, some fraction of the total response results from a placebo effect. Although placebo effects are determined by psychologic factors and not physiologic ones, the presence of a placebo response does not imply that a patient's original pathology was “all in the head.”

Not all placebo responses are beneficial; placebo responses can also be negative. If a patient believes that a medication is going to be effective, then placebo responses are likely to help promote recovery. Conversely, if a patient is convinced that a particular medication is ineffective or perhaps even harmful, then placebo effects are likely to detract from his or her progress.

Because the placebo effect depends on the patient's attitude toward medicine, fostering a positive attitude may help promote beneficial effects. In this regard, it is desirable that all members of the healthcare team present the patient with an optimistic (but realistic) assessment of the effects that therapy is likely to produce. It is also important that members of the team be consistent with one another; the beneficial placebo responses may well be decreased if, for example, nurses on the day shift repeatedly reassure a patient about the likely benefits of his or her regimen, while nurses on the night shift express pessimism about those same drugs.

Until recently, the power of the placebo effect was unquestioned by most clinicians and researchers. However, new evidence suggests that responses to placebos may be much smaller than previously believed ([Box 8-1](#)).

8.6 VARIABILITY IN ABSORPTION

Both the rate and extent of drug absorption can vary among patients. As a result, both the timing and intensity of responses can be changed. Differences in manufacturing are a major cause of variability in drug absorption. Other causes include the presence or absence of food, diarrhea or constipation, and differences in gastric emptying time. Several causes of variable absorption are discussed in previous chapters, primarily [Chapter 4](#) (Pharmacokinetics) and [Chapter 6](#) (Drug Interactions), and hence their discussion here is brief.

79
81

8.6.1 BOX 8-1 Special Interest Topic

8.6.1.1 HAS THE PLACEBO LOST ITS EFFECT?

In 1955, H. K. Beecher wrote his famous paper—"The Powerful Placebo"¹—which was heralded as solid proof for the long-held (but largely unsubstantiated) belief that placebos can effectively relieve symptoms in many patients. This widely cited paper had gone unchallenged until 2001, when two Danish scientists—Hróbjartsson and Gøtzsche—wrote their own paper on the subject, titled "Is the Placebo Powerless?"² From their research, the Danes concluded that, at least in the context of clinical trials, placebo treatment has little or no measurable effect. Who's right? Let's consider both papers and see if we can decide.

Beecher analyzed the data from 15 placebo-controlled clinical trials. In all of these trials, patients in the placebo groups were evaluated at baseline, treated with placebo for a prescribed time, and then re-evaluated. Beecher then looked to see if improvement took place between baseline and the end of the treatment period. Based on his analysis, he concluded "It is evident that placebos have a high degree of effectiveness, decided improvement ... being produced in 35.2% of cases." Pretty impressive. Unfortunately, there's a flaw: How do we know the

placebos produced the benefits? Perhaps 35.2% of the patients would have improved with no treatment, owing simply to the natural course of their disease or to other factors. After all, many people *do* get better on their own—without doctors, drugs, placebos, or anything else. Furthermore, although Beecher claims to have selected the 15 papers at random, this seems improbable in that 7 of them were his own.

To address questions left open by Beecher, Hróbjartsson and Gøtzsche took a different approach. First, they analyzed data from 114 published trials—not just 15. More than 8500 patients were involved. More importantly, in all of these trials, placebo treatment was compared with *no treatment*. That is, in each trial, some subjects received placebo treatment and some received no treatment. (Of course, in most [112] of the trials, there was a third group of subjects who received an active treatment.) The trials involved 40 clinical conditions, including anemia, asthma, hypertension, hyperglycemia, epilepsy, Parkinson's disease, schizophrenia, depression, smoking, and pain. In 38 of the trials, the measured outcomes were *objective* (eg, reduction in blood pressure, increase in red blood cell count), and in 76 the outcomes were *subjective* (eg, improvement in mood, reduction of pain). Of the 114 trials, 45 evaluated pharmacologic interventions, 26 evaluated physical interventions, and 43 evaluated psychologic interventions. The type of placebo employed was matched to the active treatment: for the pharmacologic studies, typical placebo treatment consisted of giving a lactose pill; for the physical studies (eg, evaluating the effect of transcutaneous electrical nerve stimulation on pain), typical placebo treatment consisted of performing the procedure but with the equipment turned off; and for the psychologic studies (eg, evaluating the effect of psychotherapy on depression), typical placebo treatment consisted of nondirectional, neutral discussion between the patient and the treatment provider.

What did the analysis reveal? In trials with *objective* outcomes, placebo treatment had *virtually no measurable effect*: outcomes in patients receiving placebo treatment were identical to those in patients receiving no treatment at all. However, in some trials with *subjective* outcomes, placebo treatment *did* have a convincing effect—but it was small, and limited primarily to studies of *pain*. In their conclusion, the authors stated, “We found little evidence that placebos in general have powerful clinical effects,” although they go on to say they did find “significant effects of placebo ... for the treatment of pain.” In addition, they concede that their analysis does “leave open the question of whether placebo effects in clinical practice might differ from placebo effects among research subjects.”

Is this the end of the story? Is the placebo effect really just a myth? Well, we really can't say. Yes, the Danish study, which was far superior to Beecher's, failed to reveal a powerful effect of placebo treatment. However, this does not prove there is no placebo effect. Rather, it may

simply indicate that we can't readily measure a placebo effect in clinical trials. There are some good arguments supporting this possibility:

- If the placebo response is based primarily on the clinician-patient relationship, then, even if there is a placebo response, it would be invisible in clinical trials—because subjects who receive placebo treatment and those who receive no treatment all share the same relationship with the clinician.
- Placebo responses (assuming they exist) are based on the patient's strong belief that he or she is getting an effective treatment. However, in clinical trials, there is always *doubt*—because all participants are aware that they may be getting a placebo, rather than the real deal. In the presence of significant doubt, the placebo effect may be greatly diminished. If this is true, then placebo effects would not be expected in clinical trials.
- If placebo effects exist only in real practice—and not in clinical trials—then proving their existence may well be impossible. Why? Because we'd have to do a clinical trial to prove they exist—and we already know we can't see them in clinical trials.

What's the bottom line? First, owing to a major weakness in design, Beecher's study does not constitute proof that placebos have beneficial effects. Second, by using a more appropriate design, Hróbjartsson and Gøtzsche have shown clearly that, in the context of clinical trials, placebo interventions are largely devoid of measurable effects—with the exception of producing modest reductions in pain. Third, although Hróbjartsson and Gøtzsche failed to see a placebo effect, their study does not rule out the possibility that, in the real world, placebo treatments can indeed be beneficial. However, this is yet to be proved—and possibly never will be.

1 Beecher HK: The powerful placebo. JAMA 159:1602–1606, 1955.

2 Hróbjartsson A, Gøtzsche PC: Is the placebo powerless? An analysis of clinical trials comparing placebo with no treatment. N Engl J Med 344:1594–1602, 2001.

8.6.2 Bioavailability

The term *bioavailability* refers to the ability of a drug to reach the systemic circulation from its site of administration. Different preparations of the same drug can vary in bioavailability. As discussed in [Chapter 4](#), such factors as tablet disintegration time, enteric coatings, and sustained-release formulations can alter bioavailability, and can thereby make drug responses variable.

Differences in bioavailability occur primarily with oral preparations and not with parenteral preparations. Fortunately, even with oral agents, when differences in bioavailability do exist between preparations, those differences are usually so small as to lack clinical significance.

Differences in bioavailability are of greatest concern for drugs with a narrow therapeutic range. Why? Because with these agents, a relatively small change in drug level can produce a significant change in response: A small decline in drug level may cause therapeutic failure, whereas a small increase in drug level may cause toxicity. Under these conditions, differences in bioavailability could have a significant impact.

8.6.3 Other Causes of Variable Absorption

Several factors in addition to bioavailability can alter drug absorption, and thereby lead to variations in drug responses. Alterations in gastric pH can affect absorption through the pH partitioning effect. For drugs that undergo absorption in the intestine, absorption will be delayed when gastric emptying time is prolonged. Diarrhea can reduce absorption by accelerating transport of drugs through the intestine. Conversely, constipation can enhance absorption by prolonging the time available for absorption. The presence of food in the stomach tends to *slow* the absorption of most drugs, without reducing the total amount absorbed. However, in some cases, food can decrease the *extent* of absorption as well. For example, absorption of tetracycline is reduced substantially by milk or any other dairy product that contains calcium. Lastly, there are multiple mechanisms by which drug interactions can decrease or increase absorption (see [Chapter 6](#)).

8.7 GENETICS

A patient's unique genetic makeup can lead to drug responses that are qualitatively and quantitatively different from those of the population at large. Adverse effects and therapeutic effects may be changed. The major underlying causes of altered responses are alterations in genes that code for drug-metabolizing enzymes and drug targets.

Pharmacogenomics—the study of how genes affect individual drug responses—is an active area of research. In the future, pharmacogenetic analysis should enable us to pick a drug and dosage that best fits the patient's genotype, thereby reducing the risk of adverse reactions, increasing the likelihood of a strong therapeutic response, and decreasing the cost, inconvenience, and risk associated with prescribing a drug to which the patient is unlikely to respond. Although pharmacogenomics is a young science, it is already having an effect: The Food and Drug Administration (FDA) recently recommended that patients using two drugs—warfarin [Coumadin] and carbamazepine [Tegretol]—undergo genetic testing prior to treatment.

8.7.1 Altered Drug Metabolism

The most common mechanism by which genetic differences modify drug responses is alteration of drug-metabolizing enzymes. Such gene-based changes can either accelerate or retard the metabolism of many drugs, as illustrated in the following examples:

- Warfarin—an anticoagulant with a low therapeutic index (TI)—is metabolized very slowly in some patients. Why? Because their genes code for altered forms of cytochrome P450-2C9 (CYP2C9), the enzyme that converts warfarin to an inactive form. If dosage is not kept low in these patients, warfarin may accumulate to levels that cause bleeding. To reduce the risk of bleeding, the FDA now recommends that patients be tested for variants of the gene that codes for CYP2C9.
- About 1 in 3500 Europeans metabolize succinylcholine (a muscle relaxant) very slowly, owing to production of an altered form of butyrylcholinesterase, the enzyme that, in most people, metabolizes the drug very rapidly. If given succinylcholine, people with the abnormal enzyme can experience paralysis that is dangerously prolonged.
- Among white Americans, about 52% metabolize isoniazid (a drug for tuberculosis) slowly and 48% metabolize it rapidly. Why? Because, owing to genetic differences, these people produce two different forms of *N*-acetyltransferase-2, the enzyme that metabolizes isoniazid. If dosage is not adjusted for these differences, the rapid metabolizers may experience treatment failure and the slow metabolizers may experience toxicity.
- In the United States, about 1% of the population produces a form of dihydropyrimidine dehydrogenase that does a poor job of metabolizing fluorouracil, a drug used against cancer. Several people with this inherited difference, while receiving standard doses of fluorouracil, have died from central nervous system injury owing to accumulation of the drug to toxic levels.
- Approximately 1 in 14 Caucasians has a form of cytochrome P450 that is unable to convert codeine into morphine, the active form of codeine. As a result, codeine cannot relieve their pain.

For drugs that have a high TI, altered rates of metabolism may not affect the clinical outcome. However, if the TI is low, then relatively small increases in drug levels can lead to toxicity, and relatively small decreases can lead to therapeutic failure. Clearly, in these cases, altered rates of metabolism can be of great clinical significance.

8.7.2 Altered Drug Targets

Genetic variations can alter the structure of drug receptors and other target molecules, and can thereby influence drug responses. For example, the beneficial effects of warfarin are greatly reduced in patients with a variant form of vitamin K epoxide reductase (VKORC1), the enzyme that warfarin inhibits to produce its effects. Hence, as for CYP2C9 noted above, the FDA recommends testing warfarin users for variants in the gene coding for VKORC1. Other drug targets that can be altered by gene variants include beta₂-adrenergic receptors (important in the therapy of heart disease and asthma), dopamine receptors (important in the treatment of schizophrenia), estrogen receptors (important in the treatment of osteoporosis), and 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase (important in the management of high cholesterol).

81

82

8.7.3 Other Ways Genetics Can Influence Drug Responses

Some genetically determined drug responses are based on factors other than changes in drug metabolism or drug targets. For example, some people of Asian ancestry are at high risk of life-threatening skin reactions to carbamazepine [Tegretol] owing to production of unusual human leukocyte antigens (HLAs), known as HLA-B*1502. To reduce risk, the FDA recommends that patients of Asian descent be screened for the HLA-B*1502 gene before carbamazepine is used.

Three other examples follow:

- Trastuzumab [Herceptin], a drug for breast cancer, only works against tumors that overexpress the HER2 protein.
- Tamoxifen [Nolvadex] may prevent development of breast cancer in women at high risk—but only in women with mutations in the *BRCA2* gene, not the *BRCA1* gene.
- Inherited differences in coagulation factors increase the risk of deep vein thrombosis in women using oral contraceptives.

8.8 GENDER

Men and women can respond differently to the same drug. A drug may be more effective in men than in women, or vice versa. Likewise, adverse effects may be more intense in men than in women, or vice versa. Unfortunately, for most drugs, we don't know much about gender-related differences. Why? Because, until recently, essentially all drug research was done in men. Nonetheless, enough research *has* been done to indicate that significant gender-related differences really do exist. Here are four examples:

- When used to treat heart failure, digoxin may *increase* mortality in women while having no effect on mortality in men (see [Chapter 47](#), [Box 47-1](#)).
- Alcohol is metabolized more slowly by women than by men. As a result, a woman who drinks the same amount as a man (on a weight-adjusted basis) will become more intoxicated.
- Certain opioid analgesics (eg, pentazocine, nalbuphine) are much more effective in women than in men. As a result, pain relief can be achieved at lower doses in women.
- Quinidine causes greater QT interval prolongation in women than in men. As a result, women given the drug are more likely to develop torsades de pointes, a potentially fatal cardiac dysrhythmia.

In 1997, the FDA put pressure on drug companies to include women in trials of new drugs, especially drugs directed at serious or life-threatening illnesses. The information generated by these trials will permit drug therapy in women to be more rational than is possible today. In the meantime, clinicians must keep in mind that the information currently available may fail to accurately predict responses in female patients. Accordingly, clinicians should remain alert for treatment failures and unexpected adverse effects.

It is important to appreciate that gender- and race-related differences in drug responses are, ultimately, genetically based. Hence, the preceding can be considered an extension of our discussion on pharmacogenomics.

8.9 RACE

Race-related drug responses have two primary determinants: *genetic variations* and *psychosocial factors*. Hence, to a large extent, discussion here is an extension of our discussion on pharmacogenomics. However, keep in mind that, in addition to genetics, psychosocial factors are important determinants of how individuals in a particular ethnic group respond to drugs.

In general, “race” is not very helpful as a basis for predicting individual variation in drug responses. Why? To start with, race is nearly impossible to define. Do we define it by skin color and other superficial characteristics? Or do we define it by group genetics? If we define race by skin color, how dark must skin be, for example, to define a patient as “black?” On the other hand, if we define race by group genetics, how many black ancestors must an African American have to be considered genetically “black?” And what about most people, whose ancestry is ethnically heterogeneous? Latinos, for example, represent a mix of multiple ethnic backgrounds from three continents. I think you get the picture. So, if a prescriber can't even decide what “race” a patient belongs to, it would seem very difficult indeed to use race as a basis for making therapeutic decisions.

Of course, what we really care about is not race per se, but rather the specific genetic and psychosocial factors—shared by many members of an ethnic group—that influence drug responses. Armed with this knowledge, we can identify group members who share those genetic and/or psychosocial factors and tailor drug therapy accordingly. Perhaps more importantly, application of this knowledge is not limited to members of the ethnic group from which the knowledge arose: We can use it in the management of *all* patients, regardless of ethnic background. How can this be? Owing to ethnic heterogeneity, these factors are not limited to members of any one race. Hence, once we know about a factor (eg, a specific genetic variation), we can screen all patients for it, and, if it's present, adjust drug therapy as indicated.

This discussion of race-based therapy would be incomplete without mentioning BiDil, a fixed-dose combination of two vasodilators: isosorbide dinitrate (ISDN) and hydralazine, both of which have been available separately for years. In 2005, BiDil became the first drug product approved by the FDA for treating members of just one race, specifically, African Americans. Approval was based on results of the African-American Heart Failure Trial (A-HeFT), which showed that, in self-described black patients, adding ISDN plus hydralazine to standard therapy of heart failure reduced 1-year mortality by 43%—a very impressive and welcome result. Does BiDil benefit African Americans more than white Americans? We don't know: No white patients were enrolled in A-HeFT, so the comparison can't be made. The bottom line? Even though BiDil is approved for treating a specific racial group, there's no proof that it wouldn't work just as well (or even better) in some other group. Why then, you might ask, was A-HeFT conducted? Partly because of older data suggesting a possible increased benefit in black patients. However, the principal reason seems to be a combination of regulatory and market incentives, which made it worthwhile for NitroMed, the manufacturer of BiDil, to limit research to blacks. Here's the story. NitroMed holds two patents on BiDil, one for the fixed-dose combination itself, and one for using the combination in black patients. By getting FDA approval for black patients only, NitroMed acquired patent protection through the year 2020—13 years longer than it would have gotten in the absence of the race-specific indication. Of course, now that BiDil is approved, physicians are free to prescribe it for anyone. So the ploy of getting race-specific approval did not actually limit the number of patients NitroMed could profit from. Is this a great country, or what?

82

83

8.10 FAILURE TO TAKE MEDICINE AS PRESCRIBED

Medications are not always administered as prescribed: dosage size and timing may be altered, doses may be omitted, and extra doses may be taken. Failure to administer medication as prescribed is a common explanation for variability in the response to a prescribed dose. As a rule, such failure results either from poor patient adherence (compliance) or from medication errors made by hospital staff.

Adherence can be hard to achieve. Factors that can influence adherence include manual dexterity, visual acuity, intellectual capacity, psychologic state, attitude toward drugs, and the ability to pay for medication. As noted in [Chapter 3](#), patient education that is both clear and convincing may help improve adherence, and may thereby help reduce variability.

Medication errors are an obvious source of individual variation. Medication errors can originate with physicians, nurses, technicians, and pharmacists. However, since the nurse is usually the last member of the healthcare team to check medications prior to administration, it is ultimately the nurse's responsibility to ensure that medication errors are avoided. Medication errors are discussed at length in [Chapter 7](#).

8.11 DRUG INTERACTIONS

A drug interaction is a process in which one drug alters the effects of another. Drug interactions can be an important source of variability. The mechanisms by which one drug can alter the effects of another and the clinical consequences of drug interactions are discussed at length in [Chapter 6](#).

8.12 DIET

Diet can affect responses to drugs, primarily by affecting the patient's general health status. A diet that promotes good health can enable drugs to elicit therapeutic responses and increase the patient's capacity to tolerate adverse effects. Poor nutrition can have the opposite effect.

Starvation can reduce protein binding of drugs (by decreasing the level of plasma albumin). Because of reduced binding, levels of free drug rise, thereby making drug responses more intense. For certain drugs (eg, warfarin), the resultant increase in effects could be disastrous.

Although nutrition can affect drug responses by the general mechanisms noted, there are but few examples of a specific nutrient affecting the response to a specific drug. Perhaps the best example involves the monoamine oxidase (MAO) inhibitors, drugs used to treat depression. The most serious adverse effect of these drugs is malignant hypertension, which can be triggered by foods that contain tyramine, a breakdown product of the amino acid tyrosine. Accordingly, patients taking MAO inhibitors must rigidly avoid all tyramine-rich foods (eg, beef liver, ripe cheeses, yeast products, Chianti wine). The interaction of tyramine-containing foods with MAO inhibitors is discussed at length in [Chapter 32](#).

8.12.1 KEY POINTS

- In order to maximize beneficial drug responses and minimize harm, we must adjust therapy to account for sources of individual variation.

- As a rule, small patients need smaller doses than large patients.
- Dosage adjustments made to account for size are often based on body surface area, rather than simply on body weight.
- Infants and the elderly are more sensitive to drugs than are older children and younger adults.
- Kidney disease can decrease drug excretion, thereby causing drug levels to rise. To prevent toxicity, drugs that are eliminated by the kidneys should be given in reduced dosage.
- Liver disease can decrease drug metabolism, thereby causing levels to rise. To prevent toxicity, drugs that are eliminated by the liver should be given in reduced dosage.
- When a patient becomes tolerant to a drug, the dosage must be increased to maintain beneficial effects.
- Pharmacodynamic tolerance results from adaptive changes that occur in response to prolonged drug exposure. Pharmacodynamic tolerance increases the MEC of a drug.
- Pharmacokinetic tolerance results from accelerated drug metabolism. Pharmacokinetic tolerance does not increase the MEC.
- A placebo effect is defined as the component of a drug response that can be attributed to psychologic factors, rather than to direct physiologic or biochemical actions of the drug. Solid proof that most placebo effects are real is lacking.
- Bioavailability refers to the ability of a drug to reach the systemic circulation from its site of administration.
- Differences in bioavailability matter most for drugs that have a narrow therapeutic range.
- Alterations in the genes that code for drug-metabolizing enzymes can result in increased or decreased metabolism of many drugs.

83

- Genetic variations can alter the structure of drug receptors and other target molecules, and can thereby influence drug responses.
- Therapeutic and adverse effects of drugs may differ between males and females. Unfortunately, for most drugs, data are insufficient to predict what the differences might be.

84

- Race is a poor predictor of drug responses. What really matters is not race, but rather the specific genetic variations and psychosocial factors, shared by some group members, that can influence drug responses.
- Poor patient adherence is a major source of individual variation.

⁹ CHAPTER 9 Drug Therapy During Pregnancy and Breast-Feeding

Our topic for this chapter is drug therapy in women who are pregnant or breast-feeding. The clinical challenge is to provide effective treatment for the mother while avoiding harm to the fetus or nursing infant. Unfortunately, meeting this challenge is confounded by a shortage of reliable data on toxicity from drug use during pregnancy or breast-feeding.

^{9.1} DRUG THERAPY DURING PREGNANCY: BASIC CONSIDERATIONS

Drug use during pregnancy is common: About two-thirds of pregnant women take at least one medication, and the majority take more. Some drugs are used to treat pregnancy-related conditions, such as nausea, constipation, and preeclampsia. Some are used to treat chronic disorders, such as hypertension, diabetes, and epilepsy. And some are used for infectious diseases or cancer. In addition to taking these therapeutic agents, pregnant women may take drugs of abuse, such as alcohol, cocaine, and heroin.

Drug therapy in pregnancy presents a vexing dilemma. In pregnant patients, as in all other patients, the benefits of treatment must balance the risks. Of course, when drugs are used during pregnancy, risks apply to the fetus as well as the mother. Unfortunately, the risks for most drugs used in pregnancy have not been determined—hence the dilemma: The prescriber is obliged to balance risks versus benefits, without knowing what the risks really are. The reasons that underlie our lack of knowledge are discussed below under *Identification of Teratogens*.

Despite the imposing challenge of balancing risks versus benefits, drug therapy during pregnancy cannot and should not be avoided. The health of the fetus depends on the health of the mother. Hence, conditions that threaten the mother's health must be addressed—for the sake of the baby as well as the mother. Chronic asthma is a good example. Uncontrolled maternal asthma is far more dangerous to the fetus than the drugs used to treat it. Among asthmatic women who fail to take medication, the incidence of stillbirth is doubled. If all women with asthma took medication, an estimated 2000 babies would be saved each year.

^{9.1.1} Physiologic Changes During Pregnancy and Their Impact on Drug Disposition and Dosing

Pregnancy brings on physiologic changes that can alter drug disposition. Changes in the kidney, liver, and GI tract are of particular interest. Because of these changes, a compensatory change in dosage may be needed.

By the third trimester, renal blood flow is doubled, causing a large increase in glomerular filtration rate. As a result, there is accelerated clearance of drugs that are eliminated by glomerular filtration. Elimination of lithium, for example, is increased by 100%. To compensate for accelerated excretion, dosage must be increased.

For some drugs, hepatic metabolism increases during pregnancy. Three anticonvulsants—phenytoin, carbamazepine, and valproic acid—provide examples.

Tone and motility of the bowel decrease in pregnancy, causing intestinal transit time to increase. Because of prolonged transit, there is more time for drugs to be absorbed. In theory, this could increase levels of drugs whose absorption is normally poor. Similarly, there is more time for reabsorption of drugs that undergo enterohepatic recirculation, and hence effects of these drugs could be prolonged. In both cases, a reduction in dosage might be needed.

9.1.2 Placental Drug Transfer

Essentially all drugs can cross the placenta, although some cross more readily than others. The factors that determine drug passage across the membranes of the placenta are the same factors that determine drug passage across all other membranes. Accordingly, drugs that are lipid soluble cross the placenta easily, whereas drugs that are ionized, highly polar, or protein bound cross with difficulty. Nonetheless, for practical purposes, the clinician should assume that *any drug taken during pregnancy will reach the fetus.*

85

86

9.1.3 Adverse Reactions During Pregnancy

Drugs taken during pregnancy can adversely affect both the mother and fetus. The effect of greatest concern is teratogenesis (production of birth defects). This issue is discussed separately below. Not only are pregnant women subject to the same adverse effects as everyone else, they may also suffer effects unique to pregnancy. For example, when heparin (an anticoagulant) is taken by pregnant women, it can cause osteoporosis, which in turn can cause compression fractures of the spine. Use of prostaglandins (eg, misoprostol), which stimulate uterine contraction, can cause abortion. Conversely, use of aspirin near term can suppress contractions in labor. In addition, aspirin increases the risk of serious bleeding.

Regular use of dependence-producing drugs (eg, heroin, barbiturates, alcohol) during pregnancy can result in the birth of a drug-dependent infant. If the infant is not supplied with a drug that can support its dependence, a withdrawal syndrome will ensue. Symptoms include shrill crying,

vomiting, and extreme irritability. The neonate should be weaned from dependence by giving progressively smaller doses of the drug on which he or she is dependent.

Certain pain relievers used during delivery can depress respiration in the neonate. The infant should be closely monitored until respiration is normal.

9.2 DRUG THERAPY DURING PREGNANCY: TERATOGENESIS

The term *teratogenesis* is derived from *teras*, the Greek word for monster. Translated literally, teratogenesis means *to produce a monster*. Consistent with this derivation, we usually think of birth defects in terms of gross malformations, such as cleft palate, clubfoot, and hydrocephalus. However, birth defects are not limited to distortions of gross anatomy; they also include neurobehavioral and metabolic anomalies.

9.2.1 Incidence and Causes of Congenital Anomalies

The incidence of *major* structural abnormalities (eg, abnormalities that are life threatening or require surgical correction) is between 1% and 3%. Half of these are obvious and are reported at birth. The other half involve internal organs (eg, heart, liver, GI tract) and are not discovered until later in life or at autopsy. The incidence of minor structural abnormalities is unknown, as is the incidence of functional abnormalities (eg, growth retardation, mental retardation).

Congenital anomalies have multiple causes, including genetic heritage, environmental chemicals, and drugs. Genetic factors account for about 25% of all birth defects. Of the genetically based anomalies, Down's syndrome is the most common. Less than 1% of all birth defects are caused by drugs. For the majority of congenital anomalies, the cause is unknown.

9.2.2 Teratogenesis and Stage of Development

Fetal sensitivity to teratogens changes during development, and hence the effect of a teratogen is highly dependent upon when the drug is given. As shown in [Figure 9-1](#), development occurs in three major stages: the *preimplantation/presomite period* (conception through week 2), the *embryonic period* (weeks 3 through 8), and the *fetal period* (week 9 through term). During the preimplantation/presomite period, teratogens act in an “all-or-nothing” fashion. That is, if the dose is sufficiently high, the result is death of the conceptus. Conversely, if the dose is sublethal, the conceptus is likely to recover fully.

Gross malformations are produced by exposure to teratogens during the *embryonic period* (roughly the first trimester). This is the time when the basic shape of internal organs and other structures is being established. Hence, it is not surprising that interference at this stage results in conspicuous

anatomic distortions. Because the fetus is especially vulnerable during the embryonic period, expectant mothers must take special care to avoid exposure to teratogens during this time.

Teratogen exposure during the *fetal period* (ie, the second and third trimesters) usually disrupts *function* rather than gross anatomy. Of the developmental processes that occur in the fetal period, growth and development of the brain are especially important. Disruption of brain development can result in learning deficits and behavioral abnormalities.

9.2.3 Identification of Teratogens

For the following reasons, human teratogens are extremely difficult to identify:

- The incidence of congenital anomalies is generally low.
- Animal tests may not be applicable.
- Prolonged exposure may be required.
- Teratogenic effects may be delayed.
- Behavioral effects are difficult to document.
- Controlled experiments can't be done in humans.

As a result, only a few drugs are considered *proven* teratogens. Drugs whose teratogenicity has been documented (or at least is highly suspected) are listed in [Table 9-1](#). It is important to note, however, that *lack of proof of teratogenicity does not mean that a drug is safe*; it only means that the available data are insufficient to make a definitive judgment. Conversely, *proof of teratogenicity does not mean that every exposure will result in a birth defect*. In fact, with most teratogens, the risk of malformation following exposure is only about 10%.

To prove that a drug is a teratogen, three criteria must be met:

- The drug must cause a characteristic set of malformations.
- It must act only during a specific window of vulnerability (eg, weeks 4 through 7 of gestation).
- The incidence of malformations should increase with increasing dosage and duration of exposure.

Obviously, we can't do experiments in humans to see if a drug meets these criteria. The best we can do is systematically collect

86
87

Figure 9-1 Effects of teratogens at various stages of development of the fetus.

87

and analyze data on drugs taken during pregnancy in the hope that useful information on teratogenicity will be revealed.

88

TABLE 9-1 Drugs That Should Be Avoided During Pregnancy Because of Proven or Strongly Suspected Teratogenicity*

Drug	Teratogenic Effect
Anticancer/Immunosuppressant Drugs	
Cyclophosphamide	CNS malformation, secondary cancer
Methotrexate	CNS and limb malformations
Antiseizure Drugs	
Carbamazepine	Neural tube defects
Phenytoin	Growth retardation, CNS defects
Valproic acid	Neural tube defects
Sex Hormones	
Androgens (eg, danazol)	Masculinization of the female fetus
Diethylstilbestrol	Vaginal carcinoma in female offspring
Other Drugs	
Alcohol	Fetal alcohol syndrome, stillbirth, spontaneous abortion, low birth weight, mental retardation
Angiotensin-converting enzyme inhibitors	Renal failure, renal tubular dysgenesis, skull hypoplasia (from exposure during the second and third trimesters)
Antithyroid drugs (propylthiouracil, methimazole)	Goiter and hypothyroidism
Isotretinoin and other vitamin A derivatives (etretinate, megadoses of vitamin A)	Multiple defects (CNS, craniofacial, cardiovascular, others)
Lithium	Ebstein's anomaly (cardiac defects)
Nonsteroidal anti-inflammatory drugs	Premature closure of the ductus arteriosus
Oral hypoglycemic drugs (eg, tolbutamide)	Neonatal hypoglycemia
Tetracycline	Tooth and bone anomalies
Thalidomide	Shortened limbs, internal organ defects
Warfarin	Skeletal and CNS defects
CNS = central nervous system.	

* The absence of a drug from this table does not mean that the drug is not a teratogen; it only means that teratogenicity has not been proved. For most proven teratogens, the risk of a congenital anomaly is only 10%.

Studies in animals may be of limited value, in part because teratogenicity may depend on species. That is, drugs that are teratogens in laboratory animals may nonetheless be safe in humans. Conversely, and more importantly, drugs that fail to cause anomalies in animals may later prove teratogenic in humans. The most notorious example is thalidomide. In studies with pregnant animals, thalidomide was harmless. However, when thalidomide was taken by pregnant women, about 30% had babies with severe malformations. The take-home message is this: *Lack of teratogenicity in animals is not proof of safety in humans*. Accordingly, we cannot assume that a new drug is safe for use in human pregnancy just because it has met Food and Drug Administration (FDA) requirements, which are based on tests done in pregnant animals.

Some teratogens act quickly, whereas others require prolonged exposure. Thalidomide represents a fast-acting teratogen: a single dose can cause malformation. In contrast, alcohol (ethanol) must be taken repeatedly in high doses if gross malformation is to result. (Lower doses of alcohol may produce subtle anomalies.) Because a single exposure to a rapid-acting teratogen can produce obvious malformation, rapid-acting teratogens are easier to identify than slowacting teratogens.

Teratogens that produce delayed effects are among the hardest to identify. The best example is diethylstilbestrol, an estrogenic substance that causes vaginal cancer in female offspring 18 or so years after birth.

Teratogens that affect behavior may be nearly impossible to identify. Behavioral changes are often delayed, and therefore may not become apparent until the child goes to school. By this time, it may be difficult to establish a correlation between drug use during pregnancy and the behavioral deficit. Furthermore, if the deficit is subtle, it may not even be recognized.

9.2.4 FDA Pregnancy Risk Categories

In 1983, the FDA established a system for classifying drugs according to their probable risks to the fetus. According to this system, *drugs can be put into one of five risk categories: A, B, C, D, and X* ([Table 9-2](#)). Drugs in Risk Category A are the least dangerous; controlled studies have been done in pregnant women and have failed to demonstrate a risk of fetal harm. In contrast, drugs in Category X are the most dangerous; these drugs are known to cause human fetal harm, and their risk to the fetus outweighs any possible therapeutic benefit. Drugs in Categories B, C, and D are progressively more dangerous than drugs in Category A and less dangerous than drugs in Category X. The law does not require classification of drugs that were in use before 1983; hence many drugs are not classified.

Although the current rating system is helpful, it is far from ideal, and hence the FDA has proposed major revisions. Specifically, the FDA plans to phase out the use of letter categories, and replace them with detailed information about the effects of drugs during pregnancy. The format employed will have three sections:

- *Fetal Risk Summary*—This section will describe what we know about drug effects on the fetus, and will offer a conclusion, such as, “Human data indicate this drug increases the risk of cardiac abnormalities.”

TABLE 9-2 FDA Pregnancy Risk Categories

Category	Category Description
A	<i>Remote Risk of Fetal Harm:</i> Controlled studies in women have been done and have failed to demonstrate a risk of fetal harm during the first trimester, and there is no evidence of risk in later trimesters.
B	<i>Slightly More Risk Than A:</i> Animal studies show no fetal risk, but controlled studies have not been done in women. or Animal studies do show a risk of fetal harm, but controlled studies in women have failed to demonstrate a risk during the first trimester, and there is no evidence of risk in later trimesters.
C	<i>Greater Risk Than B:</i> Animal studies show a risk of fetal harm, but no controlled studies have been done in women. or No studies have been done in women or animals.
D	<i>Proven Risk of Fetal Harm:</i> Studies in women show proof of fetal damage, but the potential benefits of use during pregnancy may be acceptable despite the risks (eg, treatment of life-threatening disease for which safer drugs are ineffective). A statement on risk will appear in the “WARNINGS” section of drug labeling.
X	<i>Proven Risk of Fetal Harm:</i> Studies in women or animals show definite risk of fetal abnormality. or Adverse reaction reports indicate evidence of fetal risk. The risks clearly outweigh any possible benefit. A statement on risk will appear in the “CONTRAINDICATIONS” section of drug labeling.

- *Clinical Considerations*—This section will describe the likely effects if a drug is taken before a woman knows she is pregnant. The section will also discuss the risks to the mother

and fetus of the disease being treated, along with dosing information, and ways to deal with complications.

- *Data*—This section will give detailed evidence from human and animal studies regarding the information presented in the Fetal Risk Summary.

9.2.5 Minimizing the Risk of Drug-Induced Teratogenesis

Common sense tells us that the best way to minimize teratogenesis is to minimize use of drugs. If possible, pregnant women should avoid drugs entirely. At the least, all *unnecessary* drug use should be eliminated. Alcohol and cocaine, for example, which are known to harm the developing fetus, have no valid indications, and their use cannot be justified. Nurses and other health professionals should warn pregnant women against use of all nonessential drugs.

As noted, some disease states (eg, epilepsy, asthma, diabetes) pose a greater risk to fetal health than do the drugs used for treatment. However, even with these disorders, in which drug therapy reduces the risk of disease-induced fetal harm, we must still take steps to minimize harm from drugs. Accordingly, drugs that pose a high risk of teratogenesis should be discontinued and safer alternatives substituted.

Rarely, a pregnant woman has a disease that requires use of drugs that have a high probability of causing teratogenesis. Some anticancer drugs, for example, are highly toxic to the developing fetus, yet cannot be ethically withheld from the pregnant patient. If a woman elects to use such drugs, termination of pregnancy should be considered.

Reducing the risk of teratogenesis also applies to female patients who are *not* pregnant. Why? Because about 50% of pregnancies are unintended. Accordingly, if a woman of reproductive age is taking a teratogenic medication, she should be educated about the teratogenic risk as well as the necessity of using at least one reliable form of birth control.

9.2.6 Responding to Teratogen Exposure

When a pregnant woman has been exposed to a known teratogen, the first step is to determine exactly when the drug was taken, and exactly when the pregnancy began. If drug exposure was not during the period of organogenesis (ie, weeks 3 through 8), the patient should be reassured that the risk of drug-induced malformation is minimal. In addition, she should be reminded that 3% of all babies have some kind of conspicuous malformation, independent of teratogen exposure. This is important because otherwise the drug is sure to be blamed if the baby is abnormal.

What should be done if the exposure *did* occur during organogenesis? First, a reference (eg, Briggs GG, Freeman RK, Yaffe SJ: *Drugs in Pregnancy and Lactation, 8th Edition*. Philadelphia: JB Lippincott, 2008) should be consulted to determine the type of malformation expected. Next, at least two ultrasound scans should be done to assess the extent of injury. If the malformation is severe, termination of pregnancy should be considered. If the malformation is minor (eg, cleft palate), it may be correctable by surgery, either shortly after birth or later in childhood.

9.3 DRUG THERAPY DURING BREAST-FEEDING

Drugs taken by lactating women can be excreted in breast milk. If drug concentrations in milk are high enough, a pharmacologic effect can occur in the infant, raising the possibility of harm. Unfortunately, very little systematic research has been done on this issue. As a result, although a few drugs are known to be hazardous ([Table 9-3](#)), the possible danger posed by many others remains undetermined.

Although nearly all drugs can enter breast milk, the extent of entry varies greatly. The factors that determine entry into breast milk are the same factors that determine passage of drugs across membranes. Accordingly, drugs that are lipid soluble enter breast milk readily, whereas drugs that are ionized, highly polar, or protein bound tend to be excluded.

89

TABLE 9-3 Drugs That Are Contraindicated During Breast-Feeding

Controlled Substances
Amphetamine
Cocaine
Heroin
Marijuana
Phencyclidine
Anticancer Agents/Immunosuppressants
Cyclophosphamide
Cyclosporine
Doxorubicin
Methotrexate
Others
Bromocriptine
Ergotamine
Lithium

Most drugs can be detected in milk, but concentrations are generally too low to be harmful. Hence, breast-feeding is usually safe, even though drugs are being taken. Nonetheless, prudence is always in order: If the nursing mother can avoid drugs, she certainly should. Moreover, when drugs *must* be used, steps should be taken to minimize risk. These include:

- Dosing immediately *after* breast-feeding (to minimize drug concentrations in milk at the next feeding)
- Avoiding drugs that have a long half-life
- Avoiding sustained-release formulations
- Choosing drugs that tend to be excluded from milk
- Choosing drugs that are least likely to affect the infant ([Table 9-4](#))

- Avoiding drugs that are known to be hazardous (see [Table 9-3](#))
- Using the lowest effective dosage for the shortest possible time

TABLE 9-4 Drugs of Choice for Breast-Feeding Women*

Drug Category	Drugs and Drug Groups of Choice	Comments
Analgesic drugs	Acetaminophen, flurbiprofen, ibuprofen, ketorolac, mefenamic acid, morphine, sumatriptan	Sumatriptan may be given for migraine. Morphine may be given for severe pain.
Anticoagulant drugs	Acenocoumarol, heparin (unfractionated and low molecular weight), warfarin	Among breast-fed infants whose mothers were taking warfarin, the drug was undetectable in plasma and bleeding time was not affected.
Antidepressant drugs	Sertraline, tricyclic antidepressants	Other antidepressants, such as fluoxetine [Prozac], may be given with caution.
Antiepileptic drugs	Carbamazepine, phenytoin, valproic acid	The estimated level of exposure to these drugs in breastfed infants is less than 10% of the therapeutic dose standardized by weight.
Antihistamines (histamine ₁ blockers)	Loratadine	Other antihistamines may be given, but data on the concentrations of these drugs in breast milk are lacking.
Antimicrobial drugs	Aminoglycosides, cephalosporins, macrolides, penicillins	Avoid chloramphenicol and tetracycline.
Beta-adrenergic antagonists	Labetalol, propranolol	Angiotensin-converting enzyme inhibitors and calcium channel– blocking agents are also considered safe.
Endocrine drugs	Insulin, levothyroxine, propylthiouracil	The estimated level of exposure to propylthiouracil in breastfed infants is less than 1% of the therapeutic dose standardized by weight; thyroid function of the infants is not affected.
Glucocorticoids	Prednisolone and prednisone	The amount of prednisolone the infant would ingest in breast milk is less than 0.1% of the therapeutic dose standardized by weight.

Adapted from Shinya I: Drug therapy for breast-feeding women. N Engl J Med 343:118–126, 2000.

* This list is not exhaustive. Cases of overdoses of these drugs must be assessed on an individual basis.

9.3.1

KEY POINTS

- Because hepatic metabolism and glomerular filtration increase during pregnancy, dosages of some drugs may need to be increased.
- Lipid-soluble drugs cross the placenta readily, whereas drugs that are ionized, polar, or protein bound cross with difficulty. Nonetheless, all drugs cross to some extent.
- When prescribing drugs during pregnancy, the clinician must try to balance the benefits of treatment versus the risks—often without knowing what the risks really are.
- About 3% of all babies are born with gross structural malformations.
- Less than 1% of birth defects are caused by drugs.

90

- Teratogen-induced gross malformations result from exposure early in pregnancy (weeks 3 through 8 of gestation), the time of organogenesis.
- Functional impairments (eg, mental retardation) result from exposure to teratogens later in pregnancy.
- For most drugs, we lack reliable data on the risks of use during pregnancy.
- Lack of teratogenicity in animals is not proof of safety in humans.
- Some drugs (eg, thalidomide) cause birth defects with just one dose, whereas others (eg, alcohol) require prolonged exposure.
- FDA Pregnancy Risk Categories indicate the relative risks of drug use. Drugs in Category X pose the highest risk of fetal harm and are contraindicated during pregnancy.
- Any woman of reproductive age who is taking a known teratogen must be counseled about the teratogenic risk and the necessity of using at least one reliable form of birth control.
- Drugs that are lipid soluble readily enter breast milk, whereas drugs that are ionized, polar, or protein bound tend to be excluded. Nonetheless, all drugs enter to some extent.
- Although most drugs can be detected in breast milk, concentrations are usually too low to harm the nursing infant.
- If possible, drugs should be avoided during breastfeeding.

91

- If drugs cannot be avoided during breast-feeding, common sense dictates choosing drugs known to be safe ([Table 9-4](#)) and avoiding drugs known to be dangerous ([Table 9-3](#)).

¹⁰CHAPTER 10 Drug Therapy in Pediatric Patients

Patients who are very young or very old respond differently to drugs than the rest of the population. Most differences are *quantitative*. Specifically, patients in both age groups are more sensitive to drugs than other patients, and they show greater individual variation. Drug sensitivity in the very young results largely from *organ system immaturity*. Drug sensitivity in the elderly results largely from *organ system degeneration*. Because of heightened drug sensitivity, patients in both age groups are at increased risk of adverse drug reactions. In this chapter we discuss the physiologic factors that underlie heightened drug sensitivity in pediatric patients, as well as ways to promote safe and effective drug use. Drug therapy in geriatric patients is the topic of [Chapter 11](#).

Pediatrics covers all patients up to the age of 16. Because of ongoing growth and development, pediatric patients in different age groups present different therapeutic challenges. Traditionally, the pediatric population is subdivided into six groups:

- Premature infants (less than 36 weeks' gestational age)
- Full-term infants (36 to 40 weeks' gestational age)
- Neonates (first 4 postnatal weeks)
- Infants (weeks 5 to 52 postnatal)
- Children (1 to 12 years)
- Adolescents (12 to 16 years)

Not surprisingly, as young patients grow older, they become more like adults physiologically, and hence more like adults with regard to drug therapy. Conversely, the very young—those less than 1 year old, and especially those less than 1 month old—are very different from adults. If drug therapy in these patients is to be safe and effective, we must account for these differences.

Pediatric drug therapy is made even more difficult by insufficient drug information: Fully two-thirds of drugs used in pediatrics have never been tested in children. As a result, we lack reliable information on dosing, pharmacokinetics, and effects, both therapeutic and adverse. Is this lack of knowledge causing adverse events and even death? Possibly, but no one knows. Is it preventing optimal treatment? Probably, but again, we just don't know. To help expand our knowledge, Congress enacted two important laws: the *Best Pharmaceuticals for Children Act*, passed in 2002, and the *Pediatric Research Equity Act of 2003*. Both are designed to promote drug research in children. What we have learned so far underscores both the state of our ignorance and the need for much more work. For example, of the drugs studied to date:

- About 20% were ineffective in children, even though they *were* effective in adults.
- About 30% caused unanticipated side effects, some of them potentially lethal.
- About 20% required dosages different from those that had been extrapolated from dosages used in adults.

As more studies are done, the huge gaps in our knowledge will shrink. In the meantime, we must still treat children with drugs—even though we lack the information needed to prescribe rationally. Hence, similar to drug therapy during pregnancy, prescribers must try to balance benefits versus risks, without knowing with precision what the benefits and risks really are.

^{10.1} PHARMACOKINETICS: NEONATES AND INFANTS

As discussed in [Chapter 4](#), pharmacokinetic factors determine the concentration of a drug at its sites of action, and hence determine the intensity and duration of responses. If drug levels are elevated, responses will be more intense. If drug elimination is delayed, responses will be prolonged. Because the organ systems that regulate drug levels are not fully developed in the very young, these patients are at risk of both possibilities: drug effects that are unusually intense *and* prolonged. By accounting for pharmacokinetic differences in the very young, we can increase the chances that drug therapy will be both effective and safe.

[Figure 10-1](#) illustrates how drug levels differ between infants and adults following administration of equivalent doses (ie, doses adjusted for body weight). When a drug is administered *intravenously* ([Fig. 10-1A](#)), levels decline more slowly in the infant than in the adult. As a result, drug levels in the infant remain above the minimum effective concentration (MEC) longer than in the adult, thereby causing effects to be prolonged. When a drug is administered *subcutaneously* ([Fig. 10-1B](#)), not only do levels in the infant remain above the MEC *longer* than in the adult, but these levels also rise *higher*,

92

Figure 10-1 **Comparison of plasma drug levels in adults and infants.** **A**, Plasma drug levels following IV injection. Dosage was adjusted for body weight. Note that plasma levels remain above the minimum effective concentration (MEC) much longer in the infant. **B**, Plasma drug levels following subQ injection. Dosage was adjusted for body weight. Note that both the maximum drug level and the duration of action are greater in the infant.

(Redrawn from Levine RR: Pharmacology: Drug Actions and Reactions. Boston: Little, Brown, 1973:238.)

causing effects to be more intense as well as prolonged. From these illustrations, it is clear that adjustment of dosage for infants on the basis of body size alone is not sufficient to achieve safe results.

If small body size is not the major reason for heightened drug sensitivity in infants, what is? The increased sensitivity of infants is due largely to the immature state of five pharmacokinetic processes: (1) drug absorption, (2) protein binding of drugs, (3) exclusion of drugs from the central nervous system (CNS) by the blood-brain barrier, (4) hepatic drug metabolism, and (5) renal drug excretion.

10.1.1 Absorption

10.1.1.1 Oral Administration.

Gastrointestinal physiology in the infant is very different from that in the adult. As a result, drug absorption may be enhanced or impeded, depending on the physicochemical properties of the drug involved.

Gastric emptying time is both prolonged and irregular in early infancy, and then gradually reaches adult values by 6 to 8 months. For drugs that are absorbed primarily from the stomach, delayed gastric emptying enhances absorption. On the other hand, for drugs that are absorbed primarily from the intestine, absorption is delayed. Because gastric emptying time is irregular, the precise impact on absorption is not predictable.

Gastric acidity is very low 24 hours after birth and does not reach adult values for 2 years. Because of low acidity, absorption of acid-labile drugs is increased.

10.1.1.2 Intramuscular Administration.

Drug absorption following IM injection in the *neonate* is *slow* and *erratic*. Delayed absorption is due in part to low blood flow through muscle during the first days of postnatal life. By early *infancy*, absorption of IM drugs becomes more *rapid* than in neonates and adults.

10.1.1.3 Percutaneous Absorption.

Because the skin of the very young is thin, percutaneous drug absorption is significantly greater than in older children and adults. This increases the risk of toxicity from topical drugs.

10.1.2 Distribution

10.1.2.1 Protein Binding.

Binding of drugs to albumin and other plasma proteins is limited in the infant. Why? Because (1) the amount of albumin is relatively low and (2) endogenous compounds (eg, fatty acids, bilirubin) compete with drugs for available binding sites. Consequently, drugs that ordinarily undergo extensive protein binding in adults undergo much less binding in infants. As a result, the concentration of *free* levels of such drugs is relatively high in the infant, thereby intensifying effects. To ensure that effects are not too intense, dosages in infants should be reduced. Protein-binding capacity reaches adult values within 10 to 12 months.

10.1.2.2 Blood-Brain Barrier.

The blood-brain barrier is not fully developed at birth. As a result, drugs and other chemicals have relatively easy access to the CNS, making the infant especially sensitive to drugs that affect CNS function. Accordingly, all medicines employed for their CNS effects (eg, morphine, phenobarbital) should be given in reduced dosage. Dosage should also be reduced for drugs used for actions *outside* the CNS if those drugs are capable of producing CNS toxicity as a side effect.

10.1.3 Hepatic Metabolism

The drug-metabolizing capacity of newborns is low. As a result, neonates are especially sensitive to drugs that are eliminated primarily by hepatic metabolism. When these drugs are used, dosages must be reduced. The capacity of the liver to metabolize many drugs increases rapidly about 1 month after birth, and approaches adult levels a few months later. Complete maturation of the liver develops by 1 year.

The data in [Table 10-1](#) illustrate the limited drug-metabolizing capacity of newborns. These data are from experiments on the metabolism and effects of hexobarbital (a CNS depressant) in newborn and adult animals. *Metabolism* was measured in microsomal enzyme preparations made from the livers of *guinea pigs*. The *effect* of hexobarbital—CNS depression—was assessed in *mice*. Duration of sleeping time following hexobarbital injection was used as the index of CNS depression.

As indicated in [Table 10-1](#), the drug-metabolizing capacity of the adult liver is much greater than the drug-metabolizing capacity of the newborn liver. Whereas the adult liver preparation metabolized an average of 33% of the hexobarbital presented to it, there was virtually no measurable metabolism by the newborn preparation.

TABLE 10-1 Comparison of the Metabolism and Effect of Hexobarbital in Adult Versus Newborn Animals

Age	Percentage of Hexobarbital Metabolized (in 1 hr)	Duration of Drug-Induced Sleep	
		10-mg/kg Dose	50-mg/kg Dose
Newborn	“0”	6 hr	Eternal*
Adult	28–39	Less than 5 min	12–22 min
Data from Jondorf WR, Maickel RP, Brodie BB: Inability of newborn mice and guinea pigs to metabolize drugs. Biochem Pharmacol 1:352, 1958.			

* The 50-mg/kg dose was lethal to newborn animals.

The physiologic impact of limited drug-metabolizing capacity is indicated by observing sleeping time in newborns versus sleeping time in adults following injection of hexobarbital. As shown in [Table 10-1](#), a low dose (10 mg/kg) of hexobarbital caused adult mice to sleep less than 5 minutes. In contrast, the same dose caused newborns to sleep 6 hours. The differential effects on adults and newborns are much more dramatic at a higher dose (50 mg/kg): Whereas the adults merely slept longer, the newborns *died*.

10.1.4 Renal Excretion

Renal drug excretion is significantly reduced at birth. Renal blood flow, glomerular filtration, and active tubular secretion are all low during infancy. Because the drug-excreting capacity of infants is limited, drugs that are eliminated primarily by renal excretion must be given in reduced dosage. Adult levels of renal function are achieved by 1 year.

The data in [Table 10-2](#) illustrate the limited ability of the infant kidney to excrete foreign compounds. These data show rates of renal excretion for two compounds: inulin and *para*-aminohippuric acid (PAH). Inulin is excreted entirely by glomerular filtration. PAH is excreted by a combination of glomerular filtration and active tubular secretion. Note that the half-life for inulin is 630 minutes in infants but only 120 minutes in adults. Since inulin is eliminated by glomerular filtration alone, these data tell us that the glomerular filtration rate in the infant is much slower than in the adult. From the data for clearance of PAH, taken together with the data for clearance of inulin, we can conclude that tubular secretion in infants is also much slower than in adults.

10.2 PHARMACOKINETICS: CHILDREN 1 YEAR AND OLDER

By the age of 1 year, most pharmacokinetic parameters in children are similar to those in adults. Hence, drug sensitivity in children over the age of 1 is more like that of adults than that of the very young. Although pharmacokinetically similar to adults, children do differ in one important way: They metabolize drugs *faster* than adults. Drug-metabolizing capacity is markedly elevated until the age of 2 years, and then gradually declines. A further sharp decline takes place at puberty, when adult values are reached. Because of enhanced drug metabolism in children, an increase in dosage or a reduction in dosing interval may be needed for drugs that are eliminated by hepatic metabolism.

TABLE 10-2 Renal Function in Adults Versus Infants

	Average Infant	Average Adult
Body Weight (kg)	3.5	70
Inulin Clearance		
Rate (mL/min)	3 (approximate)	130
Half-time (min)	630	120
Para-aminohippuric Acid (PAH) Clearance		
Rate (mL/min)	12 (approximate)	650
Half-time (min)	160	43

Adapted from Goldstein A, Aronow L, Kalman SM: Principles of Drug Action: The Basis of Pharmacology, 2nd ed. New York: Churchill Livingstone, 1974:215.

TABLE 10-3 Adverse Drug Reactions Unique to Pediatric Patients

Drug	Adverse Effect
Androgens	Premature puberty in males; reduced adult height from premature epiphyseal closure
Aspirin and other salicylates	Severe intoxication from acute overdose (acidosis, hyperthermia respiratory depression); Reye's syndrome in children with chickenpox or influenza
Chloramphenicol	Gray syndrome (neonates and infants)
Fluoroquinolones	Tendon rupture
Glucocorticoids	Growth suppression with prolonged use
Hexachlorophene	CNS toxicity (infants)
Nalidixic acid	Cartilage erosion
Phenothiazines	Sudden infant death syndrome
Sulfonamides	Kernicterus (neonates)
Tetracyclines	Staining of developing teeth

CNS = central nervous system.

10.3 ADVERSE DRUG REACTIONS

Like adults, pediatric patients are subject to adverse reactions when drug levels rise too high. In addition, pediatric patients are vulnerable to unique adverse effects related to organ system immaturity and to ongoing growth and development. Among these age-related effects are growth suppression (caused by glucocorticoids), discoloration of developing teeth (caused by tetracyclines), and kernicterus (caused by sulfonamides). [Table 10-3](#) presents a list of drugs that can cause unique

Pharmacology for Nursing Care, 7th Edition

adverse effects in pediatric patients of various ages. These drugs should be avoided in patients whose age puts them at risk.

10.4 DOSAGE DETERMINATION

Because of the pharmacokinetic factors discussed above, dosage selection for pediatric patients is difficult. Selecting a dosage is especially difficult in the very young, since pharmacokinetic factors are undergoing rapid change.

94

Pediatric doses have been established for a few drugs but not for most. For drugs that do not have an established pediatric dose, dosage can be extrapolated from adult doses. The method of conversion employed most commonly is based on body surface area:

95

Approximate child's dose = $\frac{\text{Body surface area of the child} \times \text{Adults dose}}{1.73 \text{ m}^2}$ Please note that initial

pediatric doses—whether based on established pediatric doses or extrapolated from adult doses—are at best an *approximation*. Subsequent doses must be adjusted on the basis of clinical outcome and plasma drug concentrations. These adjustments are especially important in neonates and younger infants. Clearly, if dosage adjustments are to be optimal, it is essential that we monitor the patient for therapeutic and adverse responses.

10.5 PROMOTING ADHERENCE

Achieving accurate and timely dosing requires informed participation of the child's parents or guardian and, to the extent possible, active involvement of the child. Effective education is critical. The following issues should be addressed:

- Dosage size and timing
- Route and technique of administration
- Duration of treatment
- Drug storage
- The nature and time course of desired responses
- The nature and time course of adverse responses

Written instructions should be provided. For techniques of administration that are difficult, a demonstration should be made, after which the parents should repeat the procedure to ensure they understand. With young children, spills and spitting out are common causes of inaccurate dosing; parents should be taught to estimate the amount of drug lost and to re-administer that amount, being

careful not to overcompensate. When more than one person is helping medicate a child, all participants should be warned against multiple dosing. Multiple dosing can be avoided by maintaining a drug administration chart. With some disorders—especially infections—symptoms may resolve before the prescribed course of treatment has been completed. Parents should be instructed to complete the full course nonetheless. Additional ways to promote adherence include (1) selecting the most convenient dosage form and dosing schedule, (2) suggesting mixing oral drugs with food or juice (when allowed) to improve palatability, (3) providing a calibrated medicine spoon or syringe for measuring liquid formulations, and (4) taking extra time with young or disadvantaged parents to help ensure conscientious and skilled participation.

10.5.1

KEY POINTS

- The majority of drugs used in pediatrics have never been tested in children. As a result, we lack reliable information on which to base drug selection or dosage.
- Because of organ system immaturity, very young patients are highly sensitive to drugs.
- In neonates and young infants, drug responses may be unusually intense and prolonged.
- Absorption of IM drugs in *neonates* is slower than in adults. In contrast, absorption of IM drugs in *infants* is more rapid than in adults.
- Protein-binding capacity is limited early in life. Hence, free concentrations of some drugs may be especially high.
- The blood-brain barrier is not fully developed at birth. Hence, neonates are especially sensitive to drugs that affect the CNS.
- The drug-metabolizing capacity of neonates is low. Hence, neonates are especially sensitive to drugs that are eliminated primarily by hepatic metabolism.
- Renal excretion of drugs is low in neonates. Hence, drugs that are eliminated primarily by the kidney must be given in reduced dosage.
- In children 1 year and older, most pharmacokinetic parameters are similar to those in adults. Hence, drug sensitivity is more like that of adults than the very young.
- Children (1 to 12 years) differ pharmacokinetically from adults in that children metabolize drugs faster.

- Initial pediatric doses are at best an approximation. Hence, subsequent doses must be adjusted on the basis of clinical outcome and plasma drug levels.

¹¹CHAPTER 11 Drug Therapy in Geriatric Patients

Drug use among the elderly is disproportionately high. Whereas the elderly (those 65 years and older) constitute only 12% of the U.S. population, they consume 31% of the nation's prescribed drugs. Reasons for this intensive use of drugs include increased severity of illness, multiple pathologies, and excessive prescribing.

Drug therapy in the elderly represents a special therapeutic challenge. As a rule, older patients are more sensitive to drugs than younger adults, and they show wider individual variation. In addition, the elderly experience more adverse drug reactions and drug-drug interactions. The principal factors underlying these complications are (1) altered pharmacokinetics (secondary to organ system degeneration), (2) multiple and severe illnesses, (3) multiple-drug therapy, and (4) poor adherence. To help ensure that drug therapy is as safe and effective as possible, *individualization of treatment is essential: Each patient must be monitored for desired and adverse responses, and the regimen must be adjusted accordingly*. Because the elderly typically suffer from chronic illnesses, the usual objective is to reduce symptoms and improve quality of life, since cure is generally impossible.

^{11.1} PHARMACOKINETIC CHANGES IN THE ELDERLY

The aging process can affect all phases of pharmacokinetics. From early adulthood on, there is a gradual, progressive decline in organ function. This decline can alter the absorption, distribution, metabolism, and excretion of drugs. As a rule, these pharmacokinetic changes increase drug sensitivity (largely from reduced hepatic and renal drug elimination). It should be noted, however, that the extent of change varies greatly among patients: Pharmacokinetic changes may be minimal in patients who have remained physically fit, whereas they may be dramatic in patients who have aged less fortunately. Accordingly, you should keep in mind that age-related changes in pharmacokinetics are not only a potential source of increased sensitivity to drugs, they are also a potential source of increased variability. The physiologic changes that underlie alterations in pharmacokinetics are summarized in [Table 11-1](#).

^{11.1.1} Absorption

Altered GI absorption is not a major factor in drug sensitivity in the elderly. As a rule, the *percentage* of an oral dose that becomes absorbed does not change with age. However, the *rate* of absorption may be slowed (because of delayed gastric emptying and reduced splanchnic blood flow). As a result, drug responses may be somewhat delayed. Gastric acidity is reduced in the elderly and may alter the absorption of certain drugs. Some drug formulations, for example, require high acidity to dissolve, and hence their absorption may be decreased.

11.1.2 Distribution

Four major factors can alter drug distribution in the elderly: (1) increased percent body fat, (2) decreased percent lean body mass, (3) decreased total body water, and (4) reduced concentration of serum albumin. The increase in body fat seen in the elderly provides a storage depot for *lipid-soluble* drugs (eg, thiopental). As a result, plasma levels of these drugs are reduced, causing a reduction in responses. Because of the decline in lean body mass and total body water, *water-soluble* drugs (eg, ethanol) become distributed in a smaller volume than in younger adults. As a result, the concentration of these drugs is increased, causing effects to be more intense. Although albumin levels are only slightly reduced in healthy adults, these levels can be significantly reduced in adults who are malnourished. Because of reduced albumin levels, protein binding of drugs decreases, causing levels of free drug to rise. As a result, drug effects may be more intense.

11.1.3 Metabolism

Rates of hepatic drug metabolism tend to decline with age. Principal factors underlying the decline are reduced hepatic blood flow, reduced liver mass, and decreased activity of some hepatic enzymes. Because liver function is diminished, the half-lives of certain drugs may be increased, thereby prolonging responses. Responses to oral drugs that ordinarily undergo extensive first-pass metabolism may be enhanced. It must be noted, however, that the degree of decline in drug metabolism varies greatly among individuals. As a result, we cannot predict whether drug responses will be significantly reduced in any particular patient.

11.1.4 Excretion

Renal drug function, and hence drug excretion, undergoes progressive decline beginning in early adulthood. *Drug accumulation secondary to reduced renal excretion is the most important cause of adverse drug reactions in the elderly.* The decline in renal function is the result of reductions in renal blood flow, glomerular filtration rate, active tubular secretion, and number of nephrons. Coexistence of renal pathology can further compromise kidney function. The degree of decline in renal function varies greatly among individuals. Accordingly, when patients are taking drugs that are eliminated primarily by the kidneys, renal function should be assessed. In the elderly, the proper index of renal function is *creatinine clearance*, not *serum creatinine levels*. Creatinine levels do not reflect kidney function in the elderly because the source of serum creatinine—lean muscle mass—declines in parallel with the decline in kidney function. As a result, creatinine levels may be normal even though renal function is greatly reduced.

96

97

TABLE 11-1 Physiologic Changes That Can Affect Pharmacokinetics in the Elderly

Absorption of Drugs
Increased gastric pH
Decreased absorptive surface area
Decreased splanchnic blood flow
Decreased GI motility
Delayed gastric emptying
Distribution of Drugs
Increased body fat
Decreased lean body mass
Decreased total body water
Decreased serum albumin
Decreased cardiac output
Metabolism of Drugs
Decreased hepatic blood flow
Decreased hepatic mass
Decreased activity of hepatic enzymes
Excretion of Drugs
Decreased renal blood flow
Decreased glomerular filtration rate
Decreased tubular secretion
Decreased number of nephrons

^{11.2} PHARMACODYNAMIC CHANGES IN THE ELDERLY

Alterations in receptor properties may underlie altered sensitivity to some drugs. However, information on such pharmacodynamic changes is limited. In support of the possibility of altered pharmacodynamics is the observation that beta-adrenergic blocking agents (drugs used primarily for cardiac disorders) are *less* effective in the elderly than in younger adults, even when present in the

same concentrations. Possible explanations for this observation include (1) a reduction in the number of beta receptors and (2) a reduction in the affinity of beta receptors for beta-receptor blocking agents. Other drugs (warfarin, certain central nervous system depressants) produce effects that are more intense in the elderly, suggesting a possible increase in receptor number, receptor affinity, or both. Unfortunately, our knowledge of pharmacodynamic changes in the elderly is restricted to a few families of drugs.

11.3 ADVERSE DRUG REACTIONS AND DRUG INTERACTIONS

Adverse drug reactions (ADRs) are 7 times more common in the elderly than in younger adults, accounting for about 16% of hospital admissions among older individuals and 50% of all medication-related deaths. The vast majority of these reactions are dose related, not idiosyncratic. Symptoms in the elderly are often nonspecific (eg, dizziness, cognitive impairment), making identification of ADRs difficult.

Perhaps surprisingly, the increase in ADRs seen in the elderly is not the direct result of aging per se. Rather, multiple factors predispose older patients to ADRs. The most important are:

- Drug accumulation secondary to reduced renal function
- Polypharmacy (treatment with multiple drugs)
- Greater severity of illness
- The presence of multiple pathologies
- Greater use of drugs that have a low therapeutic index (eg, digoxin, a drug for heart failure)
- Increased individual variation secondary to altered pharmacokinetics
- Inadequate supervision of long-term therapy
- Poor patient adherence

The majority of ADRs in the elderly are avoidable. Measures that can reduce their incidence include:

- Taking a thorough drug history, including over-the-counter medications
- Accounting for the pharmacokinetic and pharmacodynamic changes that occur with aging
- Initiating therapy with low doses
- Monitoring clinical responses and plasma drug levels to provide a rational basis for dosage adjustment

- Employing the simplest regimen possible
- Monitoring for drug-drug interactions and iatrogenic illness
- Periodically reviewing the need for continued drug therapy, and discontinuing medications as appropriate
- Encouraging the patient to dispose of old medications
- Taking steps to promote adherence (see below)
- Avoiding drugs on the Beers list (see below)

The *Beers list* identifies drugs with a high likelihood of causing adverse effects in the elderly. Accordingly, drugs on this list should generally be avoided. A partial listing of these drugs appears in [Table 11-2](#). The full list, updated in 2003, is available online at <http://archinte.ama-assn.org/cgi/reprint/163/22/2716>.

11.4 PROMOTING ADHERENCE

As many as 40% or more of elderly patients fail to take their medicines as prescribed. Some patients never fill their prescriptions, some fail to refill their prescriptions, and some don't follow the prescribed dosing schedule. Nonadherence can result in therapeutic failure (from underdosing or erratic dosing) or toxicity (from overdosing). Of the two possibilities, underdosing with resulting therapeutic failure is by far (90%) the more common.

97

TABLE 11-2 Some Drugs to Generally Avoid in the Elderly

Drugs	Reason for Concern	Alternative Treatments
Analgesics		
Ketorolac [Toradol]	GI bleeding	Mild pain: acetaminophen, ibuprofen
Meperidine [Demerol]	Not effective at usual doses, confusion	Moderate to severe pain: morphine, oxycodone
Propoxyphene [Darvon]	No better than acetaminophen, but has the ADRs of opioids	
Antidepressants		
Amitriptyline [Elavil]	Anticholinergic effects (constipation, urinary retention, blurred vision)	SSRIs (other than daily fluoxetine) or other antidepressants
Doxepin [Sinequan]		
Fluoxetine [Prozac], taken daily	Long half-life; agitation, insomnia, anorexia	SSRI with a shorter half-life (eg, sertraline [Zoloft])
Antihistamines, First Generation		
Chlorpheniramine [Chlor-Trimeton, others]	Anticholinergic effects (constipation, urinary retention, blurred vision)	Second-generation antihistamines, such as cetirizine [Zyrtec], fexofenadine [Allegra], or loratadine [Claritin]
Diphenhydramine [Benadryl, others]		
Hydroxyzine [Vistaril]		
Promethazine [Phenergan, others]		
Antihypertensives		
Alpha-adrenergic blocking agents	Hypotension, dry mouth, incontinence	Thiazide diuretic, ACE inhibitor, beta-adrenergic blocker, calcium channel blocker
Doxazosin [Cardura]		
Prazosin [Minipress]		
Terazosin [Hytrin]		
Clonidine [Catapres]	Orthostatic hypotension, adverse CNS effects	
Guanethidine	Orthostatic hypotension, depression	
Methyldopa [Aldomet]		
Reserpine	Bradycardia, depression	
	Depression, impotence, sedation, orthostatic hypotension	
Sedative-Hypnotics		

Pharmacology for Nursing Care, 7th Edition

Barbiturates	Physical dependence; compared with other hypnotics, higher risk of falls, confusion, cognitive impairment	Temazepam [Restoril], zolpidem [Ambien], zaleplon [Sonata], ramelteon [Rozerem], eszopiclone [Lunesta]
Benzodiazepines, long acting	Prolonged sedation	A short-acting benzodiazepine (eg, lorazepam [Ativan]) given in low dosage)
Chlordiazepoxide [Librium]		
Diazepam [Valium, others]		
Flurazepam [Dalmane]		
Drugs for Urge Incontinence		
Oxybutynin [Ditropan]	Urinary retention, confusion, hallucinations, sedation	Behavioral therapy (eg, bladder retraining, urge suppression)
Tolterodine [Detrol]		
Muscle Relaxants		
Carisoprodol [Soma]	Anticholinergic effects, sedation, cognitive impairment; may not be effective at tolerable dosage	For spasticity, use an antispasmodic (eg, baclofen [Lioresal]) or nerve block
Cyclobenzaprine [Flexeril, others]		
Metaxalone [Skelaxin]		
Methocarbamol [Robaxin]		
Adapted from Fick DM, Cooper JW, Wade WE, et al: Updating the Beers criteria for potentially inappropriate medication use in older adults. Arch Intern Med 163:2716–2724, 2003. (Note: The paper by Fick et al. lists many drugs in addition to those in this table.)		
ACE = angiotensin-converting enzyme, ADR = adverse drug reaction, CNS = central nervous system, GI = gastrointestinal, SSRI = selective serotonin reuptake inhibitor.		

Multiple factors underlie nonadherence to the prescribed regimen ([Table 11-3](#)). Among these are forgetfulness; failure to comprehend instructions (because of intellectual, visual, or auditory impairment); inability to pay for medications; and use of complex regimens (several drugs taken several times a day). All of these factors can contribute to *unintentional* nonadherence. However, in the majority of cases (about 75%), nonadherence among the elderly is *intentional*. The principal reason given for intentional nonadherence is the patient's conviction that the drug was simply not needed in the dosage prescribed. Unpleasant side effects and expense also contribute to intentional nonadherence.

Several measures can promote adherence, including:

- Simplifying the regimen so that the number of drugs and doses per day is as small as possible
- Explaining the treatment plan using clear, concise verbal and written instructions

- Choosing an appropriate dosage form (eg, a liquid formulation if the patient has difficulty swallowing)

98

TABLE 11-3 Factors That Contribute to Poor Adherence in the Elderly

99

Multiple chronic disorders
Multiple prescription medications
Multiple doses/day for each medication
Multiple prescribers
Changes in the regimen (addition of drugs, changes in dosage size or timing)
Cognitive or physical impairment (reduction in memory, hearing, visual acuity, color discrimination, or manual dexterity)
Living alone
Recent discharge from hospital
Low literacy
Inability to pay for drugs
Personal conviction that a drug is unnecessary or the dosage too high
Presence of side effects

- Labeling drug containers clearly, and avoiding containers that are difficult to open by patients with impaired dexterity (eg, those with arthritis)
- Suggesting the use of a calendar, diary, or pill counter to record drug administration
- Asking the patient if he or she has access to a pharmacy and can afford the medication
- Enlisting the aid of a friend, relative, or visiting healthcare professional
- Monitoring for therapeutic responses, adverse reactions, and plasma drug levels

It must be noted, however, that the benefits of these measures will be restricted primarily to patients whose nonadherence is *unintentional*. Unfortunately, these measures are generally inapplicable to the patient whose nonadherence is *intentional*. For these patients, intensive education may help.

11.4.1

KEY POINTS

- Older patients are generally more sensitive to drugs than are younger adults, and they show wider individual variation.
- Individualization of therapy for the elderly is essential: Each patient must be monitored for desired and adverse responses, and the regimen must be adjusted accordingly.
- Aging-related organ decline can change drug absorption, distribution, metabolism, and (especially) excretion.
- The *rate* of drug absorption may be slowed in the elderly, although the *extent* of absorption is usually unchanged.
- Plasma concentrations of lipid-soluble drugs may be low in the elderly, and concentrations of water-soluble drugs may be high.
- Reduced liver function may prolong drug effects.
- Reduced renal function, with resultant drug accumulation, is the most important cause of adverse drug reactions in the elderly.
- Because the degree of renal impairment among the elderly varies, creatinine clearance (a test of renal function) should be determined for all patients taking drugs that are eliminated primarily by the kidneys.
- Adverse drug reactions are much more common in the elderly than in younger adults.
- Factors underlying the increase in adverse reactions include polypharmacy, severe illness, multiple pathologies, and treatment with dangerous drugs.
- Nonadherence is common among the elderly.
- Reasons for *unintentional* nonadherence include forgetfulness, side effects, low income, complex regimens, and failure to comprehend instructions.
- Most cases (75%) of nonadherence among the elderly are *intentional*. Reasons include expense, side effects, and the patient's conviction that the drug is unnecessary or the dosage too high.

¹²CHAPTER 12 Basic Principles of Neuropharmacology

Neuropharmacology can be defined as *the study of drugs that alter processes controlled by the nervous system*. Neuropharmacologic drugs produce effects equivalent to those produced by excitation or suppression of neuronal activity. Neuropharmacologic agents can be divided into two broad categories: (1) peripheral nervous system drugs and (2) central nervous system (CNS) drugs.

The neuropharmacologic drugs constitute a large and important family of therapeutic agents. These drugs are used to treat conditions ranging from depression to epilepsy to hypertension to asthma. The clinical significance of these agents is reflected in the fact that over 25% of this text is dedicated to them.

Why do we have so many neuropharmacologic drugs? The answer lies in a concept discussed in [Chapter 5](#): Most therapeutic agents act by helping the body help itself. That is, most drugs produce their therapeutic effects by coaxing the body to perform normal processes in a fashion that benefits the patient. Since the nervous system participates in the regulation of practically all bodily processes, practically all bodily processes can be influenced by drugs that alter neuronal regulation. By mimicking or blocking neuronal regulation, neuropharmacologic drugs can modify such diverse processes as skeletal muscle contraction, cardiac output, vascular tone, respiration, GI function, uterine motility, glandular secretion, and functions unique to the CNS, such as ideation, mood, and perception of pain. Given the broad spectrum of processes that neuropharmacologic drugs can alter, and given the potential benefits to be gained by manipulating those processes, it should be no surprise that neuropharmacologic drugs have widespread clinical applications.

We begin our study of neuropharmacology by discussing peripheral nervous system drugs ([Chapter 14](#) through [19](#)), after which we discuss CNS drugs ([Chapters 20](#) through [39](#)). The principal rationale for this order of presentation is that our understanding of peripheral nervous system pharmacology is much clearer than our understanding of CNS pharmacology. Why? Because the peripheral nervous system is much less complex than the CNS, and also more accessible to experimentation. By placing our initial focus on the peripheral nervous system, we can establish a firm knowledge base in neuropharmacology before proceeding to the less definitive and vastly more complex realm of CNS pharmacology.

^{12.1}HOW NEURONS REGULATE PHYSIOLOGIC PROCESSES

As a rule, if we want to understand the effects of a drug on a particular physiologic process, we must first understand the process itself. Accordingly, if we wish to understand the impact of drugs on

neuronal regulation of bodily function, we must first understand how neurons regulate bodily function when drugs are absent.

[Figure 12-1](#) illustrates the basic process by which neurons elicit responses from other cells. The figure depicts two cells: a neuron and a postsynaptic cell. The postsynaptic cell might be another neuron, a muscle cell, or a cell within a secretory gland. As indicated, there are two basic steps—*axonal conduction* and *synaptic transmission*—in the process by which the neuron influences the behavior of the postsynaptic cell. Axonal conduction is simply the process of conducting an action potential down the axon of the neuron. Synaptic transmission is the process by which information is carried across the gap between the neuron and the postsynaptic cell. As shown in the figure, synaptic transmission requires the release of neurotransmitter molecules from the axon terminal followed by binding of these molecules to receptors on the postsynaptic cell. As a result of transmitter-receptor binding, a series of events is initiated in the postsynaptic cell, leading to a change in its behavior. The precise nature of the change depends on the identity of the neurotransmitter and the type of cell involved. If the postsynaptic cell is another neuron, it may increase or decrease its firing rate; if the cell is part of a

Figure 12-1 How neurons regulate other cells. There are two basic steps in the process by which neurons elicit responses from other cells: (1) axonal conduction and (2) synaptic transmission. (T = neurotransmitter.)

muscle, it may contract or relax; and if the cell is glandular, it may increase or decrease secretion.

^{12.2} BASIC MECHANISMS BY WHICH NEUROPHARMACOLOGIC AGENTS ACT

^{12.2.1} Sites of Action: Axons Versus Synapses

In order to influence a process under neuronal control, a drug can alter one of two basic neuronal activities: axonal conduction or synaptic transmission. *Most neuropharmacologic agents act by altering synaptic transmission.* Only a few alter axonal conduction. Why do drugs usually target synaptic transmission? Because drugs that alter synaptic transmission can produce effects that are much more *selective* than those produced by drugs that alter axonal conduction.

^{12.2.1.1} Axonal Conduction

Drugs that act by altering axonal conduction are not very selective. Recall that the process of conducting an impulse along an axon is essentially the same in all neurons. As a consequence, a drug that alters axonal conduction will affect conduction in all nerves to which it has access. Such a drug cannot produce selective effects.

Local anesthetics are the only drugs proved to work by altering (decreasing) axonal conduction. Because these agents produce nonselective inhibition of axonal conduction, they suppress transmission in any nerve they reach. Hence, although local anesthetics are certainly valuable, their indications are limited.

^{12.2.1.2} Synaptic Transmission

In contrast to drugs that alter axonal conduction, drugs that alter synaptic transmission can produce effects that are highly selective. Why? Because synapses, unlike axons, differ from one another. Synapses at different sites employ different transmitters. In addition, for most transmitters, the body employs more than one type of receptor. Hence, by using a drug that selectively influences a specific type of neurotransmitter or receptor, we can alter one neuronally regulated process while leaving most others unchanged. Because of their relative selectivity, drugs that alter synaptic transmission have many uses.

^{12.2.1.3} Receptors

The ability of a neuron to influence the behavior of another cell depends, ultimately, upon the ability of that neuron to alter receptor activity on the target cell. As discussed, neurons alter receptor activity by releasing transmitter molecules, which diffuse across the synaptic gap and bind to receptors on the postsynaptic cell. If the target cell lacked receptors for the transmitter that a neuron released, that neuron would be unable to affect the target cell.

The effects of neuropharmacologic drugs, like those of neurons, depend on altering receptor activity. That is, no matter what its precise mechanism of action, a neuropharmacologic drug ultimately works by influencing receptor activity on target cells. This commonsense concept is central to understanding the actions of neuropharmacologic drugs. In fact, this concept is so critical to our understanding of neuropharmacologic agents that I will repeat it: *The impact of a drug on a neuronally regulated process is dependent on the ability of that drug to directly or indirectly influence receptor activity on target cells.*

12.2.2 Steps in Synaptic Transmission

To understand how drugs alter receptor activity, we must first understand the steps by which synaptic transmission takes place, since it is by modifying these steps that neuropharmacologic drugs influence receptor function. The steps in synaptic transmission are summarized in [Figure 12-2](#).

12.2.2.1 Step 1: Transmitter Synthesis.

For synaptic transmission to take place, molecules of transmitter must be present in the nerve terminal. Hence, we can look upon transmitter synthesis as the first step in transmission. In the figure, the letters Q, R, and S represent the precursor molecules from which the transmitter (T) is made.

12.2.2.2 Step 2: Transmitter Storage.

Once transmitter is synthesized, it must be stored until the time of its release. Transmitter storage takes place within vesicles—tiny packets present in the axon terminal. Each nerve terminal contains a large number of transmitter-filled vesicles.

12.2.2.3 Step 3: Transmitter Release.

Release of transmitter is triggered by the arrival of an action potential at the axon terminal. The action potential initiates a process in which vesicles undergo fusion with the terminal membrane, causing release of their contents into the synaptic gap. Each action potential causes only a small fraction of all vesicles present in the axon terminal to discharge their contents.

Figure 12-2 **Steps in synaptic transmission.** *Step 1*, Synthesis of transmitter (T) from precursor molecules (Q, R, and S). *Step 2*, Storage of transmitter in vesicles. *Step 3*, Release of transmitter: In response to an action potential, vesicles fuse with the terminal membrane and discharge their contents into the synaptic gap. *Step 4*, Action at receptor: Transmitter binds (reversibly) to its receptor on the postsynaptic cell, causing a response in that cell. *Step 5*, Termination of transmission: Transmitter dissociates from its receptor and is then removed from the synaptic gap by (a) reuptake into the nerve terminal, (b) enzymatic degradation, or (c) diffusion away from the gap.

12.2.2.4 Step 4: Receptor Binding.

Following release, transmitter molecules diffuse across the synaptic gap and then undergo *reversible* binding to receptors on the postsynaptic cell. This binding initiates a cascade of events that result in altered behavior of the postsynaptic cell.

12.2.2.5 Step 5: Termination of Transmission.

Transmission is terminated by dissociation of transmitter from its receptors, followed by removal of free transmitter from the synaptic gap. Transmitter can be removed from the synaptic gap by three processes: (1) reuptake, (2) enzymatic degradation, and (3) diffusion. In those synapses where transmission is terminated by reuptake, axon terminals contain “pumps” that transport transmitter molecules back into the neuron from which they were released (Step 5a in [Fig. 12-2](#)). Following reuptake, molecules of transmitter may be degraded, or they may be packaged in vesicles for reuse. In synapses where transmitter is cleared by enzymatic degradation (Step 5b), the synapse contains large quantities of transmitter-inactivating enzymes. Although simple diffusion away from the synaptic gap (Step 5c) is a potential means of terminating transmitter action, this process is very slow and generally of little significance.

12.2.3 Effects of Drugs on the Steps of Synaptic Transmission

As emphatically noted, all neuropharmacologic agents (except local anesthetics) produce their effects by directly or indirectly altering receptor activity. We also noted that the way in which drugs alter receptor activity is by interfering with synaptic transmission. Because synaptic transmission has multiple steps, the process offers a number of potential targets for drugs. In this section, we examine the specific ways in which drugs can alter the steps of synaptic transmission. By way of encouragement, although this information may appear complex, it isn't. In fact, it's largely self-evident.

Before discussing specific mechanisms by which drugs can alter receptor activity, we need to understand what drugs are capable of doing to receptors in general terms. From the broadest perspective, when a drug influences receptor function, that drug can do just one of two things: it can enhance receptor activation or it can reduce receptor activation. What do we mean by receptor activation? For our purposes, we can define *activation* as *an effect on receptor function equivalent to that produced by the natural neurotransmitter at a particular synapse*. Hence, a drug whose effects mimic the effects of a natural transmitter would be said to *increase* receptor activation. Conversely, a drug whose effects were equivalent to reducing the amount of natural transmitter available for receptor binding would be said to *decrease* receptor activation.

Please note that activation of a receptor does not necessarily mean that a physiologic process will go faster; receptor activation can also make a process go slower. For example, a drug that mimics acetylcholine at receptors on the heart will cause the heart to beat more slowly. Since the effect of this drug on receptor function mimicked the effect of the natural neurotransmitter, we would say that the drug activated acetylcholine receptors, even though activation caused heart rate to decline.

Having defined receptor activation, we are ready to discuss the mechanisms by which drugs, acting on specific steps of synaptic transmission, can increase or decrease receptor activity. These mechanisms are summarized in [Table 12-1](#). As we consider these mechanisms one by one, their commonsense nature should become apparent.

TABLE 12-1 Effects of Drugs on Synaptic Transmission and the Resulting Impact on Receptor Activation

Step of Synaptic Transmission	Drug Action	Impact on Receptor Activation*
1. Synthesis of transmitter	Increased synthesis of T	Increase
	Decreased synthesis of T	Decrease
	Synthesis of “super” T	Increase
2. Storage of transmitter	Reduced storage of T	Decrease
3. Release of transmitter	Promotion of T release	Increase
	Inhibition of T release	Decrease
4. Binding to receptor	Direct receptor activation	Increase
	Enhanced response to T	Increase
	Blockade of T binding	Decrease
5. Termination of transmission	Blockade of T reuptake	Increase
	Inhibition of T breakdown	Increase
T = transmitter.		

* Receptor activation is defined as producing an effect equivalent to that produced by the natural transmitter that acts on a particular receptor.

12.2.3.1 Transmitter Synthesis.

There are three different effects that drugs are known to have on transmitter synthesis. They can (1) increase transmitter synthesis, (2) decrease transmitter synthesis, or (3) cause the synthesis of transmitter molecules that are more effective than the natural transmitter itself.

The impact of increased or decreased transmitter synthesis on receptor activity should be obvious. A drug that increases transmitter synthesis will cause receptor activation to increase. The process is this: As a result of increased transmitter synthesis, storage vesicles will contain transmitter in abnormally high amounts. Hence, when an action potential reaches the axon terminal, more transmitter will be released, and therefore more transmitter will be available to receptors on the postsynaptic cell, causing activation of those receptors to increase. Conversely, a drug that decreases transmitter synthesis will cause the transmitter content of vesicles to decline, resulting in reduced transmitter release and decreased receptor activation.

Some drugs can cause neurons to synthesize transmitter molecules whose structure is different from that of normal transmitter molecules. For example, by acting as substrates for enzymes in the axon terminal, drugs can be converted into “super” transmitters (molecules whose ability to activate receptors is greater than that of the naturally occurring transmitter at a particular site). Release of these supertransmitters will cause receptor activation to increase. In theory, it should be possible to cause the synthesis of *faulty* transmitter molecules (ie, molecules with a reduced ability to activate a particular receptor). However, we have no medicines that are known to act this way.

12.2.3.2 Transmitter Storage.

Drugs that interfere with transmitter storage will cause receptor activation to decrease. Why? Because disruption of storage depletes vesicles of their transmitter content, thereby decreasing the amount of transmitter available for release.

102

12.2.3.3 Transmitter Release.

103

Drugs can either *promote* or *inhibit* transmitter release. Drugs that promote release will increase receptor activation. Conversely, drugs that inhibit release will reduce receptor activation. The amphetamines (CNS stimulants) represent drugs that act by promoting transmitter release.

Botulinum toxin, in contrast, acts by inhibiting transmitter release.*

* Botulinum toxin blocks release of acetylcholine from the neurons that control skeletal muscles, including the muscles of respiration. The potential for disaster is obvious.

12.2.3.4 Receptor Binding.

Many drugs act directly at receptors. These agents can either (1) bind to receptors and cause activation, (2) bind to receptors and thereby block receptor activation by other agents, or (3)

bind to receptor components and thereby enhance receptor activation by the natural transmitter at the site.

In the terminology introduced in [Chapter 5](#), drugs that directly activate receptors are called *agonists*, whereas drugs that prevent receptor activation are called *antagonists*. We have no special name for drugs that bind to receptors and thereby enhance the effects of the natural transmitter. The direct-acting receptor agonists and antagonists constitute the largest and most important groups of neuropharmacologic drugs.

Examples of drugs that act directly at receptors are numerous. Drugs that bind to receptors and cause *activation* include morphine (used for its effects on the CNS), epinephrine (used mainly for its effects on the cardiovascular system), and insulin (used for its effects in diabetes). Drugs that bind to receptors and *prevent* their activation include naloxone (used to treat overdose with morphine-like drugs), antihistamines (used to treat allergic disorders), and propranolol (used to treat hypertension, angina pectoris, and cardiac dysrhythmias). The principal examples of drugs that bind to receptors and thereby enhance the actions of a natural transmitter are the benzodiazepines. Drugs in this family, which includes diazepam [Valium] and related agents, are used to treat anxiety, seizure disorders, and muscle spasm.

12.2.3.5 Termination of Transmitter Action.

Drugs can interfere with the termination of transmitter action by two mechanisms: (1) blockade of transmitter reuptake and (2) inhibition of transmitter degradation. Drugs that act by either mechanism will cause the concentration of transmitter in the synaptic gap to rise, thereby causing receptor activation to increase.

12.3 MULTIPLE RECEPTOR TYPES AND SELECTIVITY OF DRUG ACTION

As we discussed in [Chapter 1](#), selectivity is one of the most desirable qualities a drug can have. Why? Because a selective drug is able to alter a disease process while leaving other physiologic processes largely unaffected.

Many neuropharmacologic agents display a high degree of selectivity. This selectivity is possible because the nervous system works through multiple types of receptors to regulate processes under its control. If neurons had only one or two types of receptors through which to act, selective effects by neuropharmacologic drugs could not be achieved.

The relationship between multiple receptor types and selective drug action is illustrated by Mort and Merv, whose unique physiologies are depicted in [Figure 12-3](#). Let's begin with Mort. Mort can

perform four functions: he can pump blood, digest food, shake hands, and empty his bladder. As indicated in the figure, all four functions are under neuronal control, and, in all cases, that control is exerted by activation of the same type of receptor (designated A).

As long as Mort remains healthy, having only one type of receptor to regulate his various functions is no problem. Selective *physiologic* regulation can be achieved simply by sending impulses down the appropriate nerves. When there is a need to increase cardiac output, impulses are sent down the nerve to his heart; when digestion is needed, impulses are sent down the nerve to his stomach; and so forth.

Figure 12-3 Multiple drug receptors and selective drug action. **Mort**, All of Mort's organs are regulated through activation of type A receptors. Drugs that affect type A receptors on one organ will affect type A receptors on all other organs. Hence, selective drug action is impossible. **Merv**, Merv has four types of receptors (A, B, C, and D) to regulate his four organs. A drug that acts at one type of receptor will not affect the others. Hence, selective drug action is possible.

Although having only one receptor type is no disadvantage when all is well, if Mort gets sick, having only one receptor type creates a therapeutic problem. Let's assume he develops heart disease and we need to give a drug that will help increase cardiac output. To stimulate cardiac function, we need to administer a drug that will activate receptors on his heart. Unfortunately, since the receptors on his heart are the same as the receptors on his other organs, a drug that stimulates cardiac function will stimulate his other organs too. Consequently, any attempt to improve cardiac output with drugs will necessarily be accompanied by side effects. These will range from silly (compulsive handshaking) to embarrassing (enuresis) to hazardous (gastric ulcers). Such side effects are not likely to elicit either gratitude or adherence. Please note that all of these undesirable effects are the direct result of Mort having a nervous system that works through just one type of receptor to regulate all organs. That is, the presence of only one receptor type has made selective drug action impossible.

Now let's consider Merv. Although Merv appears to be Mort's twin, Merv differs in one important way: Whereas all functions in Mort are regulated through just one type of receptor, Merv employs different receptors to control each of his four functions. Because of this simple but important difference, the selective drug action that was impossible with Mort can be achieved easily with Merv. We can, for example, selectively enhance cardiac function in Merv without risking the side effects to which Mort was predisposed. This can be done simply by administering an agonist agent that binds selectively to receptors on the heart (type A receptors). If this medication is sufficiently selective for type A receptors, it will not interact with receptor types B, C, or D. Hence, function in structures regulated by those receptors will be unaffected. Note that our ability to produce selective drug action in Merv is made possible because his nervous system works through different types of receptors to regulate function in his various organs. The message from this example is clear: *The more types of receptors we have to work with, the greater our chances of producing selective drug effects.*

^{12.4} AN APPROACH TO LEARNING ABOUT PERIPHERAL NERVOUS SYSTEM DRUGS

As discussed, to understand the ways in which drugs can alter a process under neuronal control, we must first understand how the nervous system itself regulates that process. Accordingly, when preparing to study peripheral nervous system pharmacology, you must first establish a working knowledge of the peripheral nervous system itself. In particular, you need to know two basic types of information about peripheral nervous system function. First, you need to know the types of receptors through which the peripheral nervous system works when influencing the function of a specific organ. Second, you need to know what the normal response to activation of those receptors

is. All of the information you need about peripheral nervous system function is reviewed in [Chapter 13](#).

Once you understand the peripheral nervous system itself, you can go on to learn about peripheral nervous system drugs. Although learning about these drugs will require significant effort, the learning process itself is straightforward. To understand any particular peripheral nervous system drug, you need three types of information: (1) the type (or types) of receptor through which the drug acts; (2) the normal response to activation of those receptors; and (3) what the drug in question does to receptor function (ie, does it increase or decrease receptor activation?). Armed with these three types of information, you can predict the major effects of any peripheral nervous system drug.

An example will illustrate this process. Let's consider a drug named *isoproterenol*. The first information we need is the identity of the receptors at which isoproterenol acts. Isoproterenol acts at two types of receptors, named β_1 and β_2 . Next, we need to know the normal responses to activation of these receptors. The most prominent responses to activation of β_1 receptors are *increased heart rate* and *increased force of cardiac contraction*. The primary responses to activation of β_2 receptors are *bronchial dilation* and *elevation of glucose levels in blood*. Lastly, we need to know whether isoproterenol increases or decreases the activation of β_1 and β_2 receptors. At both types of receptor, isoproterenol causes *activation*. Armed with these three primary pieces of information about isoproterenol, we can now predict the principal effects of this drug. By *activating* β_1 and β_2 receptors, isoproterenol can elicit three major responses: (1) increased cardiac output (by increasing heart rate and force of contraction); (2) dilation of the bronchi; and (3) elevation of blood glucose. Depending on the patient to whom this drug is given, these responses may be beneficial or detrimental.

From this example, you can see how easy it is to predict the effects of a peripheral nervous system drug. Accordingly, I strongly encourage you to take the approach suggested when studying these agents. That is, for each peripheral nervous system drug, you should learn (1) the identity of the receptors at which that drug acts, (2) the normal responses to activation of those receptors, and (3) whether the drug increases or decreases receptor activation.

12.4.1

KEY POINTS

- Except for local anesthetics, which suppress axonal conduction, all neuropharmacologic drugs act by altering synaptic transmission.
- Synaptic transmission consists of five basic steps: transmitter synthesis, transmitter storage, transmitter release, binding of transmitter to its receptors, and termination of

transmitter action by dissociation of transmitter from the receptor followed by transmitter reuptake or degradation.

- Ultimately, the impact of a drug on a neuronally regulated process depends on the drug's ability to directly or indirectly alter receptor activity on target cells.
- Drugs can do one of two things to receptor function: they can increase receptor activation or they can decrease receptor activation.
- Drugs that increase transmitter synthesis increase receptor activation.
- Drugs that decrease transmitter synthesis decrease receptor activation.

104

- Drugs that promote synthesis of “super” transmitters increase receptor activation.
- Drugs that impede transmitter storage decrease receptor activation.
- Drugs that promote transmitter release increase receptor activation.
- Drugs that suppress transmitter release decrease receptor activation.
- Agonist drugs increase receptor activation.
- Antagonist drugs decrease receptor activation.
- Drugs that bind to receptors and enhance the actions of the natural transmitter at the receptor increase receptor activation.
- Drugs that block transmitter reuptake increase receptor activation.
- Drugs that inhibit transmitter degradation increase receptor activation.
- The presence of multiple receptor types increases our ability to produce selective drug effects.
- For each peripheral nervous system drug that you study, you should learn the identity of the receptors at which the drug acts, the normal responses to activation of those receptors, and whether the drug increases or decreases receptor activation.

105

¹³CHAPTER 13 Physiology of the Peripheral Nervous System

To understand peripheral nervous system drugs, we must first understand the peripheral nervous system itself. The purpose of this chapter is to help you develop that understanding.

It's not uncommon for students to be at least slightly apprehensive about studying the peripheral nervous system—especially the autonomic component. In fact, it's not uncommon for students who have studied this subject before to be thoroughly convinced that they will never, ever really understand it. This reaction is unfortunate in that, although there is a lot to know about the peripheral nervous system, the information is not terribly difficult. In this chapter, I take a nontraditional approach to teaching the material. Hopefully, this approach will facilitate your learning.

Since our ultimate goal concerns pharmacology—and not physiology—I do not address everything there is to know about the peripheral nervous system. Rather, I limit the discussion to those aspects of peripheral nervous system physiology that have a direct bearing on your ability to understand drugs.

^{13.1} DIVISIONS OF THE NERVOUS SYSTEM

The nervous system has two main divisions, the *central nervous system* and the *peripheral nervous system*. The central nervous system is subdivided into the brain and spinal cord.

The peripheral nervous system has two major subdivisions: (1) the *somatic motor system* and (2) the *autonomic nervous system*. The autonomic nervous system is further subdivided into the *parasympathetic nervous system* and the *sympathetic nervous system*. The somatic motor system controls voluntary movement of muscles. The two subdivisions of the autonomic nervous system regulate many “involuntary” processes.

The autonomic nervous system is the principal focus of this chapter. The somatic motor system is also considered, but discussion is brief.

^{13.2} OVERVIEW OF AUTONOMIC NERVOUS SYSTEM FUNCTIONS

The autonomic nervous system has three principal functions: (1) regulation of the *heart*; (2) regulation of *secretory glands* (salivary, gastric, sweat, and bronchial glands); and (3) regulation of *smooth muscles* (muscles of the bronchi, blood vessels, urogenital system, and GI tract). These regulatory activities are shared between the sympathetic and parasympathetic divisions of the autonomic nervous system.

13.2.1 Functions of the Parasympathetic Nervous System

The parasympathetic nervous system performs seven regulatory functions that have particular relevance to drugs. Specifically, stimulation of appropriate parasympathetic nerves causes

- Slowing of heart rate
- Increased gastric secretion
- Emptying of the bladder
- Emptying of the bowel
- Focusing the eye for near vision
- Constricting the pupil
- Contracting bronchial smooth muscle

Just how the parasympathetic nervous system elicits these responses is discussed later under *Functions of Cholinergic Receptor Subtypes*.

From the above we can see that the parasympathetic nervous system is concerned primarily with what might be called the “housekeeping” chores of the body (digestion of food and excretion of wastes). In addition, the system helps control vision and conserve energy (by reducing cardiac work).

106

107

Therapeutic agents that alter parasympathetic nervous system function are used primarily for their effects on the GI tract, bladder, and eye. Occasionally, these drugs are also used for effects on the heart and lungs.

A variety of poisons act by mimicking or blocking effects of parasympathetic stimulation. Among these are insecticides, nerve gases, and toxic compounds found in certain mushrooms and plants.

13.2.2 Functions of the Sympathetic Nervous System

The sympathetic nervous system has three main functions:

- Regulating the cardiovascular system
- Regulating body temperature

- Implementing the “fight-or-flight” reaction

The sympathetic nervous system exerts multiple influences on the heart and blood vessels. Stimulation of sympathetic nerves to the heart increases cardiac output. Stimulation of sympathetic nerves to arterioles and veins causes vasoconstriction. Release of epinephrine from the adrenal medulla results in vasoconstriction in most vascular beds and vasodilation in certain others. By influencing the heart and blood vessels, the sympathetic nervous system can achieve three homeostatic objectives:

- Maintenance of blood flow to the brain
- Redistribution of blood flow during exercise
- Compensation for loss of blood, primarily by causing vasoconstriction

The sympathetic nervous system helps regulate body temperature in three ways: (1) By regulating blood flow to the skin, sympathetic nerves can increase or decrease heat loss. By *dilating* surface vessels, sympathetic nerves increase blood flow to the skin and thereby accelerate heat loss. Conversely, *constricting* cutaneous vessels conserves heat. (2) Sympathetic nerves to sweat glands promote secretion of sweat, thereby helping the body cool. (3) By inducing piloerection (erection of hair), sympathetic nerves can promote heat conservation.

When we are faced with adversity, the sympathetic nervous system orchestrates the fight-or-flight response, which consists of

- Increasing heart rate and blood pressure
- Shunting blood away from the skin and viscera and into skeletal muscles
- Dilating the bronchi to improve oxygenation
- Dilating the pupils (perhaps to enhance visual acuity)
- Mobilizing stored energy, thereby providing glucose for the brain and fatty acids for muscles

The sensation of being “cold with fear” is brought on by shunting of blood away from the skin. The phrase “wide-eyed with fear” may be based on pupillary dilation.

Many therapeutic agents produce their effects by altering functions under sympathetic control. These drugs are used primarily for effects on the heart, blood vessels, and lungs. Agents that alter

cardiovascular function are used to treat hypertension, heart failure, angina pectoris, and other disorders. Drugs affecting the lungs are used primarily for asthma.

13.3 BASIC MECHANISMS BY WHICH THE AUTONOMIC NERVOUS SYSTEM REGULATES PHYSIOLOGIC PROCESSES

To understand how drugs influence processes under autonomic control, we must first understand how the autonomic nervous system itself regulates those activities. The basic mechanisms by which the autonomic nervous system regulates physiologic processes are discussed below.

13.3.1 Patterns of Innervation and Control

Most structures under autonomic control are innervated by sympathetic nerves *and* parasympathetic nerves. The relative influence of sympathetic and parasympathetic nerves depends on the organ under consideration.

In many organs that receive dual innervation, the influence of sympathetic nerves *opposes* that of parasympathetic nerves. For example, in the heart, *sympathetic* nerves *increase* heart rate, whereas *parasympathetic* nerves *slow* heart rate ([Fig. 13-1](#)).

In some organs that receive nerves from both divisions of the autonomic nervous system, the effects of sympathetic and parasympathetic nerves are *complementary*, rather than opposite. For example, in the male reproductive system, erection is regulated by parasympathetic nerves while ejaculation is controlled by sympathetic nerves. If attempts at reproduction are to succeed, cooperative interaction of both systems is needed.

A few structures under autonomic control receive innervation from only one division. The principal example is blood vessels, which are innervated exclusively by sympathetic nerves.

In summary, there are three basic patterns of autonomic innervation and regulation:

- Innervation by *both* divisions of the autonomic nervous system in which the effects of the two divisions are *opposed*
- Innervation by *both* divisions of the autonomic nervous system in which the effects of the two divisions are *complementary*
- Innervation and regulation by *only one* division of the autonomic nervous system

13.3.2 Feedback Regulation

Feedback regulation is a process that allows a system to adjust itself by responding to incoming information. Practically all physiologic processes are regulated at least in part by feedback control.

Figure 13-1 Opposing effects of parasympathetic and sympathetic nerves.

107

108

Figure 13-2 Feedback loop of the autonomic nervous system.

[Figure 13-2](#) depicts a feedback loop typical of those used by the autonomic nervous system. The main elements of this loop are (1) a *sensor*, (2) an *effector*, and (3) neurons connecting the sensor

to the effector. The purpose of the sensor is to monitor the status of a physiologic process. Information picked up by the sensor is sent to the central nervous system (spinal cord and brain), where it is integrated with other relevant information. Signals (instructions for change) are then sent from the central nervous system along nerves of the autonomic system to the effector. In response to these instructions, the effector makes appropriate adjustments in the process. The entire procedure is termed a *reflex*.

13.3.2.1 Baroreceptor Reflex.

From a pharmacologic perspective, the most important feedback loop of the autonomic nervous system is one that helps regulate blood pressure. This system is referred to as the *baroreceptor reflex*. (Baroreceptors are receptors that sense blood pressure.) This reflex is important to us because it frequently opposes our attempts to modify blood pressure with drugs.

Feedback (reflex) control of blood pressure is achieved as follows: (1) Baroreceptors located in the carotid sinus and aortic arch monitor changes in blood pressure and send this information to the brain. (2) In response to alterations in blood pressure, the brain sends impulses along nerves of the autonomic nervous system, instructing the heart and blood vessels to behave in such a way as to restore blood pressure to normalcy. Accordingly, when blood pressure *falls*, the baroreceptor reflex causes vasoconstriction and elevation of cardiac output so as to bring blood pressure back up. Conversely, when blood pressure *rises* too high, the baroreceptor reflex causes vasodilation and a reduction in cardiac output, thereby causing blood pressure to drop.

The baroreceptor reflex is discussed in greater detail in [Chapter 42](#) (Review of Hemodynamics).

13.3.3 Autonomic Tone

The term *autonomic tone* refers to the steady, day-to-day influence exerted by the autonomic nervous system on a particular organ or organ system. Autonomic tone provides a basal level of control over which reflex regulation is superimposed.

When an organ is innervated by both divisions of the autonomic nervous system, one division—either sympathetic or parasympathetic—provides most of the basal control, thereby obviating conflicting instruction. Recall that, when an organ receives nerves from both divisions of the autonomic nervous system, those nerves frequently exert opposing influences. If both divisions were to send impulses simultaneously, the resultant conflicting instructions would be counterproductive (like running heating and air conditioning simultaneously.) By having only one division of the autonomic nervous system provide the basal control to an organ, conflicting signals are avoided.

The branch of the autonomic nervous system that controls organ function most of the time is said to provide the *predominant tone* to that organ. *In most organs, the parasympathetic nervous system provides the predominant tone.* The vascular system, which is regulated almost exclusively by the *sympathetic* nervous system, is the principal exception.

13.4 ANATOMIC CONSIDERATIONS

Although we know a great deal about the anatomy of the peripheral nervous system, very little of this information helps us understand peripheral nervous system drugs. The few details that *do* pertain to pharmacology are summarized in [Figure 13-3](#).

13.4.1 Parasympathetic Nervous System

Pharmacologically relevant aspects of parasympathetic anatomy are shown in [Figure 13-3](#). Note that there are *two* neurons in the pathway leading from the spinal cord to organs innervated by parasympathetic nerves. The junction (synapse) between these two neurons occurs within a structure called a *ganglion*. (A ganglion is simply a lump created by a group of nerve cell bodies.) Not surprisingly, the neurons that go from the spinal cord to the parasympathetic ganglia are called *preganglionic neurons*, whereas the neurons that go from the ganglia to effector organs are called *postganglionic neurons*. The anatomy of the parasympathetic nervous system offers two general sites at which drugs can act: (1) the synapses between preganglionic neurons and postganglionic neurons and (2) the junctions between postganglionic neurons and their effector organs.

13.4.2 Sympathetic Nervous System

Pharmacologically relevant aspects of sympathetic nervous system anatomy are illustrated in [Figure 13-3](#). As you can see, these features are nearly identical to those of the parasympathetic nervous system. Like the parasympathetic nervous system, the sympathetic nervous system employs two neurons in the pathways leading from the spinal cord to organs under its control. As with the parasympathetic nervous system, the junctions between those neurons are located in *ganglia*. Neurons leading from the spinal cord to the sympathetic ganglia are termed *preganglionic neurons*, and neurons leading from ganglia to effector organs are termed *postganglionic neurons*.

The *medulla of the adrenal gland* is a feature of the sympathetic nervous system that requires comment. Although not a neuron per se, the adrenal medulla can be looked on as the functional equivalent of a postganglionic neuron of the sympathetic nervous system. (The adrenal medulla

influences the body by releasing epinephrine into the bloodstream, which then produces effects much like those that occur in response to stimulation of postganglionic sympathetic nerves.) Because the adrenal medulla is similar in

108

109

Figure 13-3 The basic anatomy of the parasympathetic and sympathetic nervous systems and the somatic motor system.

function to a postganglionic neuron, it is appropriate to refer to the nerve leading from the spinal cord to the adrenal as preganglionic, even though there is no ganglion, as such, in this pathway.

As with the parasympathetic nervous system, drugs that affect the sympathetic nervous system have two general sites of action: (1) the synapses between preganglionic and postganglionic neurons (including the adrenal medulla), and (2) the junctions between postganglionic neurons and their effector organs.

13.4.3 Somatic Motor System

Pharmacologically relevant anatomy of the somatic motor system is depicted in [Figure 13-3](#). Note that there is *only one* neuron in the pathway from the spinal cord to the muscles innervated by somatic motor nerves. Because this pathway contains only one neuron, peripherally acting drugs that affect somatic motor system function have only one site of action: the *neuromuscular junction* (ie, the junction between the somatic motor nerve and the muscle).

13.5 INTRODUCTION TO TRANSMITTERS OF THE PERIPHERAL NERVOUS SYSTEM

The peripheral nervous system employs three neurotransmitters: *acetylcholine*, *norepinephrine*, and *epinephrine*. Any given junction in the peripheral nervous system uses only one of these transmitter substances. A fourth compound—*dopamine*—may also serve as a peripheral nervous system transmitter, but this role has not been demonstrated conclusively.

To understand peripheral nervous system pharmacology, it is necessary to know the identity of the transmitter employed at each of the junctions of the peripheral nervous system. This information is summarized in [Figure 13-4](#). As indicated, *acetylcholine* is the transmitter employed at most junctions of the peripheral nervous system. Acetylcholine is the transmitter released by (1) all preganglionic neurons of the parasympathetic nervous system, (2) all preganglionic neurons of the sympathetic nervous system, (3) all postganglionic neurons of the parasympathetic nervous system, (4) all motor neurons to skeletal muscles, and (5) most postganglionic neurons of the sympathetic nervous system that go to sweat glands.

Norepinephrine is the transmitter released by practically all postganglionic neurons of the sympathetic nervous system. The only exceptions are the postganglionic sympathetic neurons that go to sweat glands, which employ acetylcholine as their transmitter.

Epinephrine is the major transmitter released by the adrenal medulla. (The adrenal medulla also releases some norepinephrine.)

Much of what follows in this chapter is based on the information summarized in [Figure 13-4](#). Accordingly, I strongly urge you to learn (memorize) this information now.

13.6 INTRODUCTION TO RECEPTORS OF THE PERIPHERAL NERVOUS SYSTEM

The peripheral nervous system works through several different types of receptors. Understanding these receptors is central to understanding peripheral nervous system pharmacology. All effort that you invest in learning about these receptors now will be richly rewarded as we discuss peripheral nervous system drugs in the chapters to come.

13.6.1 Primary Receptor Types: Cholinergic Receptors and Adrenergic Receptors

There are two basic categories of receptors associated with the peripheral nervous system: *cholinergic receptors* and *adrenergic receptors*. Cholinergic receptors are defined as receptors that mediate responses to acetylcholine. These receptors mediate responses at all junctions where

acetylcholine is the transmitter. Adrenergic receptors are defined as receptors that mediate responses to epinephrine (adrenaline) and norepinephrine. These receptors mediate responses at all junctions where norepinephrine or epinephrine is the transmitter.

109

110

Figure 13-4 Transmitters employed at specific junctions of the peripheral nervous system. Summary:

1. All *preganglionic* neurons of the *parasympathetic* and *sympathetic* nervous systems release *acetylcholine* as their transmitter.
2. All *postganglionic* neurons of the *parasympathetic* nervous system release *acetylcholine* as their transmitter.
3. Most *postganglionic* neurons of the *sympathetic* nervous system release *norepinephrine* as their transmitter.
4. *Postganglionic* neurons of the sympathetic nervous system that innervate *sweat glands* release *acetylcholine* as their transmitter.
5. *Epinephrine* is the principal transmitter released by the *adrenal medulla*.
6. All *motor neurons* to *skeletal muscles* release *acetylcholine* as their transmitter.

13.6.2 Subtypes of Cholinergic and Adrenergic Receptors

Not all cholinergic receptors are the same; likewise, not all adrenergic receptors are the same. For each of these two major receptor classes there are receptor subtypes. There are three major subtypes of cholinergic receptors, referred to as nicotinic_N, nicotinic_M, and muscarinic.* There are four major subtypes of adrenergic receptors, referred to as alpha₁, alpha₂, beta₁, and beta₂.

In addition to the four major subtypes of adrenergic receptors, there is another adrenergic receptor type, referred to as the *dopamine* receptor. Although dopamine receptors are classified as adrenergic, these receptors do not respond to epinephrine or norepinephrine. Rather, they respond only to dopamine, a neurotransmitter found primarily in the central nervous system.

* Evidence gathered over the last decade indicates that muscarinic receptors, like nicotinic receptors, come in subtypes. Five have been identified. Of these, only three—designated M₁, M₂, and M₃—have clearly identified functions. At this time, practically all drugs that affect muscarinic receptors are nonselective. Accordingly, since our understanding of these receptors is limited, and since drugs that can selectively alter their function are few, we will not discuss muscarinic receptor subtypes further in this chapter. However, we will discuss them in [Chapter 14](#), in the context of drugs for overactive bladder, one of which is highly selective for M₃ receptors.

13.7 EXPLORING THE CONCEPT OF RECEPTOR SUBTYPES

The concept of receptor subtypes is important and potentially confusing. In this section we discuss what a receptor subtype is and why receptor subtypes matter.

13.7.1 What Do We Mean by the Term **Receptor Subtype**?

Receptors that respond to the same transmitter but nonetheless are different from one another would be called receptor subtypes. For example, peripheral receptors that respond to acetylcholine can be found (1) in ganglia of the autonomic nervous system, (2) at neuromuscular junctions, and (3) on organs regulated by the parasympathetic nervous system. However, even though all of these receptors can be activated by acetylcholine, there is clear evidence that the receptors at these three sites are, in fact, different from one another. Hence, although all of these receptors belong to the same major receptor category (cholinergic), they are sufficiently different as to constitute distinct receptor subtypes.

13.7.2 How Do We Know That Receptor Subtypes Exist?

Historically, our knowledge of receptor subtypes came from observing responses to drugs. In fact, were it not for drugs, receptor subtypes might never have been discovered.

110

The data in [Table 13-1](#) illustrate the types of drug responses that led to the realization that receptor subtypes exist. These data summarize the results of an experiment designed to study the effects of a natural transmitter (acetylcholine) and a series of drugs (nicotine, muscarine, *d*-tubocurarine, and atropine) on two tissues: skeletal muscle and ciliary muscle. (The ciliary muscle is the muscle responsible for focusing the eye for near vision.) As these data indicate, although skeletal muscle and ciliary muscle both contract in response to acetylcholine, these tissues differ in their responses to drugs. In the discussion below, we examine the selective responses of these tissues to drugs and see how those responses reveal the existence of receptor subtypes.

111

At synapses on skeletal muscle and ciliary muscle, acetylcholine is the transmitter employed by neurons to elicit contraction. Because both types of muscle respond to acetylcholine, it is safe to conclude that both muscles have receptors for this substance. Because acetylcholine is the natural transmitter for these receptors, we would classify these receptors as *cholinergic*.

What do the effects of nicotine on skeletal muscle and ciliary muscle suggest? The effects of nicotine on these muscles suggest four possible conclusions: (1) Because skeletal muscle contracts when nicotine is applied, we can conclude that skeletal muscle has receptors at which nicotine can act. (2) Because ciliary muscle does *not* respond to nicotine, we can tentatively conclude that ciliary muscle does not have receptors for nicotine. (3) Because nicotine mimics the effects of acetylcholine on skeletal muscle, we can conclude that nicotine may act at the same receptors on skeletal muscle as does acetylcholine. (4) Because both types of muscle have receptors for acetylcholine, and because nicotine appears to act only at the acetylcholine receptors on skeletal muscle, we can tentatively conclude that the acetylcholine receptors on skeletal muscle are different from the acetylcholine receptors on ciliary muscle.

What do the responses to muscarine suggest? The conclusions that can be drawn regarding responses to muscarine are exactly parallel to those drawn for nicotine. These conclusions are: (1) ciliary muscle has receptors that respond to muscarine, (2) skeletal muscle may not have receptors for muscarine, (3) muscarine may be acting at the same receptors on ciliary muscle as does acetylcholine, and (4) the receptors for acetylcholine on ciliary muscle may be different from the receptors for acetylcholine on skeletal muscle.

The responses of skeletal muscle and ciliary muscle to nicotine and muscarine suggest, but do not prove, that the cholinergic receptors on these two tissues are different. However, the responses of these two tissues to *d-tubocurarine* and *atropine*, both of which are receptor *blocking agents*, eliminate any doubts as to the presence of cholinergic receptor subtypes. When both types of muscle are pretreated with *d-tubocurarine* and then exposed to acetylcholine, the response to acetylcholine is blocked—but only in skeletal muscle. Tubocurarine pretreatment does not reduce the ability of acetylcholine to stimulate ciliary muscle. Conversely, pretreatment with atropine selectively blocks the response to acetylcholine in ciliary muscle—but atropine does nothing to prevent acetylcholine from stimulating receptors on skeletal muscle. Because tubocurarine can selectively block cholinergic receptors in skeletal muscle, whereas atropine can selectively block cholinergic receptors in ciliary muscle, we can conclude with certainty that the receptors for acetylcholine in these two types of muscle must be different.

TABLE 13-1 Responses of Skeletal Muscle and Ciliary Muscle to a Series of Drugs

Drug	Response	
	Skeletal Muscle	Ciliary Muscle
Acetylcholine	Contraction	Contraction
Nicotine	Contraction	No response
Muscarine	No response	Contraction
Acetylcholine		
After <i>d</i> -tubocurarine	No response	Contraction
After atropine	Contraction	No response

The data just discussed illustrate the essential role of drugs in revealing the presence of receptor subtypes. If acetylcholine were the only probe that we had, all that we would have been able to observe is that both skeletal muscle and ciliary muscle can respond to this agent. This simple observation would provide no basis for suspecting that the receptors for acetylcholine in these two tissues were different. It is only through the use of selectively acting drugs that the presence of receptor subtypes was initially revealed.

Today, the technology for identifying receptors and their subtypes is extremely sophisticated—not that studies like the one just discussed are no longer of value. In addition to performing traditional

drug-based studies, scientists are now cloning receptors using DNA hybridization technology. As you can imagine, this allows us to understand receptors in ways that were unthinkable in the past.*

* In addition to revealing exciting new information about receptors previously identified, this spiffy technology is so powerful that new receptors and receptor subtypes are being discovered at a dizzying rate. Which means, of course, that students in the future will have many more receptors to contend with than you do. So, when it seems like you're working awfully hard to master the information on receptors in this chapter and the ones that follow, look on the bright side—you could be studying pharmacology 10 years from now.

13.7.3 How Can Drugs Be More Selective Than Natural Transmitters at Receptor Subtypes?

Drugs achieve their selectivity for receptor subtypes by having structures that are different from those of natural transmitters. The relationship between structure and receptor selectivity is illustrated in [Figure 13-5](#). In this figure, cartoon drawings are used to represent drugs (nicotine and muscarine), receptor subtypes (nicotinic and muscarinic), and acetylcholine (the natural transmitter at nicotinic and muscarinic receptors). From the structures shown, we can easily imagine how acetylcholine is able to interact with both kinds of receptor subtypes, whereas nicotine and muscarine can interact only with the receptor subtypes whose structure is complementary to their own. By synthesizing chemicals that are structurally related to natural transmitters, pharmaceutical chemists have been able to produce drugs that are more selective for specific receptor subtypes than are the natural transmitters that act at those sites.

111

112

Figure 13-5 Drug structure and receptor selectivity. These cartoon figures illustrate the relationship between structure and receptor selectivity. The structure of acetylcholine allows this transmitter to interact with both receptor subtypes. In contrast, because of their unique structures, nicotine and muscarine are selective for the cholinergic receptor subtypes whose structure complements their own.

13.7.4 Why Do Receptor Subtypes Exist?

It is not unreasonable for us to wonder why Mother Nature bothered to create more than one type of receptor for any given transmitter. Unfortunately, a definitive answer to that question will have to come from Mother Nature herself. That is, the physiologic benefits of having multiple receptor subtypes for the same transmitter are not immediately obvious. In fact, as noted earlier, were it not for drugs, we probably wouldn't know that receptor subtypes existed at all.

13.7.5 Do Receptor Subtypes Matter to Us? You Bet!

Although receptor subtypes are of uncertain physiologic relevance, from the viewpoint of therapeutics, receptor subtypes are invaluable. The presence of receptor subtypes makes possible a dramatic increase in drug selectivity. For example, thanks to the existence of subtypes of cholinergic receptors (and the development of drugs selective for those receptor subtypes), it is possible to influence the activity of certain cholinergic receptors (eg, receptors of the neuromuscular junction) without altering the activity of all other cholinergic receptors (eg, the cholinergic receptors found in all autonomic ganglia and all target organs of the parasympathetic nervous system). Were it not for the existence of receptor subtypes, a drug that acted on cholinergic receptors at one site would alter the activity of cholinergic receptors at all other sites. Clearly, the existence of receptor subtypes for a particular transmitter makes possible drug actions that are much more selective than could be achieved if all of the receptors for that transmitter were the same.

13.8 LOCATIONS OF RECEPTOR SUBTYPES

Since many of the drugs discussed in the following chapters are selective for specific receptor subtypes, knowledge of the sites at which specific receptor subtypes are located will help us predict which organs a drug will affect. Accordingly, in laying our foundation for studying peripheral nervous system drugs, it is important to learn the sites at which the subtypes of adrenergic and cholinergic receptors are located. This information is summarized in [Figure 13-6](#). You will find it very helpful to master the contents of this figure before proceeding much further. (In the interest of minimizing confusion, subtypes of adrenergic receptors in [Figure 13-6](#) are listed simply as alpha and beta rather than as α_1 , α_2 , β_1 , and β_2 . The locations of all four subtypes of adrenergic receptors are discussed in the section that follows.)

13.9 FUNCTIONS OF CHOLINERGIC AND ADRENERGIC RECEPTOR SUBTYPES

Knowledge of receptor function is an absolute requirement for understanding peripheral nervous system drugs. By knowing the receptors at which a drug acts, and by knowing what those receptors do, we can predict the major effects of any peripheral nervous system drug.

[Tables 13-2](#) and [13-3](#) summarize the pharmacologically relevant functions of peripheral nervous system receptors. [Table 13-2](#) summarizes responses elicited by activation of cholinergic receptor subtypes. [Table 13-3](#) summarizes responses to activation of adrenergic receptor subtypes. Before attempting to study specific peripheral nervous system drugs, you should master (memorize) the contents of the appropriate table. [Table 13-2](#) should be mastered before studying cholinergic drugs ([Chapters 14](#), [15](#), and [16](#)). [Table 13-3](#) should be mastered before studying adrenergic drugs ([Chapters 17](#), [18](#), and [19](#)). If you study these tables in preparation for learning about peripheral nervous system drugs, you will find the process of learning the pharmacology relatively simple (and perhaps even enjoyable). Conversely, if you attempt to study the pharmacology without first mastering the appropriate table, you are likely to meet with frustration.

13.9.1 Functions of Cholinergic Receptor Subtypes

[Table 13-2](#) summarizes the pharmacologically relevant responses to activation of the three major subtypes of cholinergic receptors: nicotinic_N, nicotinic_M, and muscarinic. Please commit the information in this table to memory.

We can group responses to cholinergic receptor activation into three major categories based on the subtype of receptor involved:

- Activation of *nicotinic_N* (neuronal) receptors promotes *ganglionic transmission* at all ganglia of the sympathetic and parasympathetic nervous systems. In addition, activation of nicotinic_N receptors promotes *release of epinephrine from the adrenal medulla*.
- Activation of *nicotinic_M* (muscle) receptors causes *contraction of skeletal muscle*.
- Activation of *muscarinic* receptors, which are located on target organs of the parasympathetic nervous system, elicits an appropriate response from the organ involved. Specifically, muscarinic activation causes (1) increased glandular secretions (from pulmonary, gastric, intestinal, and sweat glands); (2) contraction of smooth muscle in the bronchi and GI tract; (3) slowing of heart rate; (4) contraction of the sphincter muscle of the iris, resulting in miosis (reduction in pupillary diameter); (5) contraction of the ciliary

muscle of the eye, causing the lens to focus for near vision; (6) dilation of blood vessels; and (7) voiding of the urinary bladder (by causing contraction of the detrusor

112

113

Figure 13-6 Locations of cholinergic and adrenergic receptor subtypes. Summary:

1. *Nicotinic_N* receptors are located on the *cell bodies of all postganglionic neurons* of the *parasympathetic* and *sympathetic* nervous systems. *Nicotinic_N* receptors are also located on cells of the *adrenal medulla*.
2. *Nicotinic_M* receptors are located on *skeletal muscle*.
3. *Muscarinic* receptors are located on *all organs* regulated by the *parasympathetic* nervous system (ie, organs innervated by postganglionic parasympathetic nerves). *Muscarinic* receptors are also located on *sweat glands*.
4. *Adrenergic* receptors—*alpha*, *beta*, or both—are located on *all organs* (except sweat glands) regulated by the *sympathetic* nervous system (ie, organs innervated by postganglionic sympathetic nerves). *Adrenergic* receptors are also located on organs regulated by epinephrine released from the *adrenal medulla*.

muscle [which forms the bladder wall] and relaxation of the trigone and sphincter muscles [which block the bladder neck when contracted]).

Muscarinic cholinergic receptors on blood vessels require additional comment. These receptors are not associated with the nervous system in any way. That is, no nerves terminate at vascular muscarinic receptors. It is not at all clear as to how, or even if, these receptors are activated physiologically. However, regardless of their physiologic relevance, the cholinergic receptors on blood vessels do have *pharmacologic* significance. Why? Because drugs that are able to activate these receptors cause vasodilation, which in turn causes blood pressure to fall.

13.9.2 Functions of Adrenergic Receptor Subtypes

Adrenergic receptor subtypes and their functions are summarized in [Table 13-3](#). You should commit this information to memory.

13.9.2.1 Alpha₁ Receptors

Alpha₁ receptors are located in the eyes, blood vessels, male sex organs, prostatic capsule, and bladder (trigone and sphincter).

Ocular alpha₁ receptors are present on the *radial muscle* of the iris. Activation of these receptors leads to mydriasis (dilation of the pupil). As depicted in [Table 13-3](#), the fibers of the radial muscle are arranged like the spokes of a wheel. Because of this configuration, contraction of the radial muscle causes the pupil to enlarge. (If you have difficulty remembering that *mydriasis* means pupillary enlargement, whereas *miosis* means pupillary constriction, just remember that mydriasis [enlargement] is a bigger word than miosis.)

Activation of alpha₁ receptors in *blood vessels* produces *vasoconstriction*. Alpha₁ receptors are present on veins and on arterioles in many capillary beds.

Activation of alpha₁ receptors in the *sexual apparatus of males* causes *ejaculation*.

Activation of alpha₁ receptors in smooth muscle of the *bladder* (trigone and sphincter) and *prostatic capsule* causes *contraction*.

113

TABLE 13-2 Functions of Peripheral Cholinergic Receptor Subtypes

Receptor Subtype	Location	Response to Receptor Activation
Nicotinic _N	All autonomic nervous system ganglia and the adrenal medulla	Stimulation of parasympathetic and sympathetic postganglionic nerves and release of epinephrine from the adrenal medulla
Nicotinic _M	Neuromuscular junction	Contraction of skeletal muscle

- * Although sweating is due primarily to stimulation of muscarinic receptors by acetylcholine, the nerves that supply acetylcholine to sweat glands belong to the sympathetic nervous system rather than the parasympathetic nervous system.
- † Cholinergic receptors on blood vessels are not associated with the nervous system.

13.9.2.2 Alpha₂ Receptors

Alpha₂ receptors of the peripheral nervous system are located on *nerve terminals* (see [Table 13-3](#)) and not on the organs innervated by the autonomic nervous system. Because alpha₂ receptors are located on nerve terminals, these receptors are referred to as *presynaptic* or *prejunctional*. The function of these receptors is to regulate transmitter release. As depicted in [Table 13-3](#), norepinephrine can bind to alpha₂ receptors located on the same neuron from which the norepinephrine was released. The consequence of this norepinephrine-receptor interaction is suppression of further norepinephrine release. Hence, presynaptic alpha₂ receptors can help reduce transmitter release when too much transmitter has accumulated in the synaptic gap. Drug effects resulting from activation of *peripheral* alpha₂ receptors are of minimal clinical significance.

Alpha₂ receptors are also present in the central nervous system. In contrast to peripheral alpha₂ receptors, central alpha₂ receptors are therapeutically relevant. We will consider these receptors in later chapters.

13.9.2.3 Beta₁ Receptors

Beta₁ receptors are located in the heart and the kidney. *Cardiac* beta₁ receptors have great therapeutic significance. Activation of these receptors increases *heart rate*, *force of contraction*, and *velocity of impulse conduction through the atrioventricular (AV) node*.

Activation of beta₁ receptors in the *kidney* causes release of *renin* into the blood. Since renin promotes synthesis of angiotensin, a powerful vasoconstrictor, activation of renal beta₁ receptors is a means by which the nervous system helps elevate blood pressure. (The role of renin in the regulation of blood pressure is discussed in depth in [Chapter 43](#).)

13.9.2.4 Beta₂ Receptors

Beta₂ receptors mediate several important processes. Activation of beta₂ receptors in the lung leads to *bronchial dilation*. Activation of beta₂ receptors in the uterus causes *relaxation of*

uterine smooth muscle. Activation of beta₂ receptors in arterioles of the heart, lungs, and skeletal muscles causes *vasodilation* (an effect opposite to that of alpha₁ activation). Activation of beta₂ receptors in the liver and skeletal muscle promotes *glycogenolysis* (breakdown of glycogen into glucose), thereby increasing blood levels of glucose. In addition, activation of beta₂ receptors in skeletal muscle enhances contraction.

TABLE 13-3 Functions of Peripheral Adrenergic Receptor Subtypes

Receptor Subtype	Location	Response to Receptor Activation
Alpha ₁	Eye	Contraction of the radial muscle of the iris causes mydriasis (increased pupil size) 
	Arterioles	Constriction
	Skin	
	Viscera	
	Mucous membranes	
	Veins	Constriction
	Sex organs, male	Ejaculation
	Prostate capsule	Contraction
	Bladder	Contraction of trigone and sphincter 
Alpha ₂	Presynaptic nerve terminals	Inhibition of transmitter release 

Beta ₁	Heart	Increased rate Increased force of contraction Increased AV conduction velocity
	Kidney	Renin release
	Arterioles	Dilation
Beta ₂	Heart	
	Lung	
	Skeletal muscle	
	Bronchi	Dilation
	Uterus	Relaxation
	Liver	Glycogenolysis
	Skeletal muscle	Enhanced contraction, glycogenolysis
Dopamine	Kidney	Dilation of kidney vasculature

AV = atrioventricular, NE = norepinephrine, R = receptor.

* Alpha₂ receptors in the central nervous system are postsynaptic.

13.9.2.5 Dopamine Receptors

In the periphery, the only dopamine receptors of clinical significance are located in the vasculature of the kidney. Activation of these receptors *dilates renal blood vessels*, thereby enhancing renal perfusion.

In the central nervous system, receptors for dopamine are of great therapeutic significance. The functions of these receptors are discussed in [Chapter 21](#) (Drugs for Parkinson's Disease) and [Chapter 31](#) (Antipsychotic Agents and Their Use in Schizophrenia).

13... RECEPTOR SPECIFICITY OF THE ADRENERGIC TRANSMITTERS

The receptor specificity of adrenergic transmitters is more complex than the receptor specificity of acetylcholine. Whereas acetylcholine can activate all three subtypes of cholinergic receptors, not every adrenergic transmitter (epinephrine, norepinephrine, dopamine) can interact with each of the five subtypes of adrenergic receptors.

Receptor specificity of adrenergic transmitters is as follows: (1) *epinephrine* can activate all alpha and beta receptors, but not dopamine receptors; (2) *norepinephrine* can activate alpha₁, alpha₂, and beta₁ receptors, but not beta₂ or dopamine receptors; and (3) *dopamine* can activate alpha₁, beta₁, and dopamine receptors. (Note that dopamine itself is the only transmitter capable of activating dopamine receptors.) Receptor specificity of the adrenergic transmitters is summarized in [Table 13-4](#).

115

116

Knowing that epinephrine is the only transmitter that acts at β_2 receptors can serve as an aid to remembering the functions of this receptor subtype. Recall that epinephrine is released from the adrenal medulla—not from neurons—and that the function of epinephrine is to prepare the body for fight or flight. Accordingly, since epinephrine is the only transmitter that activates β_2 receptors, and since epinephrine is released only in preparation for fight or flight, times of fight or flight will be the only occasions on which β_2 receptors will undergo significant physiologic activation. As it turns out, the physiologic changes elicited by β_2 activation are precisely those needed for success in the fight-or-flight response. Specifically, activation of β_2 receptors will (1) dilate blood vessels in the heart, lungs, and skeletal muscles, thereby increasing blood flow to these organs; (2) dilate the bronchi, thereby increasing oxygenation; (3) increase glycogenolysis, thereby increasing available energy; and (4) relax uterine smooth muscle, thereby preventing delivery (a process that would be inconvenient for a pregnant woman preparing to fight or flee). Accordingly, if you think of the physiologic requirements for success during fight or flight, you will have a good picture of the responses that β_2 activation can cause.

TABLE 13-4 Receptor Specificity of Adrenergic Transmitters^{*}

^{*} Arrows indicate the range of receptors that the transmitters can activate.

13... TRANSMITTER LIFE CYCLES

In this section we consider the life cycles of acetylcholine, norepinephrine, and epinephrine. Because a number of drugs produce their effects by interfering with specific phases of the transmitters' life cycles, knowledge of these cycles helps us understand drug actions.

13.11.1 Life Cycle of Acetylcholine

The life cycle of acetylcholine (ACh) is depicted in [Figure 13-7](#). The cycle begins with synthesis of ACh from two precursors: choline and acetylcoenzyme A. Following synthesis, ACh is stored in vesicles and later released in response to an action potential. Following release, ACh binds to receptors (nicotinic_N, nicotinic_M, or muscarinic) located on the postjunctional cell. Upon dissociating from its receptors, ACh is destroyed almost instantaneously by *acetylcholinesterase* (AChE), an enzyme present in abundance on the surface of the postjunctional cell. AChE degrades ACh into two inactive products: acetate and choline. Uptake of choline into the cholinergic nerve terminal completes the life cycle of ACh. Note that an inactive substance (choline), and not the active transmitter (acetylcholine), is taken back up for reuse.

Therapeutic and toxic agents can interfere with the ACh life cycle at several points. Botulinum toxin inhibits ACh release. A number of medicines and poisons act at cholinergic receptors to mimic or block the actions of ACh. Several therapeutic and toxic agents act by inhibiting AChE, thereby causing ACh to accumulate in the junctional gap.

Figure 13-7 Life cycle of acetylcholine. Note that transmission is terminated by enzymatic degradation of ACh and not by uptake of intact ACh back into the nerve terminal. (Acetyl CoA = acetylcoenzyme A, ACh = acetylcholine, AChE = acetylcholinesterase.)

Figure 13-8 **Life cycle of norepinephrine.** Note that transmission is terminated by reuptake of NE into the nerve terminal and not by enzymatic degradation. Note also the structural similarity between epinephrine and norepinephrine. (DA = dopamine, MAO = monoamine oxidase, NE = norepinephrine.)

Transmitter	Adrenergic Receptor Subtype				
	Alpha ₁	Alpha ₂	Beta ₁	Beta ₂	Dopamine
Epinephrine	←→			←→	
Norepinephrine	←→		←→		
Dopamine	←→		←→		←→

13.11.2 Life Cycle of Norepinephrine

The life cycle of norepinephrine is depicted in [Figure 13-8](#). As indicated, the cycle begins with synthesis of norepinephrine from a series of precursors. The final step of synthesis takes place within vesicles, where norepinephrine is then stored prior to release. Following release, norepinephrine binds to adrenergic receptors. As shown in the figure, norepinephrine can interact with *postsynaptic* alpha₁ and beta receptors and with *presynaptic* alpha₂ receptors. Transmission is terminated by *reuptake* of norepinephrine back into the nerve terminal. (Note that the termination process for norepinephrine differs from that for acetylcholine, whose effects are terminated by enzymatic degradation rather than reuptake.) Following reuptake, norepinephrine can undergo one of two fates: (1) uptake into vesicles for reuse or (2) inactivation by monoamine oxidase (MAO), an enzyme found in the nerve terminal.

Practically every step in the life cycle of norepinephrine can be altered by therapeutic agents. We have drugs that alter the synthesis, storage, and release of norepinephrine; we have drugs that act at adrenergic receptors to mimic or block the effects of norepinephrine; we have drugs, such as cocaine and tricyclic antidepressants, that inhibit the reuptake of norepinephrine (and thereby intensify transmission); and we have drugs that inhibit the breakdown of norepinephrine by MAO, causing an increase in the amount of transmitter available for release.

13.11.3 Life Cycle of Epinephrine

The life cycle of epinephrine is much like that of norepinephrine—although there are significant differences. The cycle begins with synthesis of epinephrine within chromaffin cells of the adrenal medulla. These cells produce epinephrine by first making norepinephrine, which is then converted enzymatically to epinephrine. (Because sympathetic neurons lack the enzyme needed to convert norepinephrine to epinephrine, epinephrine is not produced in sympathetic nerves.) Following synthesis, epinephrine is stored in vesicles to await release. Once released, epinephrine travels via the bloodstream to target organs throughout the body. Termination of epinephrine's actions is accomplished primarily by hepatic metabolism, and not by uptake into nerves.

I know it's a lot of work, but there's really no way around it: You've got to incorporate this information into your personal database (ie, ya gotta memorize it).

13.11.3.1

KEY POINTS

- The peripheral nervous system has two major divisions: the autonomic nervous system and the somatic motor system.
- The autonomic nervous system has two major divisions: the sympathetic nervous system and the parasympathetic nervous system.
- The parasympathetic nervous system has several functions relevant to pharmacology: it slows heart rate, increases gastric secretion, empties the bladder and bowel, focuses the eye for near vision, constricts the pupil, and contracts bronchial smooth muscle.
- Principal functions of the sympathetic nervous system are regulation of the cardiovascular system, regulation of body temperature, and implementation of the fight-or-flight response.
- In some organs (eg, the heart), sympathetic and parasympathetic nerves have opposing effects. In other organs (eg, male sex organs), the sympathetic and parasympathetic systems have complementary effects. And in still other organs (notably blood vessels), function is regulated by only one branch of the autonomic nervous system.
- The baroreceptor reflex helps regulate blood pressure.
- In most organs regulated by the autonomic nervous system, the parasympathetic nervous system provides the dominant tone.

117

118

- In blood vessels, the sympathetic nervous system provides the dominant tone.
- Pathways from the spinal cord to organs under sympathetic and parasympathetic control consist of two neurons: a preganglionic neuron and a postganglionic neuron.
- The adrenal medulla is the functional equivalent of a postganglionic sympathetic neuron.
- Somatic motor pathways from the spinal cord to skeletal muscles have only one neuron.
- The peripheral nervous system employs three transmitters: acetylcholine, norepinephrine, and epinephrine.
- Acetylcholine is the transmitter released by all preganglionic neurons of the sympathetic nervous system, all preganglionic neurons of the parasympathetic nervous system, all postganglionic neurons of the parasympathetic nervous system, postganglionic neurons of the sympathetic nervous system that go to sweat glands, and all motor neurons.
- Norepinephrine is the transmitter released by all postganglionic neurons of the sympathetic nervous system, except those that go to sweat glands.
- Epinephrine is the major transmitter released by the adrenal medulla.
- There are three major subtypes of cholinergic receptors: nicotinic_N, nicotinic_M, and muscarinic.
- There are four major subtypes of adrenergic receptors: alpha₁, alpha₂, beta₁, and beta₂.
- Although receptor subtypes are of uncertain physiologic significance, they are of great pharmacologic significance.
- Activation of nicotinic_N receptors promotes transmission at all autonomic ganglia, and promotes release of epinephrine from the adrenal medulla.
- Activation of nicotinic_M receptors causes contraction of skeletal muscle.
- Activation of muscarinic receptors increases glandular secretion (from pulmonary, gastric, intestinal, and sweat glands); contracts smooth muscle in the bronchi and GI tract; slows heart rate; contracts the iris sphincter; contracts the ciliary muscle (thereby

focusing the lens for near vision); dilates blood vessels; and promotes bladder voiding (by contracting the bladder detrusor muscle and relaxing the trigone and sphincter).

- Activation of α_1 receptors contracts the radial muscle of the eye (causing mydriasis), constricts veins and arterioles, promotes ejaculation, and contracts smooth muscle in the prostatic capsule and bladder (trigone and sphincter).
- Activation of *peripheral* α_2 receptors is of minimal pharmacologic significance.
- Activation of β_1 receptors increases heart rate, force of myocardial contraction, and conduction velocity through the AV node, and promotes release of renin by the kidney.
- Activation of β_2 receptors dilates the bronchi, relaxes uterine smooth muscle, increases glycogenolysis, enhances contraction of skeletal muscle, and dilates arterioles (in the heart, lungs, and skeletal muscle).
- Activation of dopamine receptors dilates blood vessels in the kidney.
- Neurotransmission at cholinergic junctions is terminated by degradation of acetylcholine by acetylcholinesterase.
- Neurotransmission at adrenergic junctions is terminated by reuptake of intact norepinephrine into nerve terminals.
- Following reuptake, norepinephrine may be stored in vesicles for reuse or destroyed by monoamine oxidase.

¹⁴Introduction to Cholinergic Drugs

The cholinergic drugs are agents that influence the activity of cholinergic receptors. Most of these drugs act directly at cholinergic receptors, where they either mimic or block the actions of acetylcholine. Some of these drugs—the cholinesterase inhibitors—influence cholinergic receptors indirectly by preventing the breakdown of acetylcholine.

The cholinergic drugs have both therapeutic and toxicologic significance. Therapeutic applications are limited but valuable. The toxicology of cholinergic drugs is extensive, encompassing such agents as nicotine, insecticides, and compounds designed for chemical warfare.

There are six categories of cholinergic drugs. These categories, along with representative agents, are summarized in [Table 1](#). The *muscarinic agonists*, represented by bethanechol, selectively mimic the effects of acetylcholine at muscarinic receptors. The *muscarinic antagonists*, represented by atropine, selectively block the effects of acetylcholine (and other agonists) at muscarinic receptors. *Ganglionic stimulating agents*, represented by nicotine itself, selectively mimic the effects of acetylcholine at nicotinic_N receptors of autonomic ganglia. *Ganglionic blocking agents*, represented by mecamylamine, selectively block ganglionic nicotinic_N receptors. *Neuromuscular blocking agents*, represented by *d*-tubocurarine and succinylcholine, selectively block the effects of acetylcholine at nicotinic_M receptors at the neuromuscular junction. The *cholinesterase inhibitors*, represented by neostigmine and physostigmine, prevent the breakdown of acetylcholine by acetylcholinesterase, and thereby increase the activation of all cholinergic receptors.

Table 2 is your master key to understanding the cholinergic drugs. This table lists the three subtypes of cholinergic receptors (muscarinic, nicotinic_N, and nicotinic_M) and indicates for each receptor type: (1) location, (2) responses to activation, (3) drugs that produce activation (agonists), and (4) drugs that prevent activation (antagonists). This information, along with the detailed information on cholinergic receptor function summarized in [Table 13-2](#), is just about all you need to predict the actions of cholinergic drugs.

An example will demonstrate the combined value of [Tables 2](#) and [Table 13-2](#). Let's consider *bethanechol*. As indicated in [Table 2](#), bethanechol is a selective *agonist* at *muscarinic* cholinergic receptors. Referring to [Table 13-2](#), we see that activation of muscarinic receptors can produce the following: ocular effects (miosis and ciliary muscle contraction), slowing of heart rate, bronchial constriction, urination, glandular secretion, stimulation of the GI tract, penile erection, and vasodilation. Since bethanechol *activates* muscarinic receptors, the drug is capable of eliciting all of these responses. Hence, by knowing which receptors bethanechol activates (from [Table 2](#)), and by

knowing what those receptors do (from [Table 13-2](#)), you can predict the kinds of responses you might expect bethanechol to produce.

TABLE 1 Categories of Cholinergic Drugs

Category	Representative Drugs
Muscarinic agonists	Bethanechol
Muscarinic antagonists	Atropine
Ganglionic stimulating agents	Nicotine
Ganglionic blocking agents	Mecamylamine
Neuromuscular blocking agents	<i>d</i> -Tubocurarine, succinylcholine
Cholinesterase inhibitors	Neostigmine, physostigmine

TABLE 2 Summary of Cholinergic Drugs and Their Receptors

	Receptor Subtype		
	Muscarinic	Nicotinic _N	Nicotinic _M
Receptor Location	Sweat glands Blood vessels All organs regulated by the parasympathetic nervous system	All ganglia of the autonomic nervous system	Neuromuscular junctions (NMJs)
Effects of Receptor Activation	Many, including: ↓ Heart rate ↑ Gland secretion Smooth muscle contraction	Promotes ganglionic transmission	Skeletal muscle contraction
Receptor Agonists	Bethanechol Cholinesterase inhibitors: physostigmine, neostigmine (these drugs indirectly activate all cholinergic receptors)	Nicotine	(Nicotine [*])
Receptor Antagonists	Atropine	Mecamylamine	<i>d</i> -Tubocurarine, succinylcholine

* The doses of nicotine needed to activate nicotinic_M receptors of the NMJs are much higher than the doses needed to activate nicotinic_N receptors in autonomic ganglia.

In the chapters that follow, we will employ the approach just described. That is, for each cholinergic drug discussed, you will want to know (1) the receptors that the drug affects, (2) the normal responses to activation of those receptors, and (3) whether the drug in question increases or decreases receptor activation. All of this information is contained in [Tables 2](#) and [Table 13-2](#). Accordingly, if you master the information in these tables now, you will be prepared to follow discussions in succeeding chapters with relative ease—and perhaps even pleasure. In contrast, if you postpone mastery of these tables, you are likely to find it both difficult and dissatisfying to proceed.

¹⁵CHAPTER 14 Muscarinic Agonists and Antagonists

The muscarinic agonists and antagonists produce their effects through direct interaction with muscarinic receptors. The muscarinic agonists cause receptor activation; the antagonists produce receptor blockade.

^{15.1}MUSCARINIC AGONISTS

The muscarinic agonists bind to muscarinic receptors and thereby cause receptor activation. Since nearly all muscarinic receptors are associated with the parasympathetic nervous system, responses to muscarinic agonists closely resemble those produced by stimulation of parasympathetic nerves. Accordingly, muscarinic agonists are also known as *parasympathomimetic agents*.

^{15.1.1} Bethanechol

Bethanechol [Urecholine] embodies the characteristics that typify all muscarinic agonists, and hence will serve as our prototype for the group.

^{15.1.1.1} Mechanism of Action

Bethanechol is a direct-acting muscarinic agonist. The drug binds reversibly to muscarinic cholinergic receptors and causes activation. At therapeutic doses, bethanechol acts selectively at muscarinic receptors, having little or no effect on nicotinic receptors, either in ganglia or in skeletal muscle.

^{15.1.1.2} Pharmacologic Effects

Bethanechol can elicit all of the responses typical of muscarinic receptor activation. Accordingly, we can readily predict the effects of bethanechol by knowing the information on muscarinic responses summarized in [Table 13-2](#).

The principal structures affected by muscarinic activation are the *heart*, *exocrine glands*, *smooth muscles*, and *eye*. Muscarinic agonists act on the heart to cause bradycardia (decreased heart rate) and on exocrine glands to increase sweating, salivation, bronchial secretions, and secretion of gastric acid. In smooth muscles of the lung and GI tract, muscarinic agonists promote contraction. The result is constriction of the bronchi and increased tone and motility of GI smooth muscle. In the bladder, muscarinic activation causes *contraction* of the detrusor muscle and *relaxation* of the trigone and sphincter; the result is bladder emptying. In vascular smooth muscle, these drugs cause relaxation; the resultant vasodilation can produce hypotension. Activation of muscarinic receptors in the eye has two effects: (1) miosis (pupillary constriction);

and (2) contraction of the ciliary muscle, resulting in accommodation for near vision. (The ciliary muscle, which is attached to the lens, focuses the eye for near vision by altering lens curvature.)

15.1.1.3 Pharmacokinetics

Bethanechol is available for oral administration only. (A subQ formulation, available in the past, has been withdrawn.) With oral use, effects begin in 30 to 60 minutes and persist about 1 hour. Because bethanechol is a quaternary ammonium compound ([Fig. 14-1](#)), the drug crosses membranes poorly. As a result, only a small fraction of each dose is absorbed.

15.1.1.4 Therapeutic Uses

Although bethanechol can produce a broad spectrum of pharmacologic effects, its clinical applications are limited. The principal indication is urinary retention.

15.1.1.4.1 Urinary Retention.

Bethanechol relieves urinary retention by activating muscarinic receptors of the urinary tract. Muscarinic activation relaxes the trigone and sphincter muscles and increases voiding pressure (by contracting the detrusor muscle, which composes the bladder wall). Bethanechol is used to treat urinary retention in postoperative and postpartum patients. The drug should not be used to treat urinary retention caused by physical obstruction of the urinary tract. Why? Because increased pressure in the tract in the presence of blockage could cause injury. When patients are treated with bethanechol, a bedpan or urinal should be readily available.

15.1.1.4.2 Gastrointestinal Uses.

Bethanechol has been used on an investigational basis to treat *gastroesophageal reflux*. Benefits may result from increased esophageal motility and increased pressure in the lower esophageal sphincter.

Bethanechol can help treat disorders associated with GI paralysis. Benefits derive from increased tone and motility of GI smooth muscle. Specific applications are *adynamic ileus*, *gastric atony*, and *postoperative abdominal distention*. Bethanechol should not be given if physical obstruction of the GI tract is present. Why? Because, in the presence of blockage, increased propulsive contractions might result in damage to the intestinal wall.

Figure 14-1 **Structures of muscarinic agonists.** Note that, with the exception of pilocarpine, all of these agents are quaternary ammonium compounds, and hence always carry a positive charge. Because of this charge, these compounds cross membranes poorly.

15.1.1.5 Adverse Effects

In theory, bethanechol can produce the full range of muscarinic responses as side effects. However, with oral dosing, side effects are relatively rare. (When the drug was available for subQ administration, side effects were much more common.)

15.1.1.5.1 Cardiovascular System.

Bethanechol can cause *hypotension* (secondary to vasodilation) and *bradycardia*. Accordingly, the drug is contraindicated for patients with low blood pressure or low cardiac output.

15.1.1.5.2 Alimentary System.

At usual therapeutic doses, bethanechol can cause *excessive salivation*, *increased secretion of gastric acid*, *abdominal cramps*, and *diarrhea*. Higher doses can cause involuntary defecation. Bethanechol is contraindicated in patients with gastric ulcers, because stimulation of acid secretion could intensify gastric erosion, causing bleeding and possibly perforation. The drug

is also contraindicated for patients with *intestinal obstruction* and for those recovering from recent *surgery of the bowel*. In both cases, the ability of bethanechol to increase the tone and motility of intestinal smooth muscle could result in rupture of the bowel wall.

15.1.1.5.3 Urinary Tract.

Because of its ability to contract the bladder detrusor, and thereby *increase pressure within the urinary tract*, bethanechol can be hazardous to patients with urinary tract obstruction or weakness of the bladder wall. In both groups, elevation of pressure within the urinary tract could rupture the bladder. Accordingly, bethanechol is contraindicated for patients with either disorder.

15.1.1.5.4 Exacerbation of Asthma.

By activating muscarinic receptors in the lungs, bethanechol can cause bronchoconstriction. Accordingly, the drug is contraindicated for patients with latent or active asthma.

15.1.1.5.5 Dysrhythmias in Hyperthyroid Patients.

Bethanechol can cause dysrhythmias in hyperthyroid patients. Accordingly, the drug is contraindicated for these people. The mechanism of dysrhythmia induction is explained below.

If given to hyperthyroid patients, bethanechol may increase heart rate to the point of initiating a dysrhythmia. (Note that increased heart rate is opposite to the effect that muscarinic agonists have in most patients.) When hyperthyroid patients are given bethanechol, their initial cardiovascular responses are like those of anyone else: bradycardia and hypotension. In reaction to hypotension, the baroreceptor reflex attempts to return blood pressure to normal. Part of this reflex involves the release of norepinephrine from sympathetic nerves that regulate heart rate. In patients who are *not* hyperthyroid, norepinephrine release serves to increase cardiac output, and thereby helps restore blood pressure. However, in hyperthyroid patients, norepinephrine can induce cardiac dysrhythmias. The reason for this unusual response is that, in hyperthyroid patients, the heart is exquisitely sensitive to the effects of norepinephrine; hence, relatively small amounts can cause stimulation sufficient to elicit a dysrhythmia.

15.1.1.6 Preparations, Dosage, and Administration

Bethanechol [Urecholine] is available in tablets (5, 10, 25, and 50 mg) for oral therapy. (Bethanechol solution for subQ therapy has been withdrawn.) For adults, the oral dosage ranges

from 10 to 50 mg given 3 to 4 times a day. Administration with meals can cause nausea and vomiting, and hence dosing should be done 1 hour before meals or 2 hours after.

15.1.2 Other Muscarinic Agonists

15.1.2.1 Cevimeline

15.1.2.1.1 Actions and Uses.

Cevimeline [Evoxac] is a derivative of acetylcholine with actions much like those of bethanechol. The drug is indicated for relief of xerostomia (dry mouth) in patients with Sjögren's syndrome, an autoimmune disorder characterized by xerostomia, keratoconjunctivitis sicca (inflammation of the cornea and conjunctiva), and connective tissue disease (typically rheumatoid arthritis). Dry mouth results from extensive damage to salivary glands. Left untreated, dry mouth can lead to multiple complications, including periodontal disease, dental caries, altered taste, oral ulcers and candidiasis, and difficulty eating and speaking. Cevimeline relieves dry mouth by activating muscarinic receptors on residual healthy tissue in salivary glands, thereby promoting salivation. The drug also increases tear production, which can help relieve keratoconjunctivitis. Because it stimulates salivation, cevimeline may also benefit patients with xerostomia induced by radiation therapy for head and neck cancer, although the drug is not approved for this use.

15.1.2.1.2 Adverse Effects.

Adverse effects result from activating muscarinic receptors, and hence are similar to those of bethanechol. The most common effects are excessive *sweating* (18.9%), *nausea* (13.8%), *rhinitis* (11.2%), and *diarrhea* (10.3%). To compensate for fluid loss caused by sweating and diarrhea, patients should increase fluid intake. Like bethanechol, cevimeline promotes *miosis* (constriction of the pupil) and may also *blur vision*. Both actions can make driving dangerous, especially at night.

Activation of cardiac muscarinic receptors can reduce heart rate and slow cardiac conduction. Accordingly, cevimeline should be used with caution in patients with a history of heart disease.

Because muscarinic activation increases airway resistance, cevimeline is contraindicated for patients with uncontrolled asthma and should be used with caution in patients with controlled asthma, chronic bronchitis, or chronic obstructive pulmonary disease.

Because miosis can exacerbate symptoms of both narrow-angle glaucoma and iritis (inflammation of the iris), cevimeline is contraindicated for people with these disorders.

122

123

15.1.2.1.3 Drug Interactions.

Cevimeline can intensify cardiac depression caused by beta blockers (because both drugs decrease heart rate and cardiac conduction).

Beneficial effects of cevimeline can be antagonized by drugs that block muscarinic receptors. Among these are atropine, tricyclic antidepressants (eg, imipramine), antihistamines (eg, diphenhydramine), and phenothiazine antipsychotics (eg, chlorpromazine).

15.1.2.1.4 Preparations, Dosage, and Administration.

Cevimeline [Evoxac] is available in 30-mg capsules. The dosage is 30 mg 3 times a day. The drug may be administered with food to reduce gastric upset.

15.1.2.2 Pilocarpine

Pilocarpine is a muscarinic agonist used mainly for topical therapy of glaucoma, an ophthalmic disorder characterized by elevated intraocular pressure with subsequent injury to the optic nerve. The basic pharmacology of pilocarpine and its use in glaucoma are discussed in [Chapter 103](#) (Drugs for the Eye).

In addition to its use in glaucoma, pilocarpine is approved for oral therapy of dry mouth resulting from Sjögren's syndrome or from salivary gland damage caused by radiation therapy of head and neck cancer. For these applications, pilocarpine is available in 5-mg tablets under the trade name *Salagen*. The recommended dosage is 5 mg 3 or 4 times a day. At this dosage, the principal adverse effect is sweating, which occurs in 29% of patients. However, if dosage is excessive, pilocarpine can produce the full spectrum of muscarinic effects.

15.1.2.3 Acetylcholine

Clinical use of acetylcholine [Miochol-E] is limited primarily to producing rapid miosis (pupil constriction) following lens delivery in cataract surgery. Two factors explain the limited utility of this drug. First, acetylcholine lacks selectivity (in addition to activating muscarinic cholinergic receptors, acetylcholine can also activate all nicotinic cholinergic receptors). Second, because of rapid destruction by cholinesterase, acetylcholine has a half-life that is extremely short—too short for most clinical applications.

15.1.2.4 Muscarine

Although muscarine is not used clinically, this agent has historic and toxicologic significance. Muscarine is of historic interest because of its role in the discovery of cholinergic receptor

subtypes. The drug has toxicologic significance because of its presence in certain poisonous mushrooms.

15.1.3 Toxicology of Muscarinic Agonists

15.1.3.1 Sources of Muscarinic Poisoning.

Muscarinic poisoning can result from ingestion of certain mushrooms and from overdose with two kinds of medications: (1) direct-acting muscarinic agonists (eg, bethanechol, pilocarpine), and (2) cholinesterase inhibitors.

Of the mushrooms that cause poisoning, only a few do so through muscarinic activation. Mushrooms of the *Inocybe* and *Clitocybe* species have lots of muscarine, hence their ingestion can produce typical signs of muscarinic toxicity. Interestingly, *Amanita muscaria*, the mushroom from which muscarine was originally extracted, actually contains very little muscarine; poisoning by this mushroom is due to toxins other than muscarinic agonists.

15.1.3.2 Symptoms.

Manifestations of muscarinic poisoning result from excessive activation of muscarinic receptors. Prominent symptoms are profuse salivation, lacrimation (tearing), visual disturbances, bronchospasm, diarrhea, bradycardia, and hypotension. Severe poisoning can produce cardiovascular collapse.

15.1.3.3 Treatment.

Management is direct and specific: administer *atropine* (a selective muscarinic blocking agent) and provide supportive therapy. By blocking access of muscarinic agonists to their receptors, atropine can reverse most signs of toxicity.

15.2 MUSCARINIC ANTAGONISTS (ANTICHOLINERGIC DRUGS)

Muscarinic antagonists competitively block the actions of acetylcholine at muscarinic receptors. Because the majority of muscarinic receptors are located on structures innervated by parasympathetic nerves, the muscarinic antagonists are also known as *parasympatholytic drugs*. Additional names for these agents are *antimuscarinic drugs*, *muscarinic blockers*, and *anticholinergic drugs*.

The term *anticholinergic* can be a source of confusion and requires comment. This term is unfortunate in that it implies blockade at *all* cholinergic receptors. However, as normally used, the term *anticholinergic* only denotes blockade of *muscarinic* receptors. Therefore, when a drug is

Pharmacology for Nursing Care, 7th Edition

characterized as being anticholinergic, you can take this to mean that it produces selective *muscarinic* blockade—and not blockade of all cholinergic receptors. In this chapter, I use the terms *muscarinic antagonist* and *anticholinergic agent* interchangeably.

15.2.1 Atropine

Atropine [Sal-Tropine, AtroPen, others] is the best known muscarinic antagonist and will serve as our prototype for the group. The actions of all other muscarinic blockers are much like those of this drug.

Atropine is found naturally in a variety of plants, including *Atropa belladonna* (deadly nightshade) and *Datura stramonium* (aka Jimson weed, stinkweed, and devil's apple). Because of its presence in *Atropa belladonna*, atropine is referred to as a *belladonna alkaloid*.

15.2.1.1 Mechanism of Action

Atropine produces its effects through competitive blockade at muscarinic receptors. Like all other receptor antagonists, atropine has no direct effects of its own. Rather, all responses to atropine result from *preventing receptor activation* by endogenous acetylcholine (or by drugs that act as muscarinic agonists).

At therapeutic doses, atropine produces selective blockade of muscarinic cholinergic receptors. However, if the dosage is sufficiently high, the drug will produce some blockade of nicotinic receptors too.

15.2.1.2 Pharmacologic Effects

Since atropine acts by causing muscarinic receptor blockade, its effects are opposite to those caused by muscarinic activation. Accordingly, we can readily predict the effects of atropine by knowing the normal responses to muscarinic receptor activation (see [Table 13-2](#)) and by knowing that atropine will reverse those responses. Like the muscarinic agonists, the muscarinic antagonists exert their influence primarily on the *heart*, *exocrine glands*, *smooth muscles*, and *eye*.

15.2.1.2.1 Heart.

Atropine *increases heart rate*. Because activation of cardiac muscarinic receptors decreases heart rate, blockade of these receptors will cause heart rate to increase.

15.2.1.2.2 Exocrine Glands.

Atropine *decreases secretion* from salivary glands, bronchial glands, sweat glands, and the acid-secreting cells of the stomach. Note that these effects are opposite to those of muscarinic agonists, which increase secretion from exocrine glands.

15.2.1.2.3 Smooth Muscle.

By preventing activation of muscarinic receptors on smooth muscle, atropine causes *relaxation of the bronchi, decreased tone of the urinary bladder detrusor, and decreased tone and motility of the GI tract*. In the absence of an exogenous muscarinic agonist (eg, bethanechol), muscarinic blockade has no effect on vascular smooth muscle tone. Why? Because there is no parasympathetic innervation to muscarinic receptors in blood vessels.

123

124

15.2.1.2.4 Eye.

Blockade of muscarinic receptors on the iris sphincter causes *mydriasis* (dilation of the pupil). Blockade of muscarinic receptors on the ciliary muscle produces *cycloplegia* (relaxation of the ciliary muscle), thereby focusing the lens for far vision.

15.2.1.2.5 Central Nervous System (CNS).

At therapeutic doses, atropine can cause mild CNS *excitation*. Toxic doses can cause *hallucinations* and *delirium*, which can resemble psychosis. Extremely high doses can result in coma, respiratory arrest, and death.

15.2.1.2.6 Dose Dependency of Muscarinic Blockade.

It is important to note that not all muscarinic receptors are equally sensitive to blockade by atropine and most other anticholinergic drugs: At some sites, muscarinic receptors can be blocked with relatively low doses, whereas at other sites much higher doses are needed. [Table 14-1](#) indicates the sequence in which specific muscarinic receptors are blocked as the dose of atropine is increased.

Differences in receptor sensitivity to muscarinic blockers are of clinical significance. As indicated in [Table 14-1](#), the doses needed to block muscarinic receptors in the stomach and bronchial smooth muscle are higher than the doses needed to block muscarinic receptors at all other locations. Accordingly, if we want to use atropine to treat peptic ulcer disease (by suppressing gastric acid secretion) or asthma (by dilating the bronchi), we cannot do so without also affecting the heart, exocrine glands, many smooth muscles, and the eye. Because

Pharmacology for Nursing Care, 7th Edition

of these obligatory side effects, atropine and most other muscarinic antagonists are not preferred drugs for treating peptic ulcers or asthma.

15.2.1.3 Pharmacokinetics

Atropine may be administered orally, topically (to the eye), and by injection (IM, IV, and subQ). The drug is rapidly absorbed following oral administration and distributes to all tissues, including the CNS. Elimination is by a combination of hepatic metabolism and urinary excretion. Atropine has a half-life of approximately 3 hours.

TABLE 14-1 Relationship Between Dosage and Responses to Atropine

Dosage of Atropine	Response Produced
Low Doses	Salivary glands—decreased secretion
	Sweat glands—decreased secretion
	Bronchial glands—decreased secretion
	Heart—increased rate
	Eye—mydriasis, blurred vision
	Urinary tract—interference with voiding
	Intestine—decreased tone and motility
	Lung—dilation of bronchi
High Doses	Stomach—decreased acid secretion
Note that doses of atropine that are high enough to decrease gastric acid secretion or dilate the bronchi will also affect all other structures under muscarinic control. As a result, atropine and most other muscarinic antagonists are not very desirable for treating peptic ulcer disease or asthma.	

15.2.1.4 Therapeutic Uses

15.2.1.4.1 Preanesthetic Medication.

The cardiac effects of atropine can be helpful during surgery. Procedures that stimulate baroreceptors of the carotid body can initiate reflex slowing of the heart, resulting in profound bradycardia. Since this reflex is mediated by muscarinic receptors on the heart, pretreatment with atropine can prevent dangerous reductions in heart rate.

Certain anesthetics—especially ether, which is obsolete—irritate the respiratory tract, and thereby stimulate secretion from salivary, nasal, pharyngeal, and bronchial glands. If these secretions are sufficiently profuse, they can interfere with respiration. By blocking muscarinic receptors on secretory glands, atropine can help prevent excessive secretions. Fortunately, modern anesthetics are much less irritating than ether. The availability of these new anesthetics has greatly reduced the use of atropine as an antisecretagogue during anesthesia.

15.2.1.4.2 Disorders of the Eye.

By blocking muscarinic receptors in the eye, atropine can cause mydriasis and paralysis of the ciliary muscle. Both actions can be of help during eye examinations and ocular surgery. The ophthalmic uses of atropine and other muscarinic antagonists are discussed in [Chapter 103](#).

15.2.1.4.3 Bradycardia.

Atropine can accelerate heart rate in certain patients with bradycardia. Heart rate is increased because blockade of cardiac muscarinic receptors prevents the parasympathetic nervous system from slowing the heart.

15.2.1.4.4 Intestinal Hypertonicity and Hypermotility.

By blocking muscarinic receptors in the intestine, atropine can decrease both the tone and motility of intestinal smooth muscle. This can be beneficial in conditions characterized by excessive intestinal motility, such as mild dysentery and diverticulitis. When taken for these disorders, atropine can reduce both the frequency of bowel movements and associated abdominal cramps.

15.2.1.4.5 Muscarinic Agonist Poisoning.

Atropine is a specific antidote to poisoning by agents that activate muscarinic receptors. By blocking muscarinic receptors, atropine can reverse all signs of muscarinic poisoning. As discussed above, muscarinic poisoning can result from an overdose with medications that promote muscarinic activation (eg, bethanechol, cholinesterase inhibitors) or from ingestion of certain mushrooms.

15.2.1.4.6 Peptic Ulcer Disease.

Because it can suppress secretion of gastric acid, atropine has been used to treat peptic ulcer disease. Unfortunately, when administered in doses that are strong enough to block the muscarinic receptors that regulate secretion of gastric acid, atropine also blocks most other

muscarinic receptors. Hence, treatment of ulcers is necessarily associated with a broad range of antimuscarinic side effects (dry mouth, blurred vision, urinary retention, constipation, and so on). Because of these side effects, atropine is not a first-choice drug for ulcer therapy. Rather, atropine is reserved for rare cases in which symptoms cannot be relieved with preferred medications (eg, antibiotics, histamine₂ receptor antagonists, proton pump inhibitors).

15.2.1.4.7 Asthma.

By blocking bronchial muscarinic receptors, atropine can promote bronchial dilation, thereby improving respiration in patients with asthma. Unfortunately, in addition to dilating the bronchi, atropine also causes drying and thickening of bronchial secretions, effects that can be harmful to patients with asthma. Furthermore, when given in the doses needed to dilate the bronchi, atropine causes a variety of antimuscarinic side effects. Because of the potential for harm, and because superior medicines are available, atropine has a very limited role in asthma therapy.

15.2.1.4.8 Biliary Colic.

Biliary colic is characterized by intense abdominal pain brought on by passage of a gallstone through the bile duct. This pain is usually treated with morphine. In some cases, atropine may be combined with morphine to relax biliary tract smooth muscle, thereby helping alleviate discomfort.

124

15.2.1.5 Adverse Effects

125

Most adverse effects of atropine and other anticholinergic drugs are the direct result of muscarinic receptor blockade. Accordingly, they can be predicted from your knowledge of muscarinic receptor function.

15.2.1.5.1 Xerostomia (Dry Mouth).

Blockade of muscarinic receptors on salivary glands can inhibit salivation, thereby causing dry mouth. Not only is this uncomfortable, it can impede swallowing. Patients should be informed that dryness can be alleviated by chewing gum, sucking on hard candy, and sipping fluids.

15.2.1.5.2 Blurred Vision and Photophobia.

Blockade of muscarinic receptors on the ciliary muscle and the sphincter of the iris can paralyze these muscles. Paralysis of the ciliary muscle focuses the eye for far vision, causing

nearby objects to appear blurred. Patients should be forewarned about this effect and advised to avoid hazardous activities if vision is impaired.

Paralysis of the iris sphincter prevents constriction of the pupil, thereby rendering the eye unable to adapt to bright light. Patients should be advised to wear dark glasses if photophobia (intolerance to light) is a problem. Room lighting for hospitalized patients should be kept low.

15.2.1.5.3 Elevation of Intraocular Pressure.

Paralysis of the iris sphincter can cause intraocular pressure (IOP) to rise. The mechanism of this effect is discussed in [Chapter 103](#) (Drugs for the Eye). Because they can raise IOP, anticholinergic drugs are contraindicated for patients with glaucoma, a disease characterized by abnormally high IOP. In addition, these drugs should be used with caution in patients who may not have glaucoma per se but for whom a predisposition to glaucoma may be present. Included in this group are all people older than 40.

15.2.1.5.4 Urinary Retention.

Blockade of muscarinic receptors in the urinary tract reduces pressure within the bladder and increases the tone of the urinary sphincter and trigone. These effects can produce urinary hesitancy or urinary retention. In the event of severe urinary retention, catheterization or treatment with a muscarinic agonist (eg, bethanechol) may be required. Patients should be advised that urinary retention can be minimized by voiding just prior to taking their medication.

15.2.1.5.5 Constipation.

Muscarinic blockade decreases the tone and motility of intestinal smooth muscle. The resultant delay in transit through the intestine can produce constipation. Patients should be informed that constipation can be minimized by increasing dietary fiber and fluids. A laxative may be needed if constipation is severe. Because of their ability to decrease smooth muscle tone, muscarinic antagonists are contraindicated for patients with intestinal atony, a condition in which intestinal tone is already low.

15.2.1.5.6 Anhidrosis.

Blockade of muscarinic receptors on sweat glands can produce anhidrosis (a deficiency or absence of sweat). Since sweating is necessary for cooling, people who cannot sweat are at risk of hyperthermia. Patients should be warned of this possibility and advised to avoid activities that might lead to overheating (eg, exercising on a hot day).

15.2.1.5.7 Tachycardia.

Blockade of cardiac muscarinic receptors eliminates parasympathetic influence on the heart. By removing the “braking” influence of parasympathetic nerves, anticholinergic agents can cause tachycardia (excessive heart rate). Caution must be exercised in patients with pre-existing tachycardia.

15.2.1.5.8 Asthma.

In patients with asthma, antimuscarinic drugs can cause *thickening and drying of bronchial secretions*, and can thereby cause bronchial plugging. Consequently, although muscarinic antagonists can be used to treat asthma, they can also be harmful.

15.2.1.6 Drug Interactions

A number of drugs that are not classified as muscarinic antagonists can nonetheless produce significant muscarinic blockade. Among these are antihistamines, phenothiazine antipsychotics, and tricyclic antidepressants. Because of their prominent anticholinergic actions, these drugs can greatly enhance the antimuscarinic effects of atropine and related agents. Accordingly, it is wise to avoid combined use of atropine with other drugs that can cause muscarinic blockade.

15.2.1.7 Preparations, Dosage, and Administration

15.2.1.7.1 General Systemic Therapy.

Atropine sulfate is available in 0.4-mg tablets (sold as Sal-Tropine) for oral administration, and in solution (0.05 to 1 mg/mL) for IM, IV, and subQ administration. The average adult dose is 0.5 mg.

15.2.1.7.2 AtroPen for Cholinesterase Inhibitor Poisoning.

The AtroPen is a pre-filled auto-injector indicated for IM therapy of poisoning with an organophosphate cholinesterase inhibitor (nerve agent or insecticide). Three strengths are available: 0.5 mg (for children weighing 15 to 40 pounds), 1 mg (for children 40 to 90 pounds), and 2 mg (for adults and children over 90 pounds). Injections are made into the lateral thigh, directly through clothing if necessary.

15.2.1.7.3 Ophthalmology.

Formulations for ophthalmic use are discussed in [Chapter 103](#).

15.2.2 Anticholinergic Drugs for Overactive Bladder (Urge Incontinence)

15.2.2.1 Overactive Bladder: Characteristics and Overview of Treatment

Overactive bladder (OAB) is a disorder with four major symptoms: urinary urgency (a sudden, compelling desire to urinate), urinary frequency (voiding 8 or more times in 24 hours), nocturia (waking 2 or more times to void), and urge incontinence (involuntary urine leakage associated with a strong urge to void). In almost all cases, urge incontinence results from *involuntary contractions of the bladder detrusor* (the smooth muscle component of the bladder wall). These contractions are often referred to as detrusor instability or detrusor overactivity. Urge incontinence should not be confused with *stress incontinence*, defined as involuntary urine leakage caused by activities (eg, exertion, sneezing, coughing, laughter) that increase pressure within the abdominal cavity.

OAB is a common disorder, affecting up to one-third of Americans. However, relatively few (about 15%) seek medical help. The condition can develop at any age, but is most prevalent in the elderly. Among people ages 40 to 44, symptoms are reported by 3% of men and 9% of women. In comparison, among those 75 and older, symptoms are reported by 42% of men and 31% of women. Because urge incontinence, the most disturbing symptom, is both unpredictable and potentially embarrassing, many people with OAB curtail travel, social activities, and even work.

OAB can be treated with behavioral techniques and with drugs. Behavioral therapy can be highly effective—even more so than drugs—and hence should be tried first. Behavioral interventions include pelvic muscle exercises, scheduled voiding, education about bladder function, avoiding caffeine (a diuretic), and timing fluid intake appropriately. As a rule, drugs should be reserved for patients who don't respond adequately to nondrug measures.

125

15.2.2.2 Introduction to Anticholinergic Therapy of OAB

126

When drug therapy *is* indicated, *anticholinergic agents* (eg, oxybutynin, tolterodine) are preferred. These drugs block muscarinic receptors on the bladder detrusor, and thereby inhibit bladder contractions and the urge to void.

Unfortunately, drugs that block muscarinic receptors in the bladder can also block muscarinic receptors elsewhere, and hence can cause typical anticholinergic side effects. *Dry mouth* is the primary concern. Other possible effects include constipation, urinary retention, blurred vision, photophobia, tachycardia, and cognitive effects (confusion, hallucinations). All of these can be

intensified by concurrent use of other drugs that have anticholinergic actions (eg, antihistamines, tricyclic antidepressants, phenothiazine antipsychotic agents).

Anticholinergic side effects can be reduced in at least three ways: (1) using long-acting formulations, (2) using drugs that don't cross the blood-brain barrier, and (3) using drugs that are selective for muscarinic receptors in the bladder. Long-acting formulations (eg, extended-release capsules, transdermal patches) reduce side effects by providing a steady but relatively low level of drug, thereby avoiding the high peak levels that can cause intense side effects. Drugs that can't cross the blood-brain barrier are unable to cause CNS effects.

What about drugs that are selective for muscarinic receptors in the bladder? To answer this question, we must first discuss muscarinic receptor subtypes. As noted in [Chapter 13](#), there are five known muscarinic receptor subtypes. However, only three—designated M₁, M₂, and M₃—have clearly identified functions. Locations of these receptor subtypes, and responses to their activation and blockade, are summarized in [Table 14-2](#). As indicated, M₃ receptors are the most widely distributed, being found in salivary glands, the bladder detrusor, GI smooth muscle, and the eye. M₂ receptors are found only in the heart, and M₁ receptors are found in salivary glands and the CNS. At each location, responses to receptor activation are the same as we discussed in [Chapter 13](#)—although, in that chapter, we didn't identify the receptors by subtype; rather, we simply called all of them *muscarinic*.

With this background, we can consider how receptor selectivity might decrease anticholinergic side effects of drugs for OAB. To be beneficial, an anticholinergic agent must block muscarinic receptors in the bladder *detrusor*. That is, it must block the M₃ receptor subtype. Because M₃ receptors are also found in GI smooth muscle, the eye, and salivary glands, an M₃-selective blocker will still have some unwanted anticholinergic effects, namely, constipation (from reducing bowel motility), blurred vision and photophobia (from preventing contraction of the ciliary muscle and iris sphincter), dry eyes (from blocking tear production), and *some* degree of dry mouth (from blocking salivary gland M₃ receptors, while sparing salivary M₁ receptors). What an M₃-selective blocker will *not* do is cause tachycardia (because muscarinic receptors in the heart are the M₂ type) or impairment of CNS function (because muscarinic receptors in the brain are primarily the M₁ type).

15.2.2.3 Specific Anticholinergic Drugs for OAB

In the United States, we have five anticholinergic drugs approved specifically for OAB ([Table 14-3](#)). All five work by M₃-muscarinic blockade, although most block M₁ and M₂ receptors as well. With all of these drugs, we want sufficient M₃ blockade to reduce symptoms of OAB, but

not so much as to cause urinary retention. It should be noted that clinical responses to these agents are relatively modest—about 30% over the response to placebo (which produces about a 30% response by itself). None of these drugs is useful for stress incontinence.

15.2.2.3.1 Oxybutynin.

Oxybutynin [Ditropan, Ditropan XL, Oxytrol] is an anticholinergic agent that acts primarily at M₃-muscarinic receptors. The drug is approved only for OAB. Benefits derive from blocking M₃ receptors on the bladder detrusor.

Oxybutynin is available in four formulations. Two are short acting (syrup and immediate-release [IR] tablets) and two are long acting (transdermal patch and extended-release [ER] tablets). Anticholinergic side effects are less intense with the long-acting products.

15.2.2.3.1.1 Immediate-Release Tablets.

Oxybutynin IR tablets [Ditropan] can decrease the incidence of urinary urgency, urinary frequency, and urge incontinence. However, benefits are modest—and only somewhat greater than seen with placebo.

Oxybutynin is rapidly absorbed from the GI tract, achieving peak plasma levels about 1 hour after dosing. However, despite rapid absorption, absolute bioavailability is low (about 6%). Why? Because oxybutynin undergoes extensive first-pass metabolism—both in the gut wall and in the liver—primarily by CYP3A4, the 3A4 isozyme of cytochrome P450. One metabolite—*N*-desethyloxybutynin—is highly active, especially against muscarinic receptors in the salivary glands. Oxybutynin is very lipid soluble, and hence can penetrate the blood-brain barrier. The drug has a short half-life (2 to 3 hours), and hence multiple daily doses are required.

Anticholinergic side effects are common. The incidence of dry mouth is very high, in part because of muscarinic blockade by oxybutynin itself, and in part because of blockade by *N*-desethyloxybutynin. Other common side effects include constipation, tachycardia, urinary hesitancy, urinary retention, mydriasis, blurred vision, and dry eyes. In the CNS, cholinergic blockade can result in confusion, hallucinations, insomnia, and nervousness. In postmarketing reports of CNS effects, hallucinations and agitation were prominent among reports involving pediatric patients, while hallucinations, confusion, and sedation were prominent among reports involving elderly patients. Combined use of oxybutynin with other anticholinergic agents (eg, antihistamines, tricyclic antidepressants, phenothiazine antipsychotics) can intensify all anticholinergic side effects.

TABLE 14-2 Muscarinic Receptor Subtypes

Muscarinic Subtype	Location	Response to Activation	Impact of Blockade
M ₁	Salivary glands	Salivation	Dry mouth
	CNS	Enhanced cognition	Confusion, hallucinations
M ₂	Heart	Bradycardia	Tachycardia
M ₃	Salivary glands	Salivation	Dry mouth
	Bladder: detrusor	Contraction (increased pressure)	Relaxation (decreased pressure)
	GI smooth muscle	Increased tone and motility	Decreased tone and motility (constipation)
	Eye: Iris sphincter	Contraction (miosis)	Relaxation (mydriasis)
	Eye: Ciliary muscle	Contraction (accommodation)	Relaxation (blurred vision)
	Eye: Lachrymal gland	Tearing	Dry eyes
CNS = central nervous system, GI = gastrointestinal.			

Drugs that inhibit or induce CYP3A4 may alter oxybutynin blood levels, and may thereby either increase toxicity (inhibitors of CYP3A4) or reduce effectiveness (inducers of CYP3A4).

Immediate-release oxybutynin is available in 5-mg tablets. The usual dosage is 5 mg 2 or 3 times a day. The maximal dosage is 5 mg 4 times a day.

15.2.2.3.1.2 Syrup.

The basic and clinical pharmacology of oxybutynin syrup [Ditropan] is identical to that of the IR tablets. As with the IR tablets, the incidence of dry mouth and other anticholinergic side effects is high. The syrup contains 5 mg of oxybutynin/5 mL. The usual dosage is 5 mg 2 or 3 times a day. The maximal dosage is 5 mg 4 times a day.

15.2.2.3.1.3 Extended-Release Tablets.

Oxybutynin ER tablets [Ditropan XL] are as effective as the IR tablets and somewhat better tolerated. Although the incidence of dry mouth is reduced using ER tablets, it is nonetheless still high (about 60%). Other adverse effects include constipation (13%), dyspepsia (7%),

blurred vision (8%), dry eyes (6%), and CNS effects: somnolence (12%), headache (10%), and dizziness (6%).

The ER tablets are available in three strengths: 5, 10, and 15 mg. The initial dosage is 5 mg once daily. Dosage may be raised weekly in 5-mg increments to a maximum of 30 mg/day. The dosing goal is to achieve a balance between symptom reduction and tolerability of anticholinergic side effects. The ER tablets have an insoluble shell that is eliminated intact in the feces. Patients should be informed of this fact.

15.2.2.3.1.4

Transdermal Patch.

The oxybutynin transdermal system [Oxytrol] contains 39 mg of oxybutynin and delivers 3.9 mg/day. Owing to its high lipid solubility, oxybutynin from the patch is readily absorbed directly through the skin. A new patch is applied twice weekly to dry, intact skin of the abdomen, hip, or buttock, rotating the site with each change. Reduction of OAB symptoms is about the same as with the ER tablets.

Pharmacokinetically, the patch is unique in two ways. First, absorption is both slow and steady, and hence the patch produces low but stable blood levels of the drug. Second, transdermal absorption bypasses metabolism in the intestinal wall, and delays metabolism in the liver. As a result, levels of *N*-desethyloxybutynin, the active metabolite, are less than 20% of those achieved with oral therapy.

Transdermal oxybutynin is generally well tolerated. The most common side effect is application-site pruritus (itching), which develops in 15% of patients. The incidence of dry mouth is much lower than with the oral formulations (and only slightly higher than with placebo) presumably because (1) formation of *N*-desethyloxybutynin is low and (2) high peak levels of oxybutynin itself are avoided. Rates of constipation, blurred vision, and CNS effects are also low.

15.2.2.3.2

Darifenacin.

Of the anticholinergic agents used for OAB, darifenacin [Enablex] displays the greatest degree of M_3 selectivity. As a result, the drug can reduce OAB symptoms while having no effect on M_1 receptors in the brain or M_2 receptors in the heart. However, darifenacin does block M_3 receptors outside the bladder, and hence still can cause dry mouth, constipation, and other M_3 -related side effects.

Clinical benefits are similar to those of oxybutynin and tolterodine. On average, treatment decreases episodes of urge incontinence from 15/week down to 7/week (using 7.5 mg/day)

and from 17/week down to 6/week (using 15 mg/day), compared with a decrease from 16/week down to 9/week with placebo. The bottom line? As with other drugs for OAB, responses are relatively modest, and only slightly greater than those seen with placebo.

Darifenacin is administered orally in ER tablets. Absorption is adequate (15% to 19%), and not affected by food. In the blood, darifenacin is 98% protein bound. The drug undergoes extensive hepatic metabolism, primarily by CYP3A4. The resulting inactive metabolites are excreted in the urine (60%) and feces (40%). The drug's half-life is approximately 12 hours.

Darifenacin is relatively well tolerated. The most common side effect is dry mouth, which occurs in 35% of those taking 15 mg/day and 20% of those taking 7.5 mg/day, compared with only 8% of those taking placebo. In experimental animals, inhibition of salivation is less than that caused by oxybutynin, perhaps because darifenacin only blocks M₃ receptors in salivary glands, permitting salivary M₁ receptors to function normally. Constipation is also common, seen in 21% of those taking 15 mg/day and 15% of those taking 7.5 mg/day, compared with only 6% of those taking placebo. Other adverse effects include dyspepsia, gastritis, and headache. Darifenacin has little or no effect on memory, reaction time, word recognition, or cognition. The drug does not increase heart rate.

Levels of darifenacin can be raised significantly by strong inhibitors of CYP3A4. Among these are azole-type antifungal drugs (eg, ketoconazole, itraconazole), certain protease inhibitors used for HIV/AIDS (eg, ritonavir, nelfinavir), and clarithromycin (a macrolide antibiotic). If darifenacin is combined with any of these, darifenacin dosage must be kept low.

TABLE 14-3 Anticholinergic Drugs for Overactive Bladder

Drug	Formulation*	Dosage		Incidence of Dry Mouth
		Initial	Maximum	
Highly M ₃ Selective				
Darifenacin				
Enblex	ER tablets	7.5 mg once daily	15 mg once daily	20% with 7.5 mg/day; 35% with 15 mg/day
Primarily M ₃ Selective				
Oxybutynin				
Ditropan	Syrup	5 mg 2–3 times/day	5 mg 4 times/day	Dose-related; can exceed 70%
Ditropan	IR tablets	5 mg 2–3 times/day	5 mg 4 times/day	Dose-related; can exceed 70%
Ditropan XL	ER tablets	5 mg once daily	30 mg once daily†	Dose-related; can exceed 60%
Oxytrol	Transdermal patch	1 patch twice weekly (delivers 3 mg/day)	1 patch twice weekly	Low: 12% vs. 11% with placebo
Solifenacin				
VESIcare	Tablets	5 mg once daily	10 mg once daily	11% with 5 mg/day; 28% with 10 mg/day
Nonselective				
Tolterodine				
Detrol	IR tablets	1–2 mg twice daily	2 mg twice daily	35% with 2 mg twice daily
Detrol LA	ER capsules	2–4 mg once daily	4 mg once daily	Up to 40%
Trospium				
Sanctura	Tablets	20 mg twice daily‡	20 mg twice daily‡	20% with 20 mg twice daily
Sanctura XR	ER capsules	60 mg once daily‡	60 mg once daily‡	10%

* ER = extended release, IR = immediate release.

† Titrate dose upward as needed and tolerated.

‡ Administer at least 1 hour before meals or on an empty stomach.

127

128

Darifenacin [Enablex] is available in 7.5- and 15-mg ER tablets, which should be swallowed whole with liquid. The initial dosage is 7.5 mg once daily. After 2 weeks, dosage may be doubled to 15 mg once daily. In patients with moderate liver impairment, and in those taking powerful inhibitors of CYP3A4, dosage should be kept low (7.5 mg/day or less). In patients with severe liver impairment, darifenacin should be avoided.

15.2.2.3.3

Solifenacin.

Solifenacin [VESIcare] is very similar to darifenacin, although it's not quite as M₃ selective. In clinical trials, the drug reduced episodes of urge incontinence from 18/week down to 8/week (using 5 mg/day) and from 20/week down to 8/week (using 10 mg/day), compared with a decrease from 21/week down to 10/week with placebo—indicating that, like other drugs for OAB, solifenacin is only moderately more effective than placebo.

Solifenacin undergoes nearly complete absorption after oral dosing, achieving peak plasma levels in 3 to 6 hours. In the blood, the drug is highly (98%) protein bound. Like darifenacin, solifenacin undergoes extensive metabolism by hepatic CYP3A4. The resulting inactive metabolites are excreted in the urine (62%) and feces (23%). Solifenacin has a long half-life (about 50 hours), and hence can be administered just once a day.

The most common adverse effects are dry mouth (28% at 10 mg/day), constipation (13% at 10 mg/day), and blurred vision (5% at 10 mg/day). Dyspepsia, urinary retention, headache, and nasal dryness occur infrequently. At high doses (10 to 30 mg/day), solifenacin can prolong the QT interval, thereby posing a risk of a fatal dysrhythmia. Accordingly, caution is needed in patients with a history of QT prolongation and in those taking other QT-prolonging drugs. As with darifenacin, levels of solifenacin can be increased by strong inhibitors of CYP3A4 (eg, ketoconazole, ritonavir, clarithromycin).

Solifenacin [VESIcare] is available in 5- and 10-mg film-coated tablets, which should be swallowed intact with liquid. Dosing may be done with or without food. The initial dosage is 5 mg once daily. If treatment is well tolerated, the dosage can be doubled to 10 mg once daily. For patients with moderate hepatic impairment or severe renal impairment, and for those taking a powerful CYP3A4 inhibitor, dosage should not exceed 5 mg/day. For patients with severe hepatic impairment, solifenacin should be not be used.

15.2.2.3.4 Tolterodine.

Tolterodine [Detrol, Detrol LA] is a nonselective muscarinic antagonist approved only for OAB. Like oxybutynin, tolterodine is available in short- and long-acting formulations. Anticholinergic side effects are less intense with the long-acting form.

15.2.2.3.4.1 Immediate-Release Tablets.

In patients with OAB, tolterodine IR tablets [Detrol] can reduce the incidence of urge incontinence, urinary frequency, and urinary urgency. However, as with other drugs for OAB, benefits are modest.

Tolterodine is rapidly but variably absorbed from the GI tract. Plasma levels peak 1 to 2 hours after dosing. In most people, tolterodine undergoes extensive first-pass hepatic metabolism, primarily by CYP2D6 (the 2D6 isozyme of cytochrome P450), which converts much of the drug to an active metabolite. In people who lack CYP2D6 (about 7% of the population), tolterodine is metabolized by CYP3A4, which does not produce an active metabolite. In all people, parent drug and metabolites are eliminated in the urine (77%) and feces (17%). Tolterodine has a relatively short half-life, and hence twice-daily dosing is required.

Anticholinergic side effects occur less often than with IR oxybutynin. At a dosage of 2 mg twice daily, the most common side effects are dry mouth (35% vs. 70% with IR oxybutynin), constipation (7%), and dry eyes (3%). Effects on the CNS—somnolence, vertigo, dizziness—occur infrequently. The incidence of tachycardia and urinary retention is less than 1%. Anticholinergic effects can be intensified by concurrent use of other drugs with anticholinergic actions (eg, antihistamines, tricyclic antidepressants, phenothiazine antipsychotics). Drugs that inhibit CYP3A4 (eg, erythromycin, ketoconazole) can raise levels of tolterodine.

Tolterodine IR tablets are available in 1- and 2-mg strengths. The initial dosage is 2 mg twice daily, taken with or without food. If this dosage is poorly tolerated, it should be reduced to 1 mg twice daily. A dosage of 1 mg twice daily should also be used by patients with significant hepatic or renal impairment, and for those taking an inhibitor of CYP3A4.

15.2.2.3.4.2 Extended-Release Capsules.

Tolterodine ER capsules [Detrol LA] are as effective as the IR tablets, and cause less dry mouth (23% vs. 35%). The incidence of other anticholinergic effects is about the same with both formulations. Detrol LA is available in 2- and 4-mg strengths. The recommended

dosage is 4 mg once daily. As with the IR tablets, a lower dosage—2 mg once daily—should be used for patients with significant hepatic or renal impairment, and for those taking an inhibitor of CYP3A4.

15.2.2.3.5 Trospium.

Trospium [Sanctura, Sanctura XR] is a nonselective muscarinic blocker indicated only for OAB. Like oxybutynin and tolterodine, trospium is available in short- and long-acting formulations. Anticholinergic side effects are less intense with the long-acting form. Compared with other drugs for OAB, trospium is notable for its low bioavailability, lack of CNS effects, and lack of metabolism-related interactions with other drugs.

15.2.2.3.5.1 Immediate-Release Tablets.

Trospium IR tablets [Sanctura] reduce episodes of urge incontinence from 27/week down to 12/week (compared with 30/week down to 16/week with placebo). Reductions in urinary frequency are minimal.

Trospium is a quaternary ammonium compound (always carries a positive charge), and hence crosses membranes poorly. Administration is oral, and absorption is poor (only 10%) and is greatly reduced (70% to 80%) by food. Plasma levels peak 3.5 to 6 hours after dosing, and decline with a half-life of 18 hours. Trospium does not undergo hepatic metabolism, and is eliminated unchanged in the urine.

Trospium IR tablets are generally well tolerated. The most common side effects are dry mouth (20% vs. 6% with placebo) and constipation (10% vs. 5%)—about the same as with long-acting oxybutynin and tolterodine. Rarely, the drug causes dry eyes and urinary retention. Owing to its positive charge, trospium cannot cross the blood-brain barrier, and hence is devoid of CNS effects.

No drug interaction studies have been performed. However, because trospium is eliminated by the kidneys, we can assume it may compete with other drugs that undergo renal tubular excretion. Among these are vancomycin (an antibiotic), metformin (a drug for diabetes), and digoxin and procainamide (both used for cardiac disorders). Because trospium is not metabolized, the drug is unlikely to influence hepatic metabolism of other agents.

Immediate-release trospium [Sanctura] is available in 20-mg tablets. The usual dosage is 20 mg twice daily, administered at least 1 hour before meals or on an empty stomach. For patients with severe renal impairment, the recommended dosage is 20 mg once daily at bedtime.

15.2.2.3.5.2 Extended-Release Capsules.

Trospium ER capsules [Sanctura XR] are as effective as the IR tablets, and cause less dry mouth (10% vs. 20%). The incidence of constipation and other side effects is about the same. Extended-release trospium is available in 60-mg capsules for once-daily dosing.

15.2.3 Other Muscarinic Antagonists

15.2.3.1 Scopolamine.

Scopolamine is an anticholinergic drug with actions much like those of atropine, but with two exceptions: (1) whereas therapeutic doses of atropine produce mild CNS *excitation*, therapeutic doses of scopolamine produce *sedation*; and (2) scopolamine *suppresses emesis and motion sickness*, whereas atropine does not. Principal uses for scopolamine are motion sickness (see [Chapter 79](#)), production of cycloplegia and mydriasis for ophthalmic procedures (see [Chapter 103](#)), and production of preanesthetic sedation and obstetric amnesia.

15.2.3.2 Ipratropium Bromide.

Ipratropium [Atrovent] is an anticholinergic drug used to treat asthma, chronic obstructive pulmonary disease, and rhinitis caused by allergies or the common cold. The drug is administered by inhalation and systemic absorption is minimal. As a result, therapy is not associated with typical antimuscarinic side effects (dry mouth, blurred vision, urinary hesitancy, constipation, and so forth). Ipratropium is discussed at length in [Chapter 75](#).

15.2.3.3 Antisecretory Anticholinergics.

Muscarinic blockers can be used to suppress gastric acid secretion in patients with peptic ulcer disease. However, since superior antiulcer drugs are available, and since anticholinergic agents produce significant side effects (dry mouth, blurred vision, urinary retention, and so forth), most of these drugs have been withdrawn. Today, only four agents—*glycopyrrolate* [Robinul], *mepenzolate* [Cantil], *methscopolamine* [Pamine], and *propantheline* [Pro-Banthine]—remain on the market. All four are administered orally, and one—glycopyrrolate—may also be given IM and IV.

15.2.3.4 Dicyclomine.

This drug is indicated for irritable bowel syndrome (spastic colon, mucous colitis) and functional bowel disorders (diarrhea, hypermotility). Administration may be oral (40 mg 4 times

a day) or by IM injection (20 mg 4 times a day). Trade names include *Antispas*, *Bentyl*, and *Dibent*.

15.2.3.5 Pirenzepine and Telenzepine.

These drugs produce selective blockade of M₁ muscarinic receptors—the subtype of muscarinic receptor involved in regulating the secretion of gastric acid. Both drugs can effectively suppress acid secretion in patients with peptic ulcer disease, but neither is currently available in the United States. Because these drugs are selective blockers of M₁ muscarinic receptors, the incidence of dry mouth, blurred vision, and other typical antimuscarinic side effects is low.

15.2.3.6 Mydriatic Cycloplegics.

Five muscarinic antagonists—*atropine*, *homatropine*, *scopolamine*, *cyclopentolate*, and *tropicamide*—are employed to produce mydriasis and cycloplegia in ophthalmic procedures. These applications are discussed in [Chapter 103](#).

15.2.3.7 Centrally Acting Anticholinergics.

Several anticholinergic drugs, including *trihexyphenidyl* [Artane] and *benztropine* [Cogentin], are used to treat Parkinson's disease and drug-induced parkinsonism. Benefits derive from blockade of muscarinic receptors in the CNS. The centrally acting anticholinergics and their use in Parkinson's disease are discussed in [Chapter 21](#).

128

129

15.2.4 Toxicology of Muscarinic Antagonists

15.2.4.1 Sources of Antimuscarinic Poisoning.

Sources of poisoning include natural products (eg, *Atropa belladonna*, *Datura stramonium*), selective antimuscarinic drugs (eg, atropine, scopolamine), and other drugs with pronounced antimuscarinic properties (eg, antihistamines, phenothiazines, tricyclic antidepressants).

15.2.4.2 Symptoms.

Symptoms of antimuscarinic poisoning, which are the direct result of excessive muscarinic blockade, include dry mouth, blurred vision, photophobia, hyperthermia, CNS effects (hallucinations, delirium), and skin that is hot, dry, and flushed. Death results from respiratory depression secondary to blockade of cholinergic receptors in the brain.

15.2.4.3 Treatment.

Treatment consists of (1) minimizing intestinal absorption of the antimuscarinic agent and (2) administering an antidote. Absorption can be reduced by swallowing activated charcoal, which will adsorb the poison within the intestine, thereby preventing its absorption into the blood.

The most effective antidote to antimuscarinic poisoning is *physostigmine*, an inhibitor of acetylcholinesterase. By inhibiting cholinesterase, physostigmine causes acetylcholine to accumulate at all cholinergic junctions. As acetylcholine builds up, it competes with the antimuscarinic agent for receptor binding, thereby reversing excessive muscarinic blockade. The pharmacology of physostigmine is discussed in [Chapter 15](#).

15.2.4.4 Warning.

It is important to differentiate between antimuscarinic poisoning, which often resembles psychosis (hallucinations, delirium), and an actual psychotic episode. We need to make the differential diagnosis because antipsychotic drugs, which have antimuscarinic properties of their own, will intensify symptoms if given to a victim of antimuscarinic poisoning. Fortunately, since a true psychotic episode is not ordinarily associated with signs of excessive muscarinic blockade (dry mouth, hyperthermia, dry skin, and so forth), differentiation is not usually difficult.

15.2.4.4.1

KEY POINTS

- Muscarinic agonists work through direct activation of muscarinic cholinergic receptors, thereby causing bradycardia; increased secretion from sweat, salivary, bronchial, and gastric glands; contraction of intestinal and bronchial smooth muscle; contraction of the bladder detrusor and relaxation of the bladder trigone and sphincter; and, in the eye, miosis and accommodation for near vision.
- Bethanechol, the prototype of the muscarinic agonists, is used primarily to relieve urinary retention.
- Muscarinic agonist poisoning is characterized by profuse salivation, tearing, visual disturbances, bronchospasm, diarrhea, bradycardia, and hypotension.
- Muscarinic agonist poisoning is treated with atropine.
- Atropine, the prototype of the muscarinic antagonists (anticholinergic drugs), blocks the actions of acetylcholine (and all other muscarinic agonists) at muscarinic

cholinergic receptors, and thereby (1) increases heart rate; (2) reduces secretion from sweat, salivary, bronchial, and gastric glands; (3) relaxes intestinal and bronchial smooth muscle; (4) causes urinary retention (by relaxing the bladder detrusor and contracting the trigone and sphincter); (5) acts in the eye to cause mydriasis and cycloplegia; and (6) acts in the CNS to produce excitation (at low doses) and delirium and hallucinations (at toxic doses).

- Applications of anticholinergic drugs include preanesthetic medication, ophthalmic examinations, reversal of bradycardia, treatment of overactive bladder (OAB), and management of muscarinic agonist poisoning.
- Anticholinergic drugs that are selective for M_3 muscarinic receptors can still cause many anticholinergic side effects (eg, dry mouth, constipation, impaired vision), but will not slow heart rate (which is mediated by cardiac M_2 receptors) and will be largely devoid of cognitive effects (which are mediated primarily by M_1 receptors).
- Classic adverse effects of anticholinergic drugs are dry mouth, blurred vision, photophobia, tachycardia, urinary retention, constipation, and anhidrosis (suppression of sweating).
- Certain drugs—especially antihistamines, tricyclic antidepressants, and phenothiazine antipsychotics—have prominent antimuscarinic actions. These should be used cautiously, if at all, in patients receiving atropine or other muscarinic antagonists.
- The anticholinergic drugs used for OAB are only moderately effective: Symptom reduction is about 30% greater than with placebo therapy, which itself decreases symptoms by 30%.
- The short-acting anticholinergic drugs used for OAB cause more dry mouth and other anticholinergic side effects than do the long-acting drugs.
- Muscarinic antagonist poisoning is characterized by dry mouth, blurred vision, photophobia, hyperthermia, hallucinations and delirium, and skin that is hot, dry, and flushed.
- The best antidote for muscarinic antagonist poisoning is physostigmine, an inhibitor of acetylcholinesterase.

15.2.4.4.2 Summary of Major Nursing Implications*

15.2.4.4.2.1 BETHANECHOL

15.2.4.4.2.... Preadministration Assessment

15.2.4.4.2.... Therapeutic Goal

Treatment of nonobstructive urinary retention.

15.2.4.4.2.... Baseline Data

Record fluid intake and output.

15.2.4.4.2.... Identifying High-Risk Patients

Bethanechol is *contraindicated* for patients with peptic ulcer disease, urinary tract obstruction, intestinal obstruction, coronary insufficiency, hypotension, asthma, and hyperthyroidism.

15.2.4.4.2.... Implementation: Administration

15.2.4.4.2.... Route

Oral.

15.2.4.4.2.... Administration

Advise patients to take bethanechol 1 hour before meals or 2 hours after to reduce gastric upset.

Because effects on the intestine and urinary tract can be rapid and dramatic, ensure that a bedpan or bathroom is readily accessible.

15.2.4.4.2.... Ongoing Evaluation and Interventions

15.2.4.4.2.... Evaluating Therapeutic Effects

Monitor fluid intake and output to evaluate treatment of urinary retention.

15.2.4.4.2....

Minimizing Adverse Effects

Excessive muscarinic activation can cause salivation, sweating, urinary urgency, bradycardia, and hypotension. Monitor blood pressure and pulse rate. Observe for signs of muscarinic excess and report these to the physician. **Inform patients about manifestations of muscarinic excess and advise them to notify the prescriber if they occur.**

15.2.4.4.2....

Management of Acute Toxicity

Overdose produces manifestations of excessive muscarinic stimulation (salivation, sweating, involuntary urination and defecation, bradycardia, severe hypotension). Treat with parenteral atropine and supportive measures.

15.2.4.4.2.2

ATROPINE AND OTHER MUSCARINIC ANTAGONISTS (ANTICHOLINERGIC DRUGS)

15.2.4.4.2....

Preadministration Assessment

15.2.4.4.2....

Therapeutic Goal

Atropine has many applications, including preanesthetic medication and treatment of bradycardia, biliary colic, intestinal hypertonicity and hypermotility, and muscarinic agonist poisoning.

15.2.4.4.2....

Identifying High-Risk Patients

Atropine and other muscarinic antagonists are *contraindicated* for patients with glaucoma, intestinal atony, urinary tract obstruction, and tachycardia. Use with *caution* in patients with asthma.

15.2.4.4.2....

Implementation: Administration

15.2.4.4.2....

Routes

Atropine is administered PO, IV, IM, and subQ.

15.2.4.4.2....

Administration

Dry mouth from muscarinic blockade may interfere with swallowing. **Advise patients to moisten the mouth by sipping water prior to oral administration.**

15.2.4.4.2....

Ongoing Evaluation and Interventions

15.2.4.4.2....

Minimizing Adverse Effects

15.2.4.4.2....

Xerostomia (Dry Mouth).

Decreased salivation can dry the mouth. **Teach patients that xerostomia can be relieved by chewing gum, sucking on hard candy, and sipping fluids.**

15.2.4.4.2....

Blurred Vision.

Paralysis of the ciliary muscle may reduce visual acuity. **Warn patients to avoid hazardous activities if vision is impaired.**

15.2.4.4.2....

Photophobia.

Muscarinic blockade prevents the pupil from constricting in response to bright light. Keep hospital room lighting low to reduce visual discomfort. **Advise patients to wear sunglasses outdoors.**

15.2.4.4.2....

Urinary Retention.

Muscarinic blockade in the urinary tract can cause urinary hesitancy or retention. **Advise patients that urinary retention can be minimized by voiding just prior to taking anticholinergic medication.** If urinary retention is severe, catheterization or treatment with bethanechol (a muscarinic agonist) may be required.

15.2.4.4.2....

Constipation.

Reduced tone and motility of the gut may cause constipation. **Advise patients that constipation can be reduced by increasing dietary fiber and fluids.** A laxative may be needed if constipation is severe.

15.2.4.4.2....

Hyperthermia.

Suppression of sweating may result in hyperthermia. **Advise patients to avoid vigorous exercise in warm environments.**

15.2.4.4.2....

Tachycardia.

Blockade of cardiac muscarinic receptors can accelerate heart rate. Monitor pulse and report significant increases.

15.2.4.4.2....

Minimizing Adverse Interactions

Antihistamines, tricyclic antidepressants, and phenothiazines have prominent antimuscarinic actions. Combining these agents with atropine and other anticholinergic drugs can cause excessive muscarinic blockade.

15.2.4.4.2....

Management of Acute Toxicity

15.2.4.4.2....

Symptoms.

Overdose produces dry mouth, blurred vision, photophobia, hyperthermia, hallucinations, and delirium; the skin becomes hot, dry, and flushed. Differentiate muscarinic antagonist poisoning from psychosis!

15.2.4.4.2....

Treatment.

Treatment centers on limiting absorption of ingested poison (eg, by giving activated charcoal to adsorb the drug) and administering physostigmine, an inhibitor of acetylcholinesterase.

* Patient education information is highlighted as **blue text**.

¹⁶CHAPTER 15 Cholinesterase Inhibitors and Their Use in Myasthenia Gravis

Cholinesterase inhibitors are drugs that prevent the degradation of acetylcholine (ACh) by acetylcholinesterase (also known simply as cholinesterase [ChE]). By preventing the inactivation of ACh, the cholinesterase inhibitors enhance the actions of ACh released from cholinergic neurons. Hence, the cholinesterase inhibitors can be viewed as indirect-acting cholinergic agonists. Since cholinesterase inhibitors can intensify transmission at all cholinergic junctions (muscarinic, ganglionic, and neuromuscular), these drugs can elicit a broad spectrum of responses. Because they lack selectivity, cholinesterase inhibitors have limited therapeutic applications. Cholinesterase inhibitors are also known as *anticholinesterase agents*.

There are two basic categories of cholinesterase inhibitors: (1) *reversible inhibitors* and (2) *“irreversible” inhibitors*. The reversible inhibitors produce effects of moderate duration. In contrast, the irreversible inhibitors produce effects that are long lasting.

^{16.1} REVERSIBLE CHOLINESTERASE INHIBITORS

^{16.1.1} Neostigmine

Neostigmine [Prostigmin] typifies the reversible cholinesterase inhibitors and will serve as our prototype for the group. The drug's principal indication is *myasthenia gravis*.

^{16.1.1.1} Chemistry

As indicated in [Figure 15-1](#), neostigmine contains a quaternary nitrogen atom, and hence always carries a positive charge. Because of this charge, neostigmine cannot readily cross membranes, including those of the GI tract, blood-brain barrier, and placenta. Consequently, neostigmine is absorbed poorly following oral administration and has minimal effects on the brain and fetus.

^{16.1.1.2} Mechanism of Action

Neostigmine and the other reversible cholinesterase inhibitors can be envisioned as poor substrates for ChE. As indicated in [Figure 15-2](#), the normal function of ChE is to break down acetylcholine into choline and acetic acid. This process is termed a *hydrolysis* reaction because of the water molecule involved. As depicted in [Figure 15-3A](#), hydrolysis of ACh takes place in two steps: (1) binding of ACh to the active center of ChE, followed by (2) splitting of ACh, which regenerates free ChE. The overall reaction between ACh and ChE is extremely fast. As a result, one molecule of ChE can break down a huge amount of ACh in a very short time.

As depicted in [Figure 15-3B](#), the reaction between neostigmine and ChE is very similar to the reaction between ACh and ChE. The difference between the two reactions is simply that ChE splits neostigmine more slowly than it splits ACh. Hence, once neostigmine becomes bound to the active center of ChE,

Figure 15-1 Structural formulas of reversible cholinesterase inhibitors. Note that neostigmine and edrophonium are quaternary ammonium compounds, but physostigmine is not. What does this difference imply about the relative abilities of these drugs to cross membranes, including the blood-brain barrier?

the drug remains in place for a relatively long time, thereby preventing ChE from catalyzing the breakdown of ACh. ChE remains inhibited until it finally succeeds in splitting neostigmine off.

132

16.1.1.3 Pharmacologic Effects

By preventing inactivation of ACh, neostigmine and the other cholinesterase inhibitors can intensify transmission at virtually all junctions where ACh is the transmitter. In sufficient doses, cholinesterase inhibitors can produce skeletal muscle

Figure 15-2 Hydrolysis of acetylcholine by cholinesterase.

Figure 15-3 Inhibition of cholinesterase by reversible and “irreversible” inhibitors. (See text for details.)

132

stimulation, activation of muscarinic receptors, ganglionic stimulation, and activation of cholinergic receptors in the central nervous system (CNS). However, when used *therapeutically*, cholinesterase inhibitors usually affect only muscarinic receptors on organs and nicotinic receptors of the neuromuscular junction (NMJ). Ganglionic transmission and CNS function are usually unaltered.

16.1.1.3.1 Muscarinic Responses.

Muscarinic effects of the cholinesterase inhibitors are identical to those of the direct-acting muscarinic agonists. By preventing breakdown of ACh, cholinesterase inhibitors can cause increased glandular secretions, increased tone and motility of GI smooth muscle, urinary urgency, bradycardia, bronchial constriction, miosis, and focusing of the lens for near vision.

16.1.1.3.2 Neuromuscular Effects.

The effects of cholinesterase inhibitors on skeletal muscle are dose dependent. At *therapeutic* doses, these drugs *increase* force of contraction. In contrast, *toxic* doses *reduce* force of contraction. Contractile force is reduced because excessive amounts of ACh at the NMJ keep the motor end-plate in a state of constant depolarization, thereby causing depolarizing neuromuscular blockade (see [Chapter 16](#)).

16.1.1.3.3 Central Nervous System.

Effects on the CNS vary with drug concentration. *Therapeutic* levels can produce mild *stimulation*, whereas *toxic* levels *depress* the CNS, including the areas that regulate respiration. However, it must be noted that, for CNS effects to occur, the inhibitor must first penetrate the blood-brain barrier, which some cholinesterase inhibitors can do only when present in very high concentrations.

16.1.1.4 Pharmacokinetics

Neostigmine may be administered orally or by injection (IM, IV, subQ). Because neostigmine carries a positive charge, the drug is poorly absorbed following oral administration. Once absorbed, neostigmine can reach sites of action at the NMJ and peripheral muscarinic receptors, but cannot cross the blood-brain barrier to affect the CNS. Duration of action is 2 to 4 hours. Neostigmine is eliminated by enzymatic degradation: Cholinesterase, the enzyme that neostigmine inhibits, eventually converts neostigmine itself to an inactive product.

16.1.1.5 Therapeutic Uses

16.1.1.5.1 Myasthenia Gravis.

Myasthenia gravis is a major indication for neostigmine and several other reversible cholinesterase inhibitors. Treatment of myasthenia gravis is discussed separately later.

16.1.1.5.2 Reversal of Nondepolarizing Neuromuscular Blockade.

By causing accumulation of ACh at the NMJ, cholinesterase inhibitors can reverse the effects of nondepolarizing neuromuscular blocking agents (eg, pancuronium). This ability has two clinical applications: (1) reversal of neuromuscular blockade in postoperative patients and (2) treatment of overdose with a nondepolarizing neuromuscular blocker. When neostigmine is used to treat neuromuscular blocker overdose, artificial respiration must be maintained until muscle function has fully recovered. At the doses employed to reverse neuromuscular blockade, neostigmine is likely to elicit substantial muscarinic responses. If necessary, these can be reduced with atropine. It is important to note that cholinesterase inhibitors cannot be employed to counteract the effects of succinylcholine, a *depolarizing* neuromuscular blocker.

16.1.1.6 Adverse Effects

16.1.1.6.1 Excessive Muscarinic Stimulation.

Accumulation of ACh at muscarinic receptors can result in excessive salivation, increased gastric secretions, increased tone and motility of the GI tract, urinary urgency, bradycardia, sweating, miosis, and spasm of accommodation (focusing of the lens for near vision). If necessary, these responses can be suppressed with atropine.

16.1.1.6.2 Neuromuscular Blockade.

If administered in toxic doses, cholinesterase inhibitors can cause accumulation of ACh in amounts sufficient to produce depolarizing neuromuscular blockade. Paralysis of respiratory muscles can be fatal.

16.1.1.7 Precautions and Contraindications

Most of the precautions and contraindications regarding the cholinesterase inhibitors are the same as those for the direct-acting muscarinic agonists. These include (1) obstruction of the GI tract, (2) obstruction of the urinary tract, (3) peptic ulcer disease, (4) asthma, (5) coronary

insufficiency, and (6) hyperthyroidism. The rationales underlying these precautions are discussed in [Chapter 14](#). In addition to precautions related to muscarinic stimulation, cholinesterase inhibitors are contraindicated for patients receiving succinylcholine.

16.1.1.8 Drug Interactions

16.1.1.8.1 Muscarinic Antagonists.

The effects of cholinesterase inhibitors at muscarinic receptors are opposite to those of atropine (and other muscarinic antagonists). Consequently, cholinesterase inhibitors can be used to overcome excessive muscarinic blockade caused by atropine. Conversely, atropine can be used to reduce excessive muscarinic stimulation caused by cholinesterase inhibitors.

16.1.1.8.2 Nondepolarizing Neuromuscular Blockers.

By causing accumulation of ACh at the NMJ, cholinesterase inhibitors can reverse muscle relaxation induced with pancuronium and other nondepolarizing neuromuscular blocking agents.

16.1.1.8.3 Depolarizing Neuromuscular Blockers.

Cholinesterase inhibitors do not reverse the muscle-relaxant effects of succinylcholine, a depolarizing neuromuscular blocker. In fact, because cholinesterase inhibitors will decrease the breakdown of succinylcholine by cholinesterase, cholinesterase inhibitors will actually *intensify* neuromuscular blockade caused by succinylcholine.

16.1.1.9 Acute Toxicity

16.1.1.9.1 Symptoms.

Overdose with cholinesterase inhibitors causes *excessive muscarinic stimulation* and *respiratory depression*. (Respiratory depression results from a combination of depolarizing neuromuscular blockade and CNS depression.) The state produced by cholinesterase inhibitor poisoning is sometimes referred to as *cholinergic crisis*.

16.1.1.9.2 Treatment.

Intravenous *atropine* can alleviate the muscarinic effects of cholinesterase inhibition. Respiratory depression from cholinesterase inhibitors cannot be managed with drugs. Rather,

treatment consists of mechanical ventilation with oxygen. Suctioning may be necessary if atropine fails to suppress bronchial secretions.

16.1.1.10 Preparations, Dosage, and Administration

16.1.1.10.1 Preparations.

Neostigmine [Prostigmin] is available as two salts: *neostigmine bromide* (for oral use) and *neostigmine methylsulfate* (for IM, IV, and subQ use). Neostigmine bromide is available in 15-mg tablets. Neostigmine methylsulfate is available in solution (0.25, 0.5, and 1 mg/mL).

133

16.1.1.10.2 Dosage and Administration.

134

Dosages for *myasthenia gravis* are highly individualized, ranging from 15 to 375 mg/day administered PO in divided doses every 3 to 4 hours. It is important to note that oral doses are much higher than parenteral doses.

To treat *poisoning by nondepolarizing neuromuscular blockers*, the initial dose is 0.5 to 2.0 mg administered by slow IV injection. Additional doses totaling a maximum of 5 mg may be given as required.

16.1.2 Other Reversible Cholinesterase Inhibitors

16.1.2.1 Physostigmine

The basic pharmacology of physostigmine is identical to that of neostigmine—except that physostigmine readily crosses membranes whereas neostigmine does not. Why? Because, in contrast to neostigmine, physostigmine is *not* a quaternary ammonium compound and hence does *not* carry a charge. Because physostigmine is uncharged, the drug crosses membranes with ease.

Physostigmine is the drug of choice for treating *poisoning by atropine and other drugs that cause muscarinic blockade* (eg, antihistamines, tricyclic antidepressants, phenothiazine antipsychotics). Physostigmine counteracts antimuscarinic poisoning by causing ACh to build up at muscarinic junctions. The accumulated ACh competes with the muscarinic blocker for receptor binding, and thereby reverses receptor blockade. Physostigmine is preferred to neostigmine for antimuscarinic poisoning because, lacking a charge, physostigmine is able to cross the blood-brain barrier to reverse muscarinic blockade in the CNS. The usual dose to treat antimuscarinic poisoning is 2 mg given by IM or slow IV injection.

16.1.2.2 Ambenonium, Edrophonium, and Pyridostigmine

These three drugs have pharmacologic effects much like those of neostigmine, our prototype cholinesterase inhibitor. One of these drugs—edrophonium—is noteworthy for its very brief duration of action. All three drugs are used for *myasthenia gravis*. Routes of administration and indications are summarized in [Table 15-1](#).

16.1.2.3 Drugs for Alzheimer's Disease

Four cholinesterase inhibitors—*donepezil* [Aricept], *galantamine* [Razadyne], *rivastigmine* [Exelon], and *tacrine* [Cognex]—are approved for Alzheimer's disease, although one of them—tacrine—is rarely used. With all four, benefits derive from inhibiting cholinesterase in the CNS. These drugs are discussed in [Chapter 22](#).

16.2 “IRREVERSIBLE” CHOLINESTERASE INHIBITORS

The “irreversible” cholinesterase inhibitors are highly toxic. These agents are employed primarily as *insecticides*. During World War II, huge quantities of irreversible cholinesterase inhibitors were produced for possible use as *nerve agents*, but were never deployed. Today, there is concern that these agents might be employed as weapons of terrorism. The only clinical indication for the irreversible inhibitors is *glaucoma*.

TABLE 15-1 Clinical Applications of Cholinesterase Inhibitors

		Myasthenia Gravis				Reversal of Nondepolarizing Neuromuscular Blockade	Antidote to Poisoning by Muscarinic Antagonists	Alzheimer's Disease
Generic Name [Trade Name]	Routes	Diagnosis	Treatment	Glaucoma				
Reversible Inhibitors								
Neostigmine [Prostigmin]	PO, IM, IV, subQ		✓			✓		
Amibenonium [Mytelase]	PO		✓					
Pyridostigmine [Mestinon]	PO, IV		✓			✓

134

16.2.1 Basic Pharmacology

16.2.1.1 Chemistry

All irreversible cholinesterase inhibitors contain an atom of *phosphorus* ([Fig. 15-4](#)). Because of this phosphorus atom, the irreversible inhibitors are known as *organophosphate* cholinesterase inhibitors.

Almost all irreversible cholinesterase inhibitors are *highly lipid soluble*. As a result, these drugs are readily absorbed from all routes of administration. They can even be absorbed directly through the skin. Easy absorption, coupled with high toxicity, is what makes these drugs good insecticides—and gives them the potential for use as agents of chemical warfare. Once absorbed, the organophosphate inhibitors have ready access to all tissues and organs, including the CNS.

16.2.1.2 Mechanism of Action

The irreversible cholinesterase inhibitors bind to the active center of cholinesterase, thereby preventing the enzyme from hydrolyzing ACh. Although these drugs can be split from ChE, the splitting reaction takes place *extremely* slowly (see [Fig. 15-3C](#)). Hence, under normal conditions, their binding to ChE can be considered irreversible. Because binding is permanent, effects persist until new molecules of cholinesterase can be synthesized.

Although we normally consider the bond between irreversible inhibitors and cholinesterase permanent, this bond can, in fact, be broken. To break the bond, and thereby reverse the inhibition of cholinesterase, we must administer *pralidoxime* (see below).

16.2.1.3 Pharmacologic Effects

The irreversible cholinesterase inhibitors produce essentially the same spectrum of effects as the reversible inhibitors. The principal difference is that responses to irreversible inhibitors last a long time, whereas responses to reversible inhibitors are brief.

16.2.1.4 Therapeutic Uses

The irreversible cholinesterase inhibitors have only one indication: treatment of *glaucoma*. And for that indication, only one drug—echothiophate—is available. The limited indications for these drugs should be no surprise given their potential for toxicity. The use of echothiophate for glaucoma is discussed in [Chapter 103](#) (Drugs for the Eye).

16.2.2 Toxicology

16.2.2.1 Sources of Poisoning.

Poisoning by organophosphate cholinesterase inhibitors is not uncommon. Agricultural workers have been poisoned by accidental ingestion of organophosphate insecticides and by absorption of these lipidsoluble compounds through the skin. In addition, because organophosphate insecticides are readily available to the general public, poisoning may occur accidentally or from attempted homicide or suicide. Exposure could also occur if these drugs were used as instruments of warfare or terrorism (see [Chapter 109](#)).

16.2.2.2 Symptoms.

Toxic doses of irreversible cholinesterase inhibitors produce *cholinergic crisis*, a condition characterized by *excessive muscarinic stimulation and depolarizing neuromuscular blockade*. Overstimulation of muscarinic receptors results in profuse secretions from salivary and bronchial glands, involuntary urination and defecation, laryngospasm, and bronchoconstriction. Neuromuscular blockade can result in paralysis, followed by death from apnea. Convulsions of CNS origin precede paralysis and apnea.

16.2.2.3 Treatment.

Treatment involves the following: (1) mechanical ventilation using oxygen, (2) giving *atropine* to reduce muscarinic stimulation, (3) giving *pralidoxime* to reverse inhibition of cholinesterase (primarily at the NMJ), and (4) giving *diazepam* to suppress convulsions.

16.2.2.4 Pralidoxime.

Pralidoxime is a specific antidote to poisoning by the irreversible (organophosphate) cholinesterase inhibitors; the drug is *not* effective against poisoning by reversible cholinesterase inhibitors. In poisoning by irreversible inhibitors, benefits derive from causing the inhibitor to dissociate from the active center of cholinesterase. Reversal is most effective at the NMJ. The drug is much less effective at reversing cholinesterase inhibition at muscarinic and ganglionic sites. Furthermore, since pralidoxime is a quaternary ammonium compound, it cannot cross the blood-brain barrier, and therefore cannot reverse cholinesterase inhibition in the CNS.

To be effective, pralidoxime must be administered soon after organophosphate poisoning has occurred. If too much time elapses, a process called *aging* takes place. In this process, the bond between the organophosphate inhibitor and cholinesterase increases in strength. Once aging has

occurred, pralidoxime is unable to cause the inhibitor to dissociate from the enzyme. The time required for aging depends on the agent involved. For example, with a nerve agent called *soman*,

Figure 15-4 Structural formulas of “irreversible” cholinesterase inhibitors. Note that irreversible cholinesterase inhibitors contain an atom of phosphorus. Because of this atom, these drugs are known as organophosphate cholinesterase inhibitors. With the exception of echothiophate, all of these drugs are highly lipid soluble, and therefore move throughout the body with ease.

aging occurs in just 2 minutes. In contrast, with a nerve agent called *tabun* (see [Fig. 15-4](#)), aging requires 13 hours.

The usual dose for pralidoxime is 1 to 2 gm administered IV or IM. Intravenous doses should be infused slowly (over 20 to 30 minutes) to avoid hypertension. For prolonged treatment, dosing can be repeated every hour, or the drug can be given by continuous infusion (500 mg/hr).

Pralidoxime is available alone under the trade name *Protopam*, and in combination with atropine under the trade name *DuoDote*.

16.3 MYASTHENIA GRAVIS

16.3.1 Pathophysiology

Myasthenia gravis (MG) is a neuromuscular disorder characterized by fluctuating muscle weakness and a predisposition to rapid fatigue. Common symptoms include ptosis (drooping

eyelids), difficulty swallowing, and weakness of skeletal muscles. Patients with severe MG may have difficulty breathing owing to weakness of the muscles of respiration.

Symptoms of MG result from an autoimmune process in which the patient's immune system produces antibodies that attack nicotinic_M receptors on skeletal muscle. As a result, the number of functional receptors at the NMJ is reduced by 70% to 90%, thereby causing muscle weakness.

16.3.2 Treatment with Cholinesterase Inhibitors

16.3.2.1 Beneficial Effects.

Reversible cholinesterase inhibitors (eg, neostigmine) are the mainstay of therapy. By preventing ACh inactivation, anticholinesterase agents can intensify the effects of ACh released from motor neurons, and can thereby increase muscle strength. Cholinesterase inhibitors do not cure MG. Rather, they only produce symptomatic relief, and hence patients usually need therapy lifelong.

When working with a hospitalized patient, keep in mind that muscle strength may be insufficient to permit swallowing. Accordingly, you should assess the ability to swallow before giving oral medications. Assessment is accomplished by giving the patient a few sips of water. If the patient is unable to swallow the water, parenteral medication must be substituted for oral medication.

16.3.2.2 Side Effects.

Because cholinesterase inhibitors can inhibit acetylcholinesterase at any location, these drugs will cause ACh to accumulate at muscarinic junctions as well as at NMJs. If muscarinic responses are excessive, atropine may be given to suppress them. However, atropine should not be employed *routinely*. Why? Because the drug can mask the early signs (eg, excessive salivation) of overdose with anticholinesterase agents.

16.3.2.3 Dosage Adjustment.

In the treatment of MG, establishing an optimal dosage for cholinesterase inhibitors can be a challenge. Dosage determination is accomplished by administering a small initial dose followed by additional small doses until an optimal level of muscle function has been achieved. Important signs of improvement include increased ease of swallowing and increased ability to raise the eyelids. You can help establish a correct dosage by keeping records of (1) times of drug

administration, (2) times at which fatigue occurs, (3) the state of muscle strength before and after drug administration, and (4) signs of excessive muscarinic stimulation.

To maintain optimal responses, patients must occasionally modify dosage themselves. To do this, they must be taught to recognize signs of undermedication (ptosis, difficulty in swallowing) and signs of overmedication (excessive salivation and other muscarinic responses). Patients may also need to modify dosage in anticipation of exertion. For example, they may find it necessary to take supplementary medication 30 to 60 minutes prior to such activities as eating and shopping.

Usual adult dosages for the three agents used to treat myasthenia gravis are

- *Ambenonium*—15 to 100 mg/day in divided doses
- *Neostigmine*—15 to 375 mg/day in divided doses
- *Pyridostigmine*—60 to 1500 mg/day in divided doses

16.3.2.4 Myasthenic Crisis and Cholinergic Crisis.

16.3.2.4.1 Myasthenic Crisis.

Patients who are inadequately medicated may experience myasthenic crisis, a state characterized by extreme muscle weakness (caused by insufficient ACh at the NMJ). Left untreated, myasthenic crisis can result in death from paralysis of the muscles of respiration. A cholinesterase inhibitor (eg, neostigmine) is used to relieve the crisis.

16.3.2.4.2 Cholinergic Crisis.

As noted, overdose with a cholinesterase inhibitor can produce cholinergic crisis. Like myasthenic crisis, cholinergic crisis is characterized by extreme muscle weakness or frank paralysis. In addition, cholinergic crisis is accompanied by signs of excessive muscarinic stimulation. Treatment consists of respiratory support plus atropine. The offending cholinesterase inhibitor should be withheld until muscle strength has returned.

16.3.2.4.3 Distinguishing Myasthenic Crisis from Cholinergic Crisis.

Because myasthenic crisis and cholinergic crisis share similar symptoms (muscle weakness or paralysis), but are treated very differently, it is essential to distinguish between them. A history of medication use or signs of excessive muscarinic stimulation are usually sufficient to permit a differential diagnosis. If these clues are inadequate, the differential diagnosis can be

made by administering a challenging dose of *edrophonium*, an ultrashort-acting cholinesterase inhibitor. If edrophonium-induced elevation of ACh levels alleviates symptoms, the crisis is myasthenic. Conversely, if edrophonium intensifies symptoms, the crisis is cholinergic. Since the symptoms of cholinergic crisis will be made even worse by edrophonium, atropine and oxygen should be immediately available whenever edrophonium is used for this test.

16.3.2.5 Use of Identification by the Patient.

Because of the possibility of experiencing either myasthenic crisis or cholinergic crisis, and because both crises can be fatal, patients with MG should be encouraged to wear a Medic Alert bracelet or some other form of identification to inform emergency medical personnel of their condition.

136

16.3.2.5.1

KEY POINTS

- Cholinesterase inhibitors prevent breakdown of ACh by acetylcholinesterase, causing ACh to accumulate in synapses, which in turn causes activation of muscarinic receptors, nicotinic receptors in ganglia and the NMJ, and cholinergic receptors in the CNS.
- The major use of reversible cholinesterase inhibitors is treatment of myasthenia gravis. Benefits derive from accumulation of ACh at the NMJ.
- Secondary uses for reversible cholinesterase inhibitors are reversal of nondepolarizing neuromuscular blockade and treatment of glaucoma, Alzheimer's disease, and poisoning by muscarinic antagonists.
- Because physostigmine crosses membranes easily, this drug is the preferred cholinesterase inhibitor for treating poisoning by muscarinic antagonists.
- Irreversible cholinesterase inhibitors, also known as organophosphate cholinesterase inhibitors, are used primarily as insecticides. The only indication for these potentially toxic drugs is glaucoma.
- Most organophosphate cholinesterase inhibitors are highly lipid soluble. As a result, they can be absorbed directly through the skin and distribute easily to all tissues and organs.
- Overdose with cholinesterase inhibitors produces cholinergic crisis, characterized by depolarizing neuromuscular blockade plus signs of excessive muscarinic stimulation

137

(hypersalivation, tearing, sweating, bradycardia, involuntary urination and defecation, miosis, and spasm of accommodation). Death results from respiratory depression.

- Poisoning by *reversible* cholinesterase inhibitors is treated with atropine (to reverse muscarinic stimulation) plus mechanical ventilation.
- Poisoning by *organophosphate* cholinesterase inhibitors is treated with atropine, mechanical ventilation, pralidoxime (to reverse inhibition of cholinesterase, primarily at the NMJ), and diazepam (to suppress seizures).

16.3.2.5.2

Summary of Major Nursing Implications*

Tacrine

16.3.2.5.2....

Preadministration Assessment

16.3.2.5.2....

Therapeutic Goal

Cholinesterase inhibitors are used to treat myasthenia gravis, glaucoma, Alzheimer's disease, and poisoning by muscarinic antagonists and to reverse nondepolarizing neuromuscular blockade. Applications of individual agents are indicated in [Table 15-1](#).

16.3.2.5.2....

Baseline Data

16.3.2.5.2....

Myasthenia Gravis.

Determine the extent of neuromuscular dysfunction by assessing muscle strength, fatigue, ptosis, and ability to swallow.

16.3.2.5.2....

Identifying High-Risk Patients

Cholinesterase inhibitors are *contraindicated* for patients with mechanical obstruction of the intestine or urinary tract. Exercise *caution* in patients with peptic ulcer disease, bradycardia, asthma, or hyperthyroidism.

16.3.2.5.2....

Implementation: Administration

16.3.2.5.2....

Routes

These drugs are given orally, topically (PO, transdermal), and parenterally (IM, IV, subQ). Routes for individual agents are summarized in [Table 15-1](#).

16.3.2.5.2....

Administration and Dosage in Myasthenia Gravis

16.3.2.5.2....

Administration.

Assess the patient's ability to swallow before giving oral medication. If swallowing is impaired, substitute a parenteral medication.

16.3.2.5.2....	Optimizing Dosage. Monitor for therapeutic responses (see below) and adjust the dosage accordingly. Teach patients to distinguish between insufficient and excessive dosing so they can participate effectively in dosage adjustment.	
16.3.2.5.2....	Reversing Nondepolarizing Neuromuscular Blockade To reverse toxicity from overdose with a nondepolarizing neuromuscular blocking agent (eg, pancuronium), administer pyridostigmine or edrophonium IV. Support respiration until muscle strength has recovered fully.	
16.3.2.5.2....	Treating Muscarinic Antagonist Poisoning <i>Physostigmine</i> is the drug of choice for this indication. The usual dose is 2 mg administered by IM or slow IV injection.	137
16.3.2.5.2....	Implementation: Measures to Enhance Therapeutic Effects	138
16.3.2.5.2....	Myasthenia Gravis	
16.3.2.5.2....	Promoting Compliance. Inform patients that MG is not usually curable, and hence treatment is lifelong. Encourage patients to take their medication as prescribed and to play an active role in dosage adjustment.	
16.3.2.5.2....	Using Identification. Because patients with MG are at risk of fatal complications (cholinergic crisis, myasthenic crisis), encourage them to wear a Medic Alert bracelet or similar identification to inform emergency medical personnel of their condition.	

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Myasthenia Gravis.

Monitor and record (1) times of drug administration; (2) times at which fatigue occurs; (3) state of muscle strength, ptosis, and ability to swallow; and (4) signs of excessive muscarinic stimulation. Dosage is increased or decreased based on these observations.

Monitor for *myasthenic crisis* (extreme muscle weakness, paralysis of respiratory muscles), which can occur when cholinesterase inhibitor dosage is insufficient. Manage with respiratory support and increased dosage.

Be certain to distinguish myasthenic crisis from cholinergic crisis. How? By observing for signs of excessive muscarinic stimulation, which will accompany cholinergic crisis but not myasthenic crisis. If necessary, these crises can be differentiated by giving *edrophonium*, which reduces symptoms of myasthenic crisis and intensifies symptoms of cholinergic crisis.

Minimizing Adverse Effects

Excessive Muscarinic Stimulation.

Accumulation of ACh at muscarinic receptors can cause profuse salivation, increased tone and motility of the gut, urinary urgency, sweating, miosis, spasm of accommodation, bronchoconstriction, and bradycardia. **Inform patients about signs of excessive muscarinic stimulation and advise them to notify the prescriber if these occur.** Excessive muscarinic responses can be managed with *atropine*.

Cholinergic Crisis.

This condition results from cholinesterase inhibitor overdose. Manifestations are skeletal muscle paralysis (from depolarizing neuromuscular blockade) and signs of excessive muscarinic stimulation (eg, salivation, sweating, miosis, bradycardia).

Manage with mechanical ventilation and atropine. Cholinergic crisis must be distinguished from myasthenic crisis.

* Patient education information is highlighted as **blue text**.

¹⁷CHAPTER 16 Drugs That Block Nicotinic Cholinergic Transmission: Neuromuscular Blocking Agents and Ganglionic Blocking Agents

The drugs discussed in this chapter act through blockade of nicotinic cholinergic receptors. The *neuromuscular* blocking agents block nicotinic_M receptors at the neuromuscular junction. The *ganglionic* blocking agents block nicotinic_N receptors in autonomic ganglia. The neuromuscular blockers have important clinical applications. In contrast, the ganglionic blockers, once used widely for hypertension, have been largely replaced by newer drugs.

^{17.1} NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking agents prevent acetylcholine from activating nicotinic_M receptors on skeletal muscles, and thereby cause muscle relaxation. These drugs are given to produce muscle relaxation during surgery, endotracheal intubation, mechanical ventilation, and other procedures.

^{17.1.1} Control of Muscle Contraction

Before we discuss the neuromuscular blockers, we need to review physiologic control of muscle contraction. In particular, we need to understand *excitation-contraction coupling*, the process by which an action potential in a motor neuron leads to contraction of a muscle.

^{17.1.1.1} Basic Concepts: Polarization, Depolarization, and Repolarization

The concepts of *polarization*, *depolarization*, and *repolarization* are important to understanding both muscle contraction and the neuromuscular blocking drugs. In *resting* muscle there is uneven distribution of electrical charge across the inner and outer surfaces of the cell membrane. As shown in [Figure 16-1](#), positive charges cover the outer surface of the membrane and negative charges cover the inner surface. Because of this uneven charge distribution, the resting membrane is said to be *polarized*.

When the membrane *depolarizes*, positive charges move from outside to inside. So many positive charges move inward that the inside of the membrane becomes more positive than the outside (see [Fig. 16-1](#)).

Under physiologic conditions, depolarization of the muscle membrane is followed almost instantaneously by *repolarization*. Repolarization is accomplished by pumping positively

charged ions out of the cell. Repolarization restores the original resting membrane state, with positive charges on the outer surface and negative charges on the inner surface.

17.1.1.2 Steps in Muscle Contraction

The steps leading to muscle contraction are summarized in [Figure 16-2](#). The process begins with the arrival of an action potential at the terminal of a motor neuron, causing release of acetylcholine (ACh) into the subneural space. Acetylcholine then binds reversibly to nicotinic_M receptors on the motor end-plate (a specialized region of the muscle membrane that contains the receptors for ACh) and causes the end-plate to *depolarize*. This depolarization initiates a muscle action potential (ie, a wave of depolarization that spreads rapidly over the entire muscle membrane), which in turn triggers the release of calcium from the sarcoplasmic reticulum (SR) of the muscle. This calcium permits the interaction of actin and myosin, thereby causing contraction. Very rapidly, ACh dissociates from the motor end-plate, the motor end-plate repolarizes, the muscle membrane repolarizes, and calcium is taken back up into the SR. Because there is no longer any calcium available to support the interaction of actin and myosin, the muscle relaxes.

Sustained muscle contraction requires a continuous series of motor neuron action potentials. These action potentials

139

140

Figure 16-1 The depolarization-repolarization cycle of the motor end-plate and muscle membrane. (ACh acetylcholine.)

Figure 16-2 **Steps in excitation-contraction coupling.** (ACh acetylcholine.)

140

cause repeated release of ACh, which causes repeated activation of nicotinic receptors on the motor end-plate. As a result, the end-plate goes through repeating cycles of depolarization and repolarization, which results in sufficient release of calcium to sustain contraction. If for some reason the motor end-plate fails to repolarize—that is, if the end-plate remains in a *depolarized* state—the signal for calcium release will stop, calcium will undergo immediate reuptake into the SR, and contraction will cease.

141

17.1.2 Classification of Neuromuscular Blockers

The neuromuscular blockers can be classified according to *mechanism of action* and *time course of action*. When classified by mechanism of action, these drugs fall into two categories:

nondepolarizing agents and depolarizing agents. When classified by time course, these drugs fall into three categories: long acting, intermediate acting, and ultrashort acting.

17.1.3 Nondepolarizing Neuromuscular Blockers I: Tubocurarine

Tubocurarine is the oldest nondepolarizing neuromuscular blocker and will serve as our prototype for the group. However, please note that, although tubocurarine will be our prototype, the drug is no longer used in the United States. Why? Because it has been replaced by newer nondepolarizing blockers that lack certain undesirable properties of tubocurarine (see below).

The pharmacologic powers of tubocurarine were known to primitive hunters long before coming to the attention of modern scientists. Tubocurarine is one of several active principles found in *curare*, an arrow poison used for hunting by South American Indians. When shot into a monkey or other small animal, curare-tipped arrows cause relaxation (paralysis) of skeletal muscles. Death results from paralyzing the muscles of respiration.

The clinical utility of tubocurarine is based on the same action that is useful in hunting: production of skeletal muscle relaxation. Relaxation of skeletal muscles is helpful in patients undergoing surgery, endotracheal intubation, mechanical ventilation, and other procedures.

17.1.3.1 Chemistry

Tubocurarine and all other neuromuscular blocking agents contain a *quaternary nitrogen* atom ([Fig. 16-3](#)). As a result, these drugs always carry a positive charge, and therefore cannot readily cross membranes.

The inability to cross membranes has three clinical consequences. First, neuromuscular blockers cannot be administered orally. Instead, they must all be administered parenterally (almost always IV). Second, these drugs cannot cross the blood-brain barrier, and hence have no effect on the central nervous system (CNS). Third, neuromuscular blockers cannot readily cross the placenta, and hence effects on the fetus are minimal.

17.1.3.2 Mechanism of Action

Tubocurarine acts by competing with ACh for binding to nicotinic_M receptors on the motor end-plate ([Fig. 16-4](#)). Since tubocurarine does not activate these receptors, binding does not result in contraction. Muscle relaxation persists as long as the amount of tubocurarine at the neuromuscular junction (NMJ) is sufficient to prevent receptor occupation by ACh. Muscle

function can be restored by eliminating tubocurarine from the body or by increasing the amount of ACh at the NMJ.

Figure 16-3 Structural formulas of representative neuromuscular blocking agents. Note that all of these agents contain quaternary nitrogen atoms and therefore cross membranes poorly. Consequently, they must be administered parenterally and have little effect on the central nervous system or the developing fetus.

141

17.1.3.3 Pharmacologic Effects

142

17.1.3.3.1 Muscle Relaxation.

The primary effect of tubocurarine is relaxation of skeletal muscle, causing a state known as *flaccid paralysis*.

Although tubocurarine can paralyze all skeletal muscles, not all muscles are affected at once. The first to become paralyzed are the levator muscle of the eyelid and the muscles of

mastication. Paralysis occurs next in muscles of the limbs, abdomen, and glottis. The last muscles affected are the muscles of respiration—the intercostals and diaphragm.

17.1.3.3.2 Hypotension.

Tubocurarine can lower blood pressure by two mechanisms: (1) release of histamine and (2) partial ganglionic blockade. Histamine lowers blood pressure by causing vasodilation. Ganglionic blockade lowers blood pressure by decreasing sympathetic tone to arterioles and veins. Tubocurarine suppresses ganglionic transmission by causing partial blockade of nicotinic_N receptors in autonomic ganglia.

17.1.3.3.3 Central Nervous System.

As noted, tubocurarine and the other neuromuscular blocking agents are unable to cross the blood-brain barrier. Consequently, these drugs have no effect on the CNS. Please note: *Neuromuscular blockers do not diminish consciousness or perception of pain—even when administered in doses that produce complete paralysis.*

17.1.3.4 Pharmacokinetics

Paralysis develops rapidly (in minutes) following IV injection. Peak effects persist 35 to 60 minutes and then decline. Complete recovery may take several *hours*. Tubocurarine is eliminated by a combination of hepatic metabolism and renal excretion.

17.1.3.5 Therapeutic Uses

Before being withdrawn from the market, tubocurarine was used for muscle relaxation during surgery, mechanical ventilation, endotracheal intubation, and electroconvulsive therapy. These applications are discussed later under *Therapeutic Uses of Neuromuscular Blockers*.

17.1.3.6 Adverse Effects

The principal adverse effects of tubocurarine concern the respiratory and cardiovascular systems.

17.1.3.6.1 Respiratory Arrest.

Paralysis of respiratory muscles can produce respiratory arrest. Because of this risk, facilities for artificial ventilation must be immediately available. Patients must be monitored closely

and continuously. When tubocurarine is withdrawn, vital signs must be monitored until muscle function has fully recovered.

17.1.3.6.2 Cardiovascular Effects.

As noted, tubocurarine can cause *hypotension* secondary to histamine release and partial ganglionic blockade. In addition, the drug can cause *bradycardia*, *dysrhythmias*, and *cardiac arrest*. The mechanism underlying these latter effects is not clear.

17.1.3.7 Precautions and Contraindications

17.1.3.7.1 Myasthenia Gravis.

Neuromuscular blocking agents must be used with special care in patients with myasthenia gravis, a condition characterized by skeletal muscle weakness. The cause of weakness is a reduction in the number of nicotinic_M receptors on the motor end-plate. Because receptor number is reduced, neuromuscular blockade occurs readily. Also, doses that would have a minimal effect on others can produce complete paralysis in patients with myasthenia.

Figure 16-4 Mechanism of nondepolarizing neuromuscular blockade. Tubocurarine competes with acetylcholine (ACh) for binding to nicotinic_M receptors on the motor end-plate. Binding of tubocurarine does not depolarize the end-plate, and therefore does not cause contraction. At the same time, the presence of tubocurarine prevents ACh from binding to the receptor, hence contraction is prevented.

Accordingly, dosing must be done with great care. Myasthenia gravis and its treatment are discussed in [Chapter 15](#).

17.1.3.7.2 Electrolyte Disturbances.

Responses to tubocurarine can be altered by electrolyte abnormalities. For example, low potassium levels can enhance paralysis, whereas high potassium levels can reduce paralysis. Because electrolyte status can influence the depth of neuromuscular blockade, it is important to maintain normal electrolyte balance.

17.1.3.8 Drug Interactions

Tubocurarine can interact with many other drugs. Interactions of primary interest are discussed below.

17.1.3.8.1 General Anesthetics.

All inhalation anesthetics produce some degree of skeletal muscle relaxation, and can thereby enhance the actions of tubocurarine and other neuromuscular blockers. Consequently, when general anesthetics and neuromuscular blockers are combined (as they often are), the dosage of the neuromuscular blocker should be reduced to avoid excessive neuromuscular blockade.

17.1.3.8.2 Antibiotics.

Several antibiotics can intensify responses to neuromuscular blockers. Among them are aminoglycosides (eg, gentamicin), tetracyclines, and certain other nonpenicillin antibiotics.

17.1.3.8.3 Cholinesterase Inhibitors.

Cholinesterase inhibitors can *decrease* the effects of tubocurarine and other *nondepolarizing* neuromuscular blockers. (As discussed later in the chapter, cholinesterase inhibitors have the opposite effect on responses to succinylcholine, a *depolarizing* neuromuscular blocker.)

How do cholinesterase inhibitors decrease the effects of tubocurarine? Recall that nondepolarizing blockers compete with ACh for binding to nicotinic_M receptors. By decreasing the degradation of ACh, cholinesterase inhibitors increase the amount of ACh available to compete with tubocurarine. As more ACh (and less tubocurarine) occupies nicotinic_M receptors, the degree of neuromuscular blockade declines.

The ability of cholinesterase inhibitors to decrease responses to nondepolarizing neuromuscular blockers has two clinical applications: (1) management of overdose with a nondepolarizing neuromuscular blocker and (2) reversal of neuromuscular blockade following surgery and other procedures.

17.1.3.9 Toxicology

Overdose with tubocurarine has three major effects: prolonged apnea, massive histamine release, and cardiovascular collapse. Apnea is managed with respiratory support plus a cholinesterase inhibitor (eg, neostigmine) to reverse neuromuscular blockade. Antihistamines are given to counteract released histamine. Cardiovascular toxicity must be assessed and treated as indicated.

17.1.3.10 Preparations, Dosage, and Administration

Tubocurarine is no longer used in the United States. For information on dosage and administration, refer to the sixth edition of this book.

17.1.4 Nondepolarizing Neuromuscular Blockers II: Others

Only five nondepolarizing blockers are currently approved for use in the United States. Several others—doxacurium [Nuromax], mivacurium [Mivacron], metocurine [Metubine], pipecuronium [Arduan], and tubocurarine—have recently been removed from the market.

Like tubocurarine, all neuromuscular blockers interact with acetylcholine at nicotinic_M receptors on the motor end-plate. Differences among the drugs relate primarily to time course of action ([Table 16-1](#)) and cardiovascular effects. With all of these agents, respiratory depression secondary to neuromuscular blockade is the major concern. Respiratory depression can be reversed by giving a cholinesterase inhibitor.

17.1.4.1 Long-Acting Agents

Tubocurarine and all other long-acting agents—*doxacurium* [Nuromax], *metocurine* [Metubine], and *pipecuronium* [Arduan]—have been removed from the market. For information on these drugs, refer to the sixth edition of this book.

17.1.4.2 Intermediate-Acting Agents

17.1.4.2.1 Atracurium.

Atracurium [Tracrium] is approved for muscle relaxation during surgery, intubation, and mechanical ventilation. The drug can cause hypotension secondary to histamine release. Like succinylcholine, atracurium is eliminated primarily by *plasma cholinesterases*, not by the liver or kidneys. Hence, atracurium may be desirable for patients with renal or hepatic dysfunction, since these disorders will not prolong the drug's effects.

143

144

TABLE 16-1 Neuromuscular Blockers: Time Course of Action*

Generic Name	Route	Time to Maximum Paralysis (min)	Duration of Effective Paralysis (min)	Time to Nearly Full Spontaneous Recovery†
Long Acting				
Tubocurarine‡	IV, IM§	2–5	60–90	Hours
Intermediate Acting				
Atracurium [Tracrium]	IV	2–5	20–35	60–70 min
Cisatracurium [Nimbex]	IV	2–5	20–35	—
Pancuronium	IV	3–4	35–45	60–70 min
Rocuronium [Zemuron]	IV	1–3	20–40	—
Vecuronium [Norcuron]	IV	3–5	25–30	45–60 min
Ultrashort Acting				
Succinylcholine [Anectine, Quelicin]	IV, IM§	1	4–6	—

* Time course of action can vary widely with dosage and route of administration. The values presented are for an average adult dose administered as a single IV injection.

- † Because spontaneous recovery can take a long time, recovery from the *nondepolarizing* agents (all of the drugs listed except succinylcholine) is often accelerated by giving a cholinesterase inhibitor.
- ‡ Tubocurarine is no longer available in the United States.
- § Intramuscular administration is rare.

17.1.4.2.2 Cisatracurium.

Cisatracurium [Nimbex], a close relative of atracurium, is approved for muscle relaxation during surgery, intubation, and mechanical ventilation. Elimination is by spontaneous degradation, not by hepatic metabolism or renal excretion. Hence, like atracurium, cisatracurium would seem desirable for patients with kidney or liver dysfunction. Histamine release is minimal.

17.1.4.2.3 Pancuronium.

Pancuronium, formerly available as Pavulon, is approved for muscle relaxation during general anesthesia, intubation, and mechanical ventilation. The drug does not cause histamine release, ganglionic blockade, or hypotension. Vagolytic effects may produce tachycardia. Elimination is primarily renal.

17.1.4.2.4 Rocuronium.

Rocuronium [Zemuron] has a rapid onset and intermediate duration of action. The only neuromuscular blocker with a faster onset is succinylcholine. In contrast to succinylcholine, whose effects fade relatively quickly, rocuronium has effects that persist for 20 to 40 minutes. Rocuronium does not cause histamine release. Elimination is by hepatic metabolism. The drug is approved for muscle relaxation during intubation, surgery, and mechanical ventilation.

17.1.4.2.5 Vecuronium.

Vecuronium [Norcuron], an analog of pancuronium, is used for muscle relaxation during intubation and general anesthesia. The drug does not produce ganglionic or vagal block and does not release histamine. Consequently, cardiovascular effects are minimal. Vecuronium is excreted primarily in the bile, and hence paralysis may be prolonged in patients with liver dysfunction. Paralysis may also be prolonged in obese patients.

17.1.4.3 Short-Acting Agent: Mivacurium

Mivacurium [Mivacron] is the shortest acting *nondepolarizing* neuromuscular blocker. The only neuromuscular blocker with a shorter duration is succinylcholine, a *depolarizing* neuromuscular blocker. Paralysis with mivacurium is maximal 2 to 5 minutes after IV injection and persists only 10 to 15 minutes. Like the long-acting neuromuscular blockers, mivacurium is no longer available in the United States.

17.1.5 Depolarizing Neuromuscular Blockers: Succinylcholine

Succinylcholine, an ultrashort-acting drug, is the only depolarizing neuromuscular blocker in clinical use. This drug differs from the nondepolarizing blockers with regard to mechanism of action, mode of elimination, interaction with cholinesterase inhibitors, and management of toxicity.

17.1.5.1 Mechanism of Action

Succinylcholine produces a state known as *depolarizing neuromuscular blockade*. Like acetylcholine, succinylcholine binds to nicotinic_M receptors on the motor end-plate and thereby causes depolarization. This depolarization produces transient muscle contractions (fasciculations). Then, instead of dissociating rapidly from the receptor, succinylcholine remains bound, and thereby prevents the end-plate from repolarizing. That is, succinylcholine maintains the end-plate in a state of *constant depolarization*. Because the end-plate must repeatedly depolarize and repolarize to maintain muscle contraction, succinylcholine's ability to keep the end-plate depolarized causes paralysis (following the brief initial period of contraction). Paralysis persists until plasma levels of succinylcholine decline, thereby allowing the drug to dissociate from its receptors.

17.1.5.2 Pharmacologic Effects

17.1.5.2.1 Muscle Relaxation.

The muscle-relaxant effects of succinylcholine are much like those of tubocurarine: both drugs produce a state of flaccid paralysis. However, despite this similarity, there are two important differences: (1) paralysis from succinylcholine is preceded by transient contractions and (2) paralysis from succinylcholine abates much more rapidly.

17.1.5.2.2 Central Nervous System.

Like tubocurarine, succinylcholine has no effect on the CNS. The drug can produce complete paralysis without decreasing consciousness or the ability to feel pain.

17.1.5.3 Pharmacokinetics

Succinylcholine has an extremely short duration of action. Paralysis peaks about 1 minute after IV injection and fades completely 4 to 10 minutes later.

Paralysis is brief because succinylcholine is rapidly degraded by *pseudocholinesterase*, an enzyme present in plasma. (This enzyme is called pseudocholinesterase to distinguish it from “true” cholinesterase, the enzyme found at synapses where ACh is the transmitter.) Because of its presence in plasma, pseudocholinesterase is also known as *plasma cholinesterase*. In most individuals, pseudocholinesterase is highly active and can eliminate succinylcholine in minutes.

17.1.5.4 Therapeutic Uses

Succinylcholine is used primarily for muscle relaxation during endotracheal intubation, electroconvulsive therapy, endoscopy, and other short procedures. Because of its brief duration, succinylcholine is less desirable than the nondepolarizing blockers for use in prolonged procedures (ie, surgery and mechanical ventilation). Clinical applications are discussed further under *Therapeutic Uses of Neuromuscular Blockers*.

17.1.5.5 Adverse Effects

17.1.5.5.1 Prolonged Apnea in Patients with Low Pseudocholinesterase Activity.

A few people, because of their genetic makeup, produce a form of pseudocholinesterase that has extremely low activity. As a result, they are unable to degrade succinylcholine rapidly. If succinylcholine is given to these people, paralysis can persist for hours, rather than just a few minutes. Not surprisingly, succinylcholine is contraindicated for these individuals.

Patients suspected of having low pseudocholinesterase activity should be tested for this possibility before receiving full succinylcholine doses. Pseudocholinesterase activity can be assessed by direct measurement of a blood sample or by administering a tiny test dose of succinylcholine. If the test dose produces muscle relaxation that is unexpectedly intense and prolonged, pseudocholinesterase activity is probably low.

17.1.5.5.2 Malignant Hyperthermia.

Malignant hyperthermia is a rare and potentially fatal condition that can be triggered by succinylcholine, and by all inhalation anesthetics as well. The condition is characterized by muscle rigidity associated with a profound elevation of body temperature—sometimes to as high as 43°C. Temperature becomes elevated owing to excessive and uncontrolled metabolic activity in muscle, secondary to increased release of calcium from the SR. Left untreated, the condition can rapidly prove fatal. Malignant hyperthermia is a genetically determined reaction that has an incidence of about 1 in 25,000. Individuals with a family history of the reaction should not receive succinylcholine.

Treatment of malignant hyperthermia includes (1) immediate discontinuation of succinylcholine and the accompanying anesthetic, (2) cooling the patient with external ice packs and IV infusion of cold saline, and (3) administering intravenous *dantrolene*, a drug that stops heat generation by acting directly on skeletal muscle to reduce its metabolic activity. 144
145

The pharmacology of dantrolene is discussed in [Chapter 25](#) (Drugs for Muscle Spasm and Spasticity).

17.1.5.5.3 Postoperative Muscle Pain.

Between 10% and 70% of patients receiving succinylcholine experience postoperative muscle pain, most commonly in the neck, shoulders, and back. Pain develops 12 to 24 hours after surgery and may persist several hours or even days. The cause may be the muscle contractions that occur during the initial phase of succinylcholine action.

17.1.5.5.4 Hyperkalemia.

Succinylcholine promotes release of potassium from tissues. Rarely, potassium release is sufficient to cause severe hyperkalemia. Death from cardiac arrest has resulted. Significant hyperkalemia is most likely in patients with major burns, multiple trauma, denervation of skeletal muscle, or upper motor neuron injury. Accordingly, the drug is contraindicated for these patients.

17.1.5.6 Drug Interactions

17.1.5.6.1 Cholinesterase Inhibitors.

These drugs *potentiate* (intensify) the effects of succinylcholine. How? By decreasing the activity of pseudocholinesterase, the enzyme that inactivates succinylcholine. Note that the effect of cholinesterase inhibitors on succinylcholine is opposite to the effect on *nondepolarizing* neuromuscular blockers.

17.1.5.6.2 Antibiotics.

The effects of succinylcholine, like those of tubocurarine, can be intensified by certain antibiotics. Among these are aminoglycosides, tetracyclines, and certain other nonpenicillin antibiotics.

17.1.5.7 Toxicology

Overdose can produce prolonged apnea. Since there is no specific antidote to succinylcholine poisoning, management is purely supportive. Recall that, with tubocurarine overdose, paralysis can be reversed with a cholinesterase inhibitor. Since cholinesterase inhibitors *delay* the degradation of succinylcholine, use of these agents would prolong—not reverse—succinylcholine toxicity.

17.1.5.8 Preparations, Dosage, and Administration

Succinylcholine chloride [Anectine, Quelicin] is available in solution and as a powder. The drug is usually administered IV but can also be given IM. Solutions of succinylcholine are unstable and should be used within 24 hours. Multidose vials are stable for up to 2 weeks.

Dosage must be individualized and depends on the specific application. A typical adult dose for a brief procedure is 0.6 mg/kg, administered as a single IV injection. For prolonged procedures, succinylcholine may be administered by infusion at a rate of 2.5 to 4.3 mg/min.

17.1.6 Therapeutic Uses of Neuromuscular Blockers

The primary applications of the neuromuscular blocking agents are discussed below. No one agent is used for every application.

17.1.6.1 Muscle Relaxation During Surgery

Production of muscle relaxation during surgery offers two benefits. First, relaxation of skeletal muscles, especially those of the abdominal wall, makes the surgeon's work easier. Second, muscle relaxants allow us to decrease the dosage of the general anesthetic, thereby decreasing the risks associated with anesthesia. Before neuromuscular blockers became available, surgical muscle relaxation had to be achieved with the general anesthetic alone, often requiring high levels of anesthetic. (As noted earlier, inhalation anesthetics have muscle relaxant properties of their own.) By combining a neuromuscular blocker with the general anesthetic, we can achieve adequate surgical muscle relaxation with less anesthetic than was possible when paralysis had to be achieved with an anesthetic by itself. By allowing a reduction in anesthetic levels, neuromuscular blockers have decreased the risk of respiratory depression from anesthesia. In addition, because less anesthetic is administered, recovery from anesthesia occurs faster.

Whenever neuromuscular blockers are employed during surgery, it is very, very important that anesthesia be maintained at a level sufficient to produce unconsciousness. Recall that neuromuscular blockers do not enter the CNS, and therefore have no effect on hearing, thinking, or the ability to feel pain; all these drugs do is produce paralysis. Neuromuscular blockers are obviously and definitely not a substitute for anesthesia. It does not require much imagination to appreciate the horror of the surgical patient who is completely paralyzed from neuromuscular blockade yet fully awake because of inadequate anesthesia. Does this really happen? Yes. In fact, it happens in between 0.1% and 0.2% of surgeries in which neuromuscular blockers are used. Clearly, full anesthesia must be provided whenever surgery is performed on a patient who is under neuromuscular blockade.

With the agents in current use, full recovery from surgical neuromuscular blockade takes about an hour. (With the long-acting agents, which are no longer used, recovery could take several hours.) During the recovery period, patients must be monitored closely to ensure adequate ventilation. A patent airway should be maintained until the patient can swallow or speak. Recovery from the effects of *nondepolarizing* neuromuscular blockers (eg, tubocurarine) can be accelerated with a cholinesterase inhibitor.

17.1.6.2 Facilitation of Mechanical Ventilation

Some patients who require mechanical ventilation still have some spontaneous respiratory movements, which can fight the rhythm of the respirator. By suppressing these movements, neuromuscular blocking agents can reduce resistance to ventilation.

When neuromuscular blockers are used to facilitate mechanical ventilation, patients should be treated as if they were awake—even though they appear to be asleep. (Remember that the patient is paralyzed, and hence there is no way to assess state of consciousness.) Because the patient may be fully awake, steps should be taken to ensure comfort at all times. Furthermore, because neuromuscular blockade does not affect hearing, nothing should be said in the patient's presence that might be inappropriate for him or her to hear.

Being fully awake but completely paralyzed can be a stressful and generally horrific experience. Think about it. Accordingly, many clinicians do not recommend routine use of neuromuscular blockers during prolonged mechanical ventilation in intensive care units.

17.1.6.3 Adjunct to Electroconvulsive Therapy

Electroconvulsive therapy is an effective treatment for severe depression (see [Chapter 32](#)).

Benefits derive strictly from the effects of electroshock on the brain; the convulsive movements that can accompany electroshock don't help relieve depression. Since convulsions per se serve no useful purpose, and since electroshock-induced convulsions can be harmful, neuromuscular blockers are now used to prevent convulsive movements during electroshock therapy. Because of its short duration of action, succinylcholine is the preferred neuromuscular blocker for this application.

145

146

17.1.6.4 Endotracheal Intubation

An endotracheal tube is a large catheter that is inserted past the glottis and into the trachea to facilitate ventilation. Gag reflexes can fight tube insertion. By suppressing these reflexes, neuromuscular blockers can make intubation easier. Because of its short duration of action, succinylcholine is the preferred agent for this use.

17.1.6.5 Diagnosis of Myasthenia Gravis

An intermediate-acting neuromuscular blocker can be used to diagnose myasthenia gravis when safer diagnostic procedures have been inconclusive. To diagnose MG, a small test dose of the

blocker is administered. Because the dose is too small to affect individuals who do not have MG, a significant reduction in muscle strength would be diagnostic of MG. If the test dose does decrease strength, neostigmine (a cholinesterase inhibitor) should be administered immediately; the resultant elevation in ACh at the NMJ will reverse neuromuscular blockade. It must be stressed that use of a neuromuscular blocker to diagnose myasthenia gravis is not without risk: If the patient does have MG, the challenging dose may be sufficient to cause pronounced respiratory depression. Consequently, facilities for artificial ventilation must be immediately available.

17.2 GANGLIONIC BLOCKING AGENTS

Ganglionic blocking agents produce a broad spectrum of pharmacologic effects. Because they lack selectivity, ganglionic blockers have limited applications. These drugs are used only to lower blood pressure—and then only under special circumstances. At this time, mecamylamine is the only ganglionic blocker available in the United States.

17.2.1 Mecamylamine

17.2.1.1 Mechanism of Action

Mecamylamine [Inversine] interrupts impulse transmission through ganglia of the autonomic nervous system. The drug blocks transmission by competing with ACh for binding to nicotinic_N receptors in autonomic ganglia. Because the nicotinic_N receptors of sympathetic and parasympathetic ganglia are the same, mecamylamine blocks transmission at *all* autonomic ganglia. By doing so, the drug can, in effect, shut down the entire autonomic nervous system, thereby depriving organs of autonomic regulation.

17.2.1.2 Pharmacologic Effects

Because mecamylamine acts by depriving organs of autonomic regulation, to predict the drug's effects, we need to know how the autonomic nervous system is affecting specific organs when the drug is given. That is, we need to know which branch of the autonomic nervous system is providing the predominant tone to specific organs. By knowing the source of predominant tone to an organ, and by knowing that ganglionic blockade will remove that tone, we can predict the effects that ganglionic blockade will produce.

[Table 16-2](#) indicates (1) the major structures innervated by autonomic nerves, (2) the branch of the autonomic nervous system that provides the predominant tone to those structures, and (3)

the responses to ganglionic blockade. As indicated, *the predominant autonomic tone to most organs is provided by the parasympathetic nervous system*. The sympathetic branch provides the predominant tone only to *sweat glands, arterioles, and veins*.

Since the parasympathetic nervous system provides the predominant tone to most organs, and since the parasympathetic nervous system works through muscarinic receptors to influence organ function, *most responses to ganglionic blockade resemble those produced by muscarinic antagonists*. These responses include dry mouth, blurred vision, photophobia, urinary retention, constipation, tachycardia, and anhidrosis.

In addition to their parasympatholytic effects, ganglionic blockers produce *hypotension*. The mechanism is blockade of sympathetic nerve traffic to arterioles and veins, which results in vasodilation.

17.2.1.3 Pharmacokinetics

Mecamylamine is well absorbed following oral administration. Effects begin within 2 hours and persist up to 12 hours. The drug is lipid soluble and hence crosses the placenta and blood-brain barrier with ease. Mecamylamine is eliminated unchanged in the urine.

17.2.1.4 Therapeutic Use

Mecamylamine is indicated for essential hypertension in selected patients. The drug is reserved for those rare cases in which blood pressure cannot be reduced with more desirable medications.

17.2.1.5 Adverse Effects

Mecamylamine can produce a broad spectrum of undesired effects, all the predictable consequence of generalized inhibition of the autonomic nervous system. Adverse effects fall into two major groups: (1) antimuscarinic effects, caused by parasympathetic blockade; and (2) hypotension, caused largely by sympathetic blockade.

17.2.1.5.1 Antimuscarinic Effects.

Blockade of *parasympathetic* ganglia produces typical antimuscarinic responses: dry mouth, blurred vision, photophobia, urinary retention, constipation, tachycardia, and anhidrosis. Antimuscarinic responses are discussed in detail in [Chapter 14](#).

17.2.1.5.2 Orthostatic Hypotension.

Orthostatic hypotension, defined as a drop in blood pressure when we stand up, is the principal concern with this drug. The mechanism is dilation of veins, which causes blood to “pool” in veins when we move from a recumbent to an upright position. As a result of venous pooling, return of blood to the heart is greatly reduced, causing a reduction in cardiac output and a subsequent fall in blood pressure. Inform patients that orthostatic hypotension can be minimized by moving slowly when assuming an erect posture. Because hypotension can cause fainting, advise patients to sit or lie down if they become dizzy or lightheaded.

TABLE 16-2 Predominant Autonomic Tone and Responses to Ganglionic Blockade

Location	Predominant Tone	Response to Ganglionic Blockade
Salivary glands	Parasympathetic	Dry mouth
Ciliary muscle	Parasympathetic	Blurred vision
Iris sphincter	Parasympathetic	Photophobia (from mydriasis)
Urinary bladder	Parasympathetic	Urinary retention
Gastrointestinal tract	Parasympathetic	Constipation
Heart	Parasympathetic	Tachycardia
Sweat glands	Sympathetic*	Anhidrosis
Arterioles	Sympathetic	Hypotension (from vasodilation)
Veins	Sympathetic	Orthostatic hypotension (from pooling of blood in veins secondary to venous dilation)

* Sympathetic nerves to sweat glands release acetylcholine as their transmitter, which acts at muscarinic receptors on the sweat glands.

Overdose can cause a profound drop in blood pressure. If this occurs, pressure can be restored with a vasoconstrictor (eg, norepinephrine).

17.2.1.5.3 CNS Effects.

Because it readily crosses the blood-brain barrier, mecamylamine can cause CNS effects, including tremor, convulsions, and mental aberrations. However, these reactions are rare.

17.2.1.6 Preparations, Dosage, and Administration

Mecamylamine [Inversine] is available in 2.5-mg tablets for oral use. Dosing is begun at 2.5 mg twice daily, and then gradually increased until the target blood pressure is achieved. The average daily maintenance dose is 25 mg.

17.2.1.6.1

KEY POINTS

All of these key points apply to the *neuromuscular blocking* agents—not to ganglionic blocking agents.

- Sustained contraction of skeletal muscle results from repetitive activation of nicotinic_M receptors on the motor end-plate, causing the end-plate to go through repeating cycles of depolarization and repolarization.
- Neuromuscular blockers interfere with nicotinic_M receptor activation, and thereby cause muscle relaxation.
- Nondepolarizing neuromuscular blockers act by competing with ACh for binding to nicotinic_M receptors.
- Succinylcholine, the only depolarizing neuromuscular blocker in use, binds to nicotinic_M receptors, causing the end-plate to depolarize; the drug then remains bound, which keeps the end-plate from repolarizing.
- Neuromuscular blockers are used to produce muscle relaxation during surgery, endotracheal intubation, mechanical ventilation, and electroshock therapy.
- Neuromuscular blockers do not reduce consciousness or pain.
- The major adverse effect of neuromuscular blockers is respiratory depression.
- Cholinesterase inhibitors can reverse the effects of nondepolarizing neuromuscular blockers but will intensify the effects of succinylcholine.
- Succinylcholine can cause malignant hyperthermia, a life-threatening condition.
- Succinylcholine is eliminated by plasma cholinesterases. Accordingly, effects are greatly prolonged in patients with low plasma cholinesterase activity.

- All of the neuromuscular blockers are quaternary ammonium compounds, and therefore must be administered parenterally (almost always IV).

17.2.1.6.2

Summary of Major Nursing Implications*

17.2.1.6.2.1

NEUROMUSCULAR BLOCKING AGENTS

Atracurium

Cisatracurium

Pancuronium

Rocuronium

Succinylcholine

Vecuronium

Except where noted, the implications summarized below apply to all neuromuscular blocking agents.

17.2.1.6.2....

Preadministration Assessment

17.2.1.6.2....

Therapeutic Goal

Provision of muscle relaxation during surgery, endotracheal intubation, mechanical ventilation, electroconvulsive therapy, and other procedures.

17.2.1.6.2....

Identifying High-Risk Patients

Use all neuromuscular blockers with *caution* in patients with myasthenia gravis.

Succinylcholine is *contraindicated* for patients with low pseudocholinesterase activity, a personal or familial history of malignant hyperthermia, or conditions that

predispose to hyperkalemia (major burns, multiple trauma, denervation of skeletal muscle, upper motor neuron injury).

Implementation: Administration

Routes

Intravenous.

All neuromuscular blockers.

Intramuscular.

Only *succinylcholine*.

Administration

Neuromuscular blockers are dangerous drugs that should be administered by clinicians skilled in their use.

Implementation: Measures to Enhance Therapeutic Effects

Neuromuscular blockers do not affect consciousness or perception of pain. When used during surgery, these drugs must be accompanied by adequate anesthesia. When neuromuscular blockers are used for prolonged paralysis during mechanical ventilation, care should be taken to ensure comfort (eg, positioning the patient comfortably, moistening the mouth periodically). Because patients may be awake (but won't appear to be), conversations held in their presence should convey only information appropriate for them to hear.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Apnea.

All neuromuscular blockers can cause respiratory arrest. Facilities for intubation and mechanical ventilation should be immediately available.

	Monitor respiration constantly during the period of peak drug action. When drug administration is discontinued, take vital signs at least every 17 minutes until recovery is complete. A cholinesterase inhibitor can be used to reverse respiratory depression caused by <i>nondepolarizing</i> neuromuscular blockers, but not by succinylcholine, a <i>depolarizing</i> blocker.	147
17.2.1.6.2....	Hypotension. Some neuromuscular blockers can cause hypotension secondary to ganglionic blockade or release of histamine. Antihistamines may help counteract this effect.	148
17.2.1.6.2....	Malignant Hyperthermia. Succinylcholine can trigger malignant hyperthermia. Predisposition to this reaction is genetic. Assess for a family history of the reaction.	
17.2.1.6.2....	Hyperkalemia with Cardiac Arrest. Succinylcholine can cause severe hyperkalemia resulting in cardiac arrest if given to patients with major burns, multiple trauma, denervation of skeletal muscle, or upper motor neuron injury. Accordingly, the drug is contraindicated for these people.	
17.2.1.6.2....	Muscle Pain. <i>Succinylcholine</i> may cause muscle pain. Reassure the patient that this response, although unpleasant, is not unusual.	
17.2.1.6.2....	Minimizing Adverse Interactions	
17.2.1.6.2....	Antibiotics. Certain antibiotics, including <i>aminoglycosides</i> and <i>tetracyclines</i>, can intensify neuromuscular blockade. Use them with caution.	

17.2.1.6.2....

Cholinesterase Inhibitors.

These drugs delay inactivation of *succinylcholine*, thereby greatly prolonging paralysis. Accordingly, cholinesterase inhibitors are contraindicated for patients receiving succinylcholine.

* Patient education information is highlighted as **blue text**.

¹⁸CHAPTER 17 Adrenergic Agonists

By definition, adrenergic agonists produce their effects by activating adrenergic receptors. Since the sympathetic nervous system acts through these same receptors, responses to adrenergic agonists and responses to stimulation of the sympathetic nervous system are very similar. Because of this similarity, adrenergic agonists are often referred to as *sympathomimetics*. Adrenergic agonists have a broad spectrum of indications, ranging from heart failure to asthma to preterm labor.

Learning about adrenergic agonists can be a challenge. To facilitate the process, our approach to these drugs has four stages. We begin with the general mechanisms by which drugs can activate adrenergic receptors. Next we establish an overview of the major adrenergic agonists, focusing on their receptor specificity and chemical classification. After that, we address the adrenergic receptors themselves; for each receptor type—alpha₁, alpha₂, beta₁, beta₂, and dopamine—we discuss the beneficial and harmful effects that can result from receptor activation. Finally, we integrate all of this information by discussing the characteristic properties of representative sympathomimetic drugs.

Please note that this chapter is intended only as an *introduction* to the adrenergic agonists. Our objective here is to discuss the basic properties of the sympathomimetic drugs and establish an overview of their applications and adverse effects. In later chapters, we will discuss the clinical applications of these agents in depth.

^{18.1}MECHANISMS OF ADRENERGIC RECEPTOR ACTIVATION

Drugs can activate adrenergic receptors by four basic mechanisms: (1) direct receptor binding, (2) promotion of norepinephrine (NE) release, (3) blockade of NE reuptake, and (4) inhibition of NE inactivation. Note that only the first mechanism is *direct*. With the other three, receptor activation occurs by an *indirect* process. Examples of drugs that act by these four mechanisms are presented in [Table 17-1](#).

^{18.1.1} Direct Receptor Binding.

Direct interaction with receptors is the most common mechanism by which drugs activate peripheral adrenergic receptors. The direct-acting receptor stimulants produce their effects by binding to adrenergic receptors and mimicking the actions of natural transmitters (NE, epinephrine, dopamine). In this chapter, all of the drugs discussed activate receptors directly.

18.1.2 Promotion of NE Release.

By acting on terminals of sympathetic nerves to cause NE release, drugs can bring about activation of adrenergic receptors. Agents that activate receptors by this mechanism include the amphetamines and ephedrine. (Ephedrine can also activate adrenergic receptors directly.)

18.1.3 Inhibition of NE Reuptake.

Recall that reuptake of NE into terminals of sympathetic nerves is the major mechanism by which adrenergic transmission is terminated. By blocking NE reuptake, drugs can cause NE to accumulate within the synaptic gap, and can thereby increase receptor activation. Agents that act by this mechanism include cocaine and the tricyclic antidepressants (eg, imipramine).

18.1.4 Inhibition of NE Inactivation.

As discussed in [Chapter 13](#), some of the NE in terminals of adrenergic neurons is subject to inactivation by monoamine oxidase (MAO). Hence, drugs that inhibit MAO can increase the amount of NE available for release, and can thereby enhance receptor activation. (It should be noted that, in addition to being present in sympathetic nerves, MAO is present in the liver and the intestinal wall. The significance of MAO at these other sites is considered later in the chapter.)

In this chapter, which is dedicated to *peripherally* acting sympathomimetics, practically all of the drugs discussed act exclusively by *direct* receptor activation. The only exception is *ephedrine*, an agent that works by a combination of direct receptor activation and promotion of NE release.

149

TABLE 17-1 Mechanisms of Adrenergic Receptor Activation

Mechanism of Stimulation	Examples
Direct Mechanism	
Binding to receptor to cause activation	Epinephrine Isoproterenol Ephedrine*
Indirect Mechanisms	
Promotion of NE release	Ephedrine* Amphetamines
Inhibition of NE reuptake	Cocaine Tricyclic antidepressants
Inhibition of MAO	MAO inhibitors
MAO = monoamine oxidase, NE = norepinephrine.	

* Ephedrine is a mixed-acting drug that activates receptors directly and also promotes release of norepinephrine.

Most of the indirect-acting adrenergic agonists are used for their ability to activate adrenergic receptors in the central nervous system (CNS)—not for their effects in the periphery. The indirect-acting sympathomimetics (eg, amphetamine, cocaine) are mentioned here to emphasize that, although these agents are employed for effects on the brain, they can and will cause activation of adrenergic receptors in the periphery. Peripheral activation is responsible for certain toxicities of these drugs (eg, cardiac dysrhythmias, hypertension).

18.2 OVERVIEW OF THE ADRENERGIC AGONISTS

18.2.1 Chemical Classification: Catecholamines Versus Noncatecholamines

The adrenergic agonists fall into two major chemical classes: catecholamines and noncatecholamines. As discussed below, the catecholamines and noncatecholamines differ in three important respects: (1) oral usability, (2) duration of action, and (3) the ability to act in the CNS. Accordingly, if we know which category a particular adrenergic agonist belongs to, we will know three of its prominent features.

18.2.1.1 Catecholamines

The catecholamines are so named because they contain a *catechol* group and an *amine* group. A catechol group is simply a benzene ring that has hydroxyl groups on two adjacent carbons ([Fig. 17-1](#)). The amine component of the catecholamines is *ethylamine*. Structural formulas for each of the major catecholamines—epinephrine, norepinephrine, isoproterenol, dopamine, and dobutamine—are presented in [Figure 17-1](#). Because of their chemistry, all catecholamines have three properties in common: (1) they cannot be used orally, (2) they have a brief duration of action, and (3) they cannot cross the blood-brain barrier.

The actions of two enzymes—*monoamine oxidase* and *catechol-O-methyltransferase* (COMT)—explain why the catecholamines have short half-lives and cannot be used orally. MAO and COMT are located in the liver and the intestinal wall. Both enzymes are very active and quickly destroy catecholamines administered by any route. Because these enzymes are located in the liver and intestinal wall, catecholamines that are administered orally become inactivated before they can reach the systemic circulation. Hence, catecholamines are ineffective if given by mouth. Because of rapid inactivation by MAO and COMT, three catecholamines—norepinephrine, dopamine, and dobutamine—are effective only if administered by continuous infusion. Administration by other parenteral routes (eg, subQ, IM) will not yield adequate blood levels.

Catecholamines are polar molecules, and hence cannot cross the blood-brain barrier. (Recall from [Chapter 4](#) that polar compounds penetrate membranes poorly.) The polar nature of the catecholamines is due to the hydroxyl groups on the catechol portion of the molecule. Because they cannot cross the blood-brain barrier, catecholamines have minimal effects on the CNS.

Be aware that catecholamine-containing solutions, which are colorless when first prepared, turn pink or brown over time. This pigmentation is caused by oxidation of the catecholamine molecule. As a rule, *catecholamine solutions should be discarded as soon as discoloration develops*. The only exception to this rule is dobutamine, which can be used up to 24 hours after the solution was made, even if discoloration appears.

18.2.1.2 Noncatecholamines

The noncatecholamines have ethylamine in their structure (see [Fig. 17-1](#)), but do not contain the catechol moiety that characterizes the catecholamines. In this chapter, we discuss three noncatecholamines: ephedrine, phenylephrine, and terbutaline.

The noncatecholamines differ from the catecholamines in three important respects. First, because they lack a catechol group, noncatecholamines are not substrates for COMT and are metabolized slowly by MAO. As a result, the half-lives of noncatecholamines are much longer than those of catecholamines. Second, because they do not undergo rapid degradation by MAO and COMT, noncatecholamines can be given orally, whereas catecholamines cannot. Third, noncatecholamines are considerably less polar than catecholamines, and hence are more able to cross the blood-brain barrier.

18.2.2 Receptor Specificity

To understand the actions of individual adrenergic agonists, we need to know their receptor specificity. Since the sympathomimetic drugs differ widely with respect to the receptors they can activate, learning the receptor specificity of these drugs will take some effort.

Variability in receptor specificity among the adrenergic agonists can be illustrated with three drugs: terbutaline, isoproterenol, and epinephrine. Terbutaline is highly selective, acting at beta₂ receptors only. Isoproterenol is less selective, acting at beta₁ receptors and beta₂ receptors. Epinephrine is less selective yet, acting at all four adrenergic receptor subtypes: alpha₁, alpha₂, beta₁, and beta₂.

The receptor specificities of the major adrenergic agonists are summarized in [Table 17-2](#). In the upper part of the table, receptor specificity is presented in tabular form. In the lower part, the same information is presented schematically. By learning (memorizing) the content of [Table 17-2](#), you will be well on your way toward understanding the pharmacology of the sympathomimetic drugs.

150

Figure 17-1 Structures of catecholamines and noncatecholamines. Catecholamines: Note that all of the catecholamines share the same basic chemical formula. Because of their biochemical properties, the catecholamines cannot be used orally, cannot cross the blood-brain barrier, and have short half-lives (owing to rapid inactivation by MAO and COMT). Noncatecholamines: Although structurally similar to catecholamines, noncatecholamines differ from catecholamines in three important ways: they can be used orally; they can cross the blood-brain barrier; and, because they are not rapidly metabolized by MAO or COMT, they have much longer half-lives.

Please note that the concept of receptor specificity is relative, not absolute. The ability of a drug to selectively activate certain receptors to the exclusion of others is dependent on dosage: at low doses, selectivity is maximal; as dosage increases, selectivity declines. For example, when terbutaline is administered in low to moderate doses, the drug is highly selective for beta₂-adrenergic receptors. However, if the dosage is high, terbutaline will activate beta₁ receptors as well. The information on receptor specificity in [Table 17-2](#) refers to usual therapeutic doses. So-called selective agents will activate additional adrenergic receptors if the dosage is abnormally high.

18.3 THERAPEUTIC APPLICATIONS AND ADVERSE EFFECTS OF ADRENERGIC RECEPTOR ACTIVATION

In this section we discuss the responses—both therapeutic and adverse—that can be elicited with sympathomimetic drugs. Since many adrenergic agonists activate more than one type of receptor (see [Table 17-2](#)), it could be quite confusing if we were to talk about the effects of the sympathomimetics while employing specific drugs as examples. Consequently, rather than attempting to structure this presentation around representative drugs, we discuss the actions of the adrenergic agonists one receptor at a time. Our discussion begins with alpha₁ receptors, and then moves to alpha₂ receptors, beta₁ receptors, beta₂ receptors, and dopamine receptors. For each receptor type, we discuss both the therapeutic and adverse responses that can result from receptor activation.

151

152

TABLE 17-2 Receptor Specificity of Representative Adrenergic Agonists

Catecholamines		Noncatecholamines	
Drug	Receptors Activated	Drug	Receptors Activated
Epinephrine	α ₁ , α ₂ , β ₁ , β ₂	Ephedrine*	α ₁ , α ₂ , β ₁ , β ₂
Norepinephrine	α ₁ , α ₂ , β ₁	Phenylephrine	α ₁
Isoproterenol	β ₁ , β ₂	Terbutaline	β ₂
Dobutamine	β ₁		
Dopamine†	α ₁ , β ₁ , dopamine		

Receptors Activated‡				
Alpha ₁	Alpha ₂	Beta ₁	Beta ₂	Dopamine
		Epinephrine		
		Ephedrine*		
	Norepinephrine			
Phenylephrine		Isoproterenol		
		Dobutamine	Terbutaline	
Dopamine†		Dopamine†		Dopamine†

*Ephedrine is a mixed-acting agent that causes NE release and also activates alpha and beta receptors directly.

†Receptor activation by dopamine is dose dependent.

‡This chart represents in graphic form the same information on receptor specificity given above. Arrows indicate the range of receptors that the drugs can activate (at usual therapeutic doses).

α alpha, β beta.

To understand the effects of any specific adrenergic agonist, all you need is two types of information: (1) the identity of the receptors at which the drug acts and (2) the effects produced by activating those receptors. Combining these two types of information will reveal a profile of drug action. This is the same approach to understanding neuropharmacologic agents that we discussed in [Chapter 12](#).

Before you go deeper into this chapter, I encourage you (strongly advise you) to review [Table 13-3](#). Since we are about to discuss the clinical consequences of adrenergic receptor activation, and since [Table 13-3](#) summarizes the responses to activation of those receptors, the benefits of being familiar with [Table 13-3](#) are obvious. If you choose not to memorize [Table 13-3](#) now, at least be prepared to refer back to it as we discuss the consequences of receptor activation.

18.3.1 Clinical Consequences of Alpha₁ Activation

In this section we discuss the therapeutic and adverse effects that can result from activation of alpha₁-adrenergic receptors. As shown in [Table 17-2](#), drugs capable of activating alpha₁ receptors include epinephrine, NE, phenylephrine, ephedrine, and dopamine.

18.3.1.1 Therapeutic Applications of Alpha₁ Activation

Activation of alpha₁ receptors elicits two responses that can be of therapeutic use: (1) *vasoconstriction* (in blood vessels of the skin, viscera, and mucous membranes); and (2) *mydriasis*. Of the two, vasoconstriction is the one for which alpha₁ agonists are used most often. Using these drugs for mydriasis is relatively rare.

18.3.1.1.1 Hemostasis.

Hemostasis is defined as the arrest of bleeding, which alpha₁ agonists accomplish through vasoconstriction. Alpha₁ stimulants are given to stop bleeding primarily in the skin and mucous membranes. Epinephrine, applied topically, is the alpha₁ agonist used most for this purpose.

18.3.1.1.2 Nasal Decongestion.

Nasal congestion results from dilation and engorgement of blood vessels in the nasal mucosa. Drugs can relieve congestion by causing alpha₁-mediated vaso-constriction. Specific alpha₁-activating agents employed as nasal decongestants include phenylephrine (applied topically) and ephedrine (taken orally).

18.3.1.1.3 Adjunct to Local Anesthesia.

Alpha₁ agonists are frequently combined with local anesthetics to delay anesthetic absorption. The mechanism is alpha₁-mediated vasoconstriction, which reduces blood flow to the site of anesthetic administration. Why delay anesthetic absorption? Because doing so prolongs anesthesia, allows a reduction in anesthetic dosage, and reduces the systemic effects that a local anesthetic might produce. The drug used most frequently to delay anesthetic absorption is epinephrine.

18.3.1.1.4 Elevation of Blood Pressure.

Because of their ability to cause vasoconstriction, alpha₁ agonists can elevate blood pressure in hypotensive patients. Please note, however, that alpha₁ agonists are not the primary therapy for hypotension. Rather, they are reserved for situations in which fluid replacement and other measures have failed to restore blood pressure to a satisfactory level.

18.3.1.1.5 Mydriasis.

Activation of alpha₁ receptors on the radial muscle of the iris causes mydriasis (dilation of the pupil), which can facilitate eye examinations and ocular surgery. Note that producing mydriasis is the only clinical use of alpha₁ activation that is not based on vasoconstriction.

152

18.3.1.2 Adverse Effects of Alpha₁ Activation

153

All of the adverse effects caused by alpha₁ activation result directly or indirectly from vasoconstriction.

18.3.1.2.1 Hypertension.

Alpha₁ agonists can produce hypertension by causing widespread vasoconstriction. Severe hypertension is most likely with parenteral administration. Accordingly, when alpha₁ agonists are given parenterally, cardiovascular status must be monitored continuously. Never leave the patient unattended.

18.3.1.2.2 Necrosis.

If the IV line employed to administer an alpha₁ agonist becomes extravasated, local seepage of the drug may result in necrosis (tissue death). The cause is lack of blood flow secondary to intense local vasoconstriction. If extravasation occurs, the area should be infiltrated with an

alpha₁-blocking agent (eg, phentolamine), which will counteract alpha₁-mediated vasoconstriction, and thereby help minimize injury.

18.3.1.2.3 Bradycardia.

Alpha₁ agonists can cause reflex slowing of the heart. The mechanism is this: Alpha₁-mediated vasoconstriction elevates blood pressure, which triggers the baroreceptor reflex, causing heart rate to decline. In patients with marginal cardiac reserve, the decrease in cardiac output may compromise tissue perfusion.

18.3.2 Clinical Consequences of Alpha₂ Activation

As discussed in [Chapter 13](#), alpha₂ receptors in the periphery are located *presynaptically*, and their activation inhibits NE release. Several adrenergic agonists (eg, epinephrine, NE, ephedrine) are capable of causing alpha₂ activation. However, their ability to activate alpha₂ receptors in the periphery has little clinical significance. There are no therapeutic applications related to activation of peripheral alpha₂ receptors. Furthermore, activation of these receptors rarely causes significant adverse effects.

In contrast to alpha₂ receptors in the *periphery*, alpha₂ receptors in the *CNS* are of great clinical significance. By activating central alpha₂ receptors, we can produce two useful effects: (1) *reduction* of sympathetic outflow to the heart and blood vessels and (2) relief of severe pain. The central alpha₂ agonists used for effects on the heart and blood vessels, and the agents used to relieve pain, are discussed in [Chapters 19](#) and [28](#), respectively.

18.3.3 Clinical Consequences of Beta₁ Activation

All of the clinically relevant responses to activation of beta₁ receptors result from activating beta₁ receptors in the *heart*; activation of renal beta₁ receptors is not associated with either beneficial or adverse effects. As indicated in [Table 17-2](#), beta₁ receptors can be activated by epinephrine, NE, isoproterenol, dopamine, dobutamine, and ephedrine.

18.3.3.1 Therapeutic Applications of Beta₁ Activation

18.3.3.1.1 Cardiac Arrest.

By activating cardiac beta₁ receptors, drugs can initiate contraction in a heart that has stopped beating. It should be noted, however, that drugs are not the preferred treatment for cardiac arrest. Rather, drugs should be used only after more desirable procedures—mechanical

thumping, direct-current cardioversion—have failed to restart the heart. When a beta₁ agonist is indicated, epinephrine—injected directly into the heart—is the preferred drug.

18.3.3.1.2 Heart Failure.

Heart failure is characterized by a reduction in the force of myocardial contraction, resulting in insufficient cardiac output. Because activation of beta₁ receptors in the heart has a positive inotropic effect (ie, increases the force of contraction), drugs that activate these receptors can improve cardiac performance.

18.3.3.1.3 Shock.

This condition is characterized by profound hypotension and greatly reduced tissue perfusion. The primary goal of treatment is to maintain blood flow to vital organs. By increasing heart rate and force of contraction, beta₁ stimulants can increase cardiac output and can thereby improve tissue perfusion.

18.3.3.1.4 Atrioventricular Heart Block.

Atrioventricular (AV) heart block is a condition in which impulse conduction from the atria to the ventricles is either impeded or blocked entirely. As a consequence, the ventricles are no longer driven at an appropriate rate. Since activation of cardiac beta₁ receptors can enhance impulse conduction through the AV node, beta₁ stimulants can help overcome AV block. It should be noted, however, that drugs are only a temporary form of treatment. For long-term management, a pacemaker is implanted.

18.3.3.2 Adverse Effects of Beta₁ Activation

All of the adverse effects of beta₁ activation result from activating beta₁ receptors in the heart; activating renal beta₁ receptors is not associated with untoward effects.

18.3.3.2.1 Altered Heart Rate or Rhythm.

Overstimulation of cardiac beta₁ receptors can produce *tachycardia* (excessive heart rate) and *dysrhythmias* (irregular heartbeat).

18.3.3.2.2 Angina Pectoris.

In some patients, drugs that activate beta₁ receptors can precipitate an attack of angina pectoris, a condition characterized by substernal pain in the region of the heart. Anginal pain

occurs when cardiac oxygen supply (blood flow) is insufficient to meet cardiac oxygen needs. The most common cause of angina is coronary atherosclerosis (accumulation of lipids and other substances in coronary arteries). Since β_1 agonists increase cardiac oxygen demand (by increasing heart rate and force of contraction), patients with compromised coronary circulation are at risk of an anginal attack.

18.3.4 Clinical Consequences of β_2 Activation

18.3.4.1 Therapeutic Applications of β_2 Activation

Therapeutic applications of β_2 activation are limited to the *lungs* and *uterus*. Drugs used for their β_2 -activating ability include ephedrine, epinephrine, isoproterenol, and terbutaline.

18.3.4.1.1 Asthma.

Asthma is a chronic condition characterized by inflammation and bronchoconstriction occurring in response to a variety of stimuli. During a severe attack, airflow can be reduced so much as to threaten life. Since drugs that activate β_2 receptors in the lung promote bronchodilation, these drugs can help relieve or prevent asthma attacks.

For therapy of asthma, adrenergic agonists that are *selective for β_2 receptors* (eg, terbutaline) are preferred to less selective agents (eg, epinephrine, isoproterenol). This is especially true for patients who also suffer from *angina pectoris* or *tachycardia*. Why? Because drugs that can activate β_1 receptors would aggravate these cardiac disorders.

Several of the β_2 agonists used to treat asthma are administered by *inhalation*. This route is desirable in that it helps minimize adverse systemic effects. It should be noted, however, that inhalation does not guarantee safety: Serious systemic toxicity can result from overdosing with inhaled sympathomimetics. Accordingly, patients must be warned against inhaling too much drug.

18.3.4.1.2 Delay of Preterm Labor.

Activation of β_2 receptors in the uterus relaxes uterine smooth muscle. This action can be exploited to delay preterm labor.

18.3.4.2 Adverse Effects of Beta₂ Activation

18.3.4.2.1 Hyperglycemia.

The most important adverse response to beta₂ activation is hyperglycemia (elevation of blood glucose). The mechanism is activation of beta₂ receptors in the liver and skeletal muscles, which promotes breakdown of glycogen into glucose. As a rule, beta₂ agonists cause hyperglycemia only in patients with *diabetes*; in patients with normal pancreatic function, insulin release will maintain blood glucose at an appropriate level. If hyperglycemia develops in the diabetic patient, insulin dosage should be increased.

18.3.4.2.2 Tremor.

Tremor is the most common side effect of beta₂ agonists. It occurs because activation of beta₂ receptors in skeletal muscle enhances contraction. Tremor generally fades over time and can be minimized by initiating therapy at low doses.

18.3.5 Clinical Consequences of Dopamine Receptor Activation

Activation of peripheral dopamine receptors causes dilation of the vasculature of the kidneys. This effect is exploited in the treatment of *shock*: by dilating renal blood vessels, we can improve renal perfusion and can thereby reduce the risk of renal failure. *Dopamine* itself is the only drug available that can activate dopamine receptors. It should be noted that, when dopamine is given to treat shock, the drug also enhances cardiac performance (because it activates beta₁ receptors in the heart).

18.3.6 Multiple Receptor Activation: Treatment of Anaphylactic Shock

18.3.6.1 Pathophysiology of Anaphylaxis.

Anaphylactic shock is a manifestation of severe allergy. The reaction is characterized by *hypotension* (from widespread vasodilation), *bronchoconstriction*, and *edema of the glottis*. Although histamine contributes to these responses, symptoms are due largely to release of other mediators (eg, leukotrienes). Anaphylaxis can be triggered by a variety of substances, including bee venom, wasp venom, latex rubber, certain foods (eg, peanuts, shellfish), and certain drugs (eg, penicillins).

18.3.6.2 Treatment.

Epinephrine, injected IM, is the treatment of choice for anaphylactic shock. Benefits derive from activating three types of adrenergic receptors: α_1 , β_1 , and β_2 . By activating these receptors, epinephrine can reverse the most severe manifestations of the anaphylactic reaction. Activation of β_1 receptors increases cardiac output, thereby helping elevate blood pressure. Blood pressure is also increased because epinephrine promotes α_1 -mediated vasoconstriction. In addition to increasing blood pressure, vasoconstriction helps suppress glottal edema. By activating β_2 receptors, epinephrine can counteract bronchoconstriction. Individuals who are prone to severe allergic responses should carry an epinephrine auto-injector at all times (see [Box 17-1](#)). Antihistamines are not especially useful against anaphylaxis because histamine is only a minor contributor to the reaction.

18.4 PROPERTIES OF REPRESENTATIVE ADRENERGIC AGONISTS

Our aim in this section is to establish an overview of the adrenergic agonists. The information is presented in the form of “drug digests” that highlight characteristic features of representative sympathomimetic agents.

As noted, there are two keys to understanding individual adrenergic agonists: (1) knowledge of the receptors that the drug can activate and (2) knowledge of the therapeutic and adverse effects that receptor activation can elicit. By integrating these two types of information, you can easily predict the spectrum of effects that a particular drug can produce.

Unfortunately, knowing the effects that a drug is *capable* of producing does not always indicate how that drug is *actually used* in a clinical setting. Why? Because some adrenergic agonists are not used for all the effects they can produce. Norepinephrine, for example, can activate α_1 receptors and can therefore produce mydriasis. However, although NE can produce mydriasis, the drug is not actually used for this purpose. Similarly, although isoproterenol is capable of producing uterine relaxation (through β_2 activation), isoproterenol is not employed clinically for this effect. Because receptor specificity is not always a predictor of the therapeutic applications of a particular adrenergic agonist, for each of the drugs discussed below, approved clinical applications are indicated.

18.4.1 Epinephrine

- *Receptor specificity:* α_1 , α_2 , β_1 , β_2
- *Chemical classification:* catecholamine

Epinephrine [Adrenalin, others] was among the first adrenergic agonists employed clinically and can be considered the prototype of the sympathomimetic drugs. Because of its prototypic status, epinephrine is discussed in detail.

18.4.1.1 Therapeutic Uses

Epinephrine can activate all four subtypes of adrenergic receptors. As a consequence, the drug can produce a broad spectrum of beneficial sympathomimetic effects:

- Because it can cause α_1 -mediated vasoconstriction, epinephrine is used to (1) delay absorption of local anesthetics, (2) control superficial bleeding, and (3) elevate blood pressure. In the past, epinephrine-induced vasoconstriction was also used for nasal decongestion.
- Activation of α_1 receptors on the iris can be used to produce mydriasis during ophthalmologic procedures.
- Because it can activate β_1 receptors, epinephrine is used to (1) overcome AV heart block and (2) restore cardiac function in patients experiencing cardiac arrest.
- Activation of β_2 receptors in the lung promotes bronchodilation, which can be useful in patients with asthma (although other drugs are preferred).
- Because it can activate a combination of alpha and beta receptors, epinephrine is the treatment of choice for anaphylactic shock.

154

18.4.1.1.1

BOX 17-1 Special Interest Topic

156

18.4.1.1.1.1

THE EPIPEN: DON'T LEAVE HOME WITHOUT IT!

The EpiPen is an epinephrine auto-injector, the only one available in the United States. The device is indicated for emergency treatment of anaphylaxis, a life-threatening allergic reaction caused by severe hypersensitivity to insect venoms (eg, from bees, wasps, fire ants), certain foods (eg, peanuts, walnuts, shellfish), and certain drugs (especially penicillins). Every year, anaphylaxis kills about 6000 Americans: 125 who have food allergies, between 40 and 400 who have venom allergies, and over 5400 who have penicillin allergy. Could most of these deaths be avoided? Yes—through immediate injection of epinephrine. Unfortunately, many of the people at risk don't carry an epinephrine injector, and many of those who do aren't sure how to use it. So listen up: By

encouraging highly allergic clients to carry an EpiPen, and by teaching them when and how to use it, you could well save someone's life.

18.4.1.1.1....

EpiPen Description and Dosage

The EpiPen auto-injector is a single-use delivery device, featuring a spring-activated needle, designed for IM injection of epinephrine. Two strengths are available. The larger one, sold as EpiPen, delivers a 0.3-mg dose (for individuals weighing 66 pounds or more). The smaller one, sold as EpiPen Jr, delivers a 0.15-mg dose (for individuals between 33 and 66 pounds). If one injection fails to completely reverse symptoms, a second injection (using a second EpiPen) may be given. The EpiPen is available only by prescription.

18.4.1.1.1....

EpiPen Storage and Replacement

Epinephrine is sensitive to extreme heat and light, and hence the EpiPen should be stored at room temperature in a dark place. The factory-issue storage tube provides additional protection from UV light. Refrigeration can compromise the injection mechanism, and therefore should be avoided. If the epinephrine solution turns brown, if a precipitate forms, or if the expiration date has passed, the unit should be replaced. (The distributor offers a free service to remind patients when their EpiPen is about to expire.)

18.4.1.1.1....

Who Should Carry an EpiPen and When Should They Use It?

Anyone who has experienced a severe, systemic allergic reaction should *always* carry at least one epinephrine auto-injector! Anaphylaxis can develop within minutes after allergen exposure. To prevent a full-blown reaction, epinephrine should be injected as soon as early symptoms appear (eg, swelling, shortness of breath). People who do not carry an EpiPen, and hence must wait for an emergency response team, greatly increase their risk of death.

18.4.1.1.1....

What's the Self-Injection Procedure?

The EpiPen auto-injector is a tubular device with three prominent external features: a black tip (the needle comes out through this end), a clear window (for examining the epinephrine solution), and a gray cap (which prevents activation until being removed).

Injectons are made into the outer thigh as follows:

1. Form a fist around the unit with the black tip pointing down.
2. With the free hand, pull off the gray activation cap.
3. Jab the device firmly into the outer thigh, at an angle perpendicular to the thigh, and hold it there for 10 seconds. (The injection may be made directly through clothing.)

4. Remove the unit and massage the area for 10 seconds to facilitate absorption.

To ensure the injection was made, examine the used EpiPen: If the needle is projecting through the black tip, the procedure was a success; if the needle is not projecting, jab the device in again. *Note:* The EpiPen contains 2 mL of epinephrine solution, but only 0.3 mL is actually injected. Hence, even after a successful injection, the device will not be empty.

18.4.1.1.1....

What Should Be Done After the Injection?

Following epinephrine injection, it is important to get immediate medical attention. Why? Because (1) the effects of epinephrine begin to fade in 10 to 20 minutes and (2) anaphylactic reactions can be biphasic and prolonged. Accordingly, to ensure a good outcome, hospitalization (up to 6 hours) is recommended. Hospital staff should be informed that epinephrine has been injected, and should be shown the used EpiPen (to confirm the dosage). Prednisone may be given to manage delayed or persistent symptoms.

18.4.1.1.1....

Does IM Epinephrine Have Side Effects?

Of course. The injection itself may cause discomfort, and the epinephrine may cause tachycardia, palpitations, and a feeling of nervousness. The drug may also cause sweating, dizziness, headache, nausea, and vomiting.

18.4.1.2 Pharmacokinetics

18.4.1.2.1 Absorption.

Epinephrine may be administered topically or by injection. The drug cannot be given orally because, as discussed, epinephrine and other catecholamines undergo destruction by MAO and COMT before reaching the systemic circulation. Following subQ injection, absorption is slow owing to epinephrine-induced local vasoconstriction. Absorption is more rapid following IM injection. When epinephrine is inhaled (to treat asthma), systemic absorption is usually minimal. However, if dosage is excessive, systemic absorption can be sufficient to cause toxicity.

18.4.1.2.2 Inactivation.

Epinephrine has a short half-life because of two processes: enzymatic inactivation and uptake into adrenergic nerves. The enzymes that inactivate epinephrine and other catecholamines are MAO and COMT.

18.4.1.3 Adverse Effects

Because it can activate the four major adrenergic receptor subtypes, epinephrine can produce multiple adverse effects.

18.4.1.3.1 Hypertensive Crisis.

Vasoconstriction secondary to excessive α_1 activation can produce a dramatic increase in blood pressure. Cerebral hemorrhage can occur. Because of the potential for severe hypertension, patients receiving *parenteral* epinephrine must undergo continuous cardiovascular monitoring.

18.4.1.3.2 Dysrhythmias.

Excessive activation of β_1 receptors in the heart can produce dysrhythmias. Because of their sensitivity to catecholamines, hyperthyroid patients are at high risk for epinephrine-induced dysrhythmias.

18.4.1.3.3 Angina Pectoris.

By activating β_1 receptors in the heart, epinephrine can increase cardiac work and oxygen demand. If the increase in oxygen demand is big enough, an anginal attack may ensue. Precipitation of angina is especially likely in patients with coronary atherosclerosis.

18.4.1.3.4 Necrosis Following Extravasation.

If an IV line containing epinephrine becomes extravasated, the resultant localized vasoconstriction may result in necrosis. Because of this possibility, patients receiving IV epinephrine should be monitored closely. If extravasation occurs, injury can be minimized by local injection of phentolamine, an alpha-adrenergic antagonist.

18.4.1.3.5 Hyperglycemia.

In diabetic patients, epinephrine can cause hyperglycemia. How? By causing breakdown of glycogen secondary to activation of β_2 receptors in liver and skeletal muscle. If hyperglycemia develops, insulin dosage should be increased.

18.4.1.4 Drug Interactions

18.4.1.4.1 MAO Inhibitors.

As their name implies, MAO inhibitors suppress the activity of MAO. These drugs are used primarily to treat depression (see [Chapter 32](#)). Because MAO is one of the enzymes that inactivate epinephrine and other catecholamines, inhibition of MAO will prolong and intensify epinephrine's effects. As a rule, patients receiving an MAO inhibitor should not receive epinephrine.

18.4.1.4.2 Tricyclic Antidepressants.

Tricyclic antidepressants block the uptake of catecholamines into adrenergic neurons. Since neuronal uptake is one mechanism by which the actions of norepinephrine and other catecholamines are terminated, blocking uptake can intensify and prolong epinephrine's

effects. Accordingly, patients receiving a tricyclic antidepressant may require a reduction in epinephrine dosage.

TABLE 17-3 Epinephrine Solutions: Concentrations for Different Routes of Administration

Concentration of Epinephrine Solution	Route of Administration
1% (1:100)	Oral inhalation
0.1% (1:1000)	Subcutaneous
	Intramuscular
	Intraspinal
0.01% (1:10,000)	Intravenous
	Intracardiac
0.001% (1:100,000)	In combination with local anesthetics

18.4.1.4.3 General Anesthetics.

Several inhalation anesthetics render the myocardium hypersensitive to activation by β_1 agonists. When the heart is in this hypersensitive state, exposure to epinephrine and other β_1 agonists can cause tachydysrhythmias.

18.4.1.4.4 Alpha-Adrenergic Blocking Agents.

Drugs that block alpha-adrenergic receptors can prevent receptor activation by epinephrine. Alpha blockers (eg, phentolamine) can be used to treat toxicity (eg, hypertension, local vasoconstriction) caused by excessive epinephrine-induced alpha activation.

18.4.1.4.5 Beta-Adrenergic Blocking Agents.

Drugs that block beta-adrenergic receptors can prevent receptor activation by epinephrine. Beta-blocking agents (eg, propranolol) can reduce adverse effects (eg, dysrhythmias, anginal pain) caused by epinephrine and other β_1 agonists.

18.4.1.5 Preparations, Dosage, and Administration

Epinephrine [Adrenalin, EpiPen, Primatene Mist, others] is supplied in solution for administration by several routes: IV, IM, subQ, intracardiac, intraspinal, inhalation, and topical. As indicated in [Table 17-3](#), the strength of the epinephrine solution employed depends on the route of administration. Note that solutions intended for *intravenous* administration are *less*

concentrated than solutions intended for administration by most other routes. Why? Because *intravenous administration of a concentrated epinephrine solution can produce potentially fatal reactions* (severe dysrhythmias and hypertension). Therefore, *before you give epinephrine IV, check carefully to ensure that the concentration is appropriate!* Aspirate prior to IM or subQ injection to avoid inadvertent injection into a vein.

Patients receiving IV epinephrine should be monitored constantly. They should be observed for signs of excessive cardiovascular activation (eg, tachydysrhythmias, hypertension) and for possible extravasation of the IV line. If systemic toxicity develops, epinephrine should be discontinued; if indicated, an alpha-adrenergic blocker, a betaadrenergic blocker, or both should be given to suppress symptoms. If an epinephrine-containing IV line becomes extravasated, administration should be discontinued and the region of extravasation infiltrated with an alpha-adrenergic blocker.

Treatment of anaphylaxis using the EpiPen auto-injector is discussed in [Box 17-1](#).

156

18.4.2 Norepinephrine

157

- *Receptor specificity:* α_1 , α_2 , β_1
- *Chemical classification:* catecholamine

Norepinephrine [Levophed] is similar to epinephrine in several respects. With regard to receptor specificity, NE differs from epinephrine only in that NE does not activate β_2 receptors.

Accordingly, NE can elicit all of the responses that epinephrine can—except those that are β_2 mediated. Because NE is a catecholamine, the drug is subject to rapid inactivation by MAO and COMT, and hence cannot be given orally. Adverse effects are nearly identical to those of epinephrine: tachydysrhythmias, angina, hypertension, and local necrosis upon extravasation. In contrast to epinephrine, NE does not promote hyperglycemia, a response that is β_2 mediated. As with epinephrine, responses to NE can be modified by MAO inhibitors, tricyclic antidepressants, general anesthetics, and adrenergic blocking agents.

Despite its similarity to epinephrine, NE has limited clinical applications. The only recognized indications are *hypotensive states* and *cardiac arrest*.

Norepinephrine is supplied in solution (1 mg/mL) for administration by IV infusion only. Never leave the patient unattended. Monitor cardiovascular status continuously. Take care to avoid extravasation.

18.4.3 Isoproterenol

- *Receptor specificity:* beta₁ and beta₂
- *Chemical classification:* catecholamine

Isoproterenol [Isuprel] differs significantly from NE and epinephrine in that isoproterenol acts only at beta-adrenergic receptors. Isoproterenol was the first beta-selective agent employed clinically and will serve as our prototype of the beta-selective adrenergic agonists.

18.4.3.1 Therapeutic Uses

18.4.3.1.1 Cardiovascular.

By activating beta₁ receptors in the heart, isoproterenol can benefit patients with cardiovascular disorders. Specifically, it can help overcome AV heart block, restart the heart following cardiac arrest, and increase cardiac output during shock.

18.4.3.1.2 Asthma.

By activating beta₂ receptors in the lung, isoproterenol can cause bronchodilation, thereby decreasing airway resistance. Following its introduction, isoproterenol became a mainstay of asthma therapy. However, because we now have even more selective beta-adrenergic agonists (ie, drugs that activate beta₂ receptors only), use of isoproterenol for asthma has been abandoned.

18.4.3.1.3 Bronchospasm.

Although isoproterenol is no longer used for asthma, it *is* used to treat bronchospasm during anesthesia. Benefits derive from activating beta₂ receptors in the lung.

18.4.3.2 Adverse Effects

Because isoproterenol does not activate alpha-adrenergic receptors, it produces fewer adverse effects than NE or epinephrine. The major undesired responses are cardiac. Excessive activation of beta₁ receptors in the heart can cause *tachydysrhythmias* and *angina pectoris*. In diabetic patients, isoproterenol can cause *hyperglycemia* (by promoting beta₂-mediated glycogenolysis).

18.4.3.3 Drug Interactions

The major drug interactions of isoproterenol are nearly identical to those of epinephrine. Effects are enhanced by MAO inhibitors and tricyclic antidepressants and reduced by beta-adrenergic blocking agents. Like epinephrine, isoproterenol can cause dysrhythmias in patients receiving certain inhalation anesthetics.

18.4.3.4 Preparations and Administration

Isoproterenol hydrochloride [Isuprel] is available in solution (0.2 and 0.02 mg/mL) for parenteral administration.

When used to *stimulate the heart*, isoproterenol can be administered IV and IM and by intracardiac injection. The dosage for IM administration is about 10 times greater than the dosage employed by the other two routes.

When used to relieve *bronchospasm*, isoproterenol is administered IV.

18.4.4 Dopamine

- *Receptor specificity:* dopamine, β_1 , and, at high doses, α_1
- *Chemical classification:* catecholamine

18.4.4.1 Receptor Specificity

Dopamine (formerly available as Intropin) has *dose-dependent* receptor specificity. When administered in low therapeutic doses, dopamine acts on dopamine receptors only. At moderate therapeutic doses, dopamine activates β_1 receptors in addition to dopamine receptors. And at very high doses, dopamine activates α_1 receptors along with β_1 and dopamine receptors.

18.4.4.2 Therapeutic Uses

18.4.4.2.1 Shock.

The major indication for dopamine is shock. Benefits derive from effects on the heart and renal blood vessels. By activating β_1 receptors in the heart, dopamine can increase cardiac output, thereby improving tissue perfusion. By activating dopamine receptors in the kidney, dopamine can dilate renal blood vessels, thereby improving renal perfusion. Success can be evaluated by monitoring output of urine.

18.4.4.2.2 Heart Failure.

Heart failure is characterized by reduced tissue perfusion secondary to reduced cardiac output. Dopamine can help alleviate symptoms by activating beta₁ receptors on the heart, which increases myocardial contractility, and thereby increases cardiac output.

18.4.4.2.3 Acute Renal Failure.

Because of its ability to increase renal blood flow and urine output, low-dose dopamine has long been used in efforts to preserve renal function in patients with evolving acute renal failure (ARF). However, we now have evidence that the drug is not effective: In patients with early ARF, dopamine failed to protect renal function, shorten hospital stays, or reduce the number of patients needing a kidney transplant. Accordingly, it would appear that it is time to abandon low-dose dopamine as a treatment for ARF.

18.4.4.3 Adverse Effects

The most common adverse effects of dopamine—*tachycardia*, *dysrhythmias*, and *anginal pain*—result from activation of beta₁ receptors in the heart. Because of its cardiac actions, dopamine is contraindicated for patients with tachydysrhythmias or ventricular fibrillation. Since high concentrations of dopamine cause alpha₁ activation, extravasation may result in *necrosis* from localized vasoconstriction; tissue injury can be minimized by local infiltration of phentolamine, an alpha-adrenergic blocking agent.

18.4.4.4 Drug Interactions

MAO inhibitors can intensify the effects of dopamine on the heart and blood vessels. If a patient is receiving an MAO inhibitor, the dosage of dopamine must be reduced by at least 90%. 157

Tricyclic antidepressants can also intensify dopamine's actions, but not to the extent seen with MAO inhibitors. Certain general anesthetics can sensitize the myocardium to stimulation by dopamine and other catecholamines, thereby creating a risk of dysrhythmias. Diuretics can complement the beneficial effects of dopamine on the kidney. 158

18.4.4.5 Preparations, Dosage, and Administration

18.4.4.5.1 Preparations.

Dopamine hydrochloride is supplied in aqueous solutions that range in concentration from 40 to 320 mg/mL.

18.4.4.5.2 Dosage.

Dopamine must be diluted prior to infusion. For treatment of *shock*, a dilution of 400 mcg/mL can be used. The recommended initial rate of infusion is 2 to 5 mcg/kg/min. If needed, the infusion rate can be gradually increased to a maximum of 20 to 50 mcg/kg/min.

18.4.4.5.3 Administration.

Dopamine is administered IV. Because of extremely rapid inactivation by MAO and COMT, the drug must be given by *continuous infusion*. A metering device is needed to control flow rate. Cardiovascular status must be closely monitored. If extravasation occurs, the infusion should be stopped and the affected area infiltrated with an alpha-adrenergic antagonist (eg, phentolamine).

18.4.5 Dobutamine

- *Receptor specificity:* β_1
- *Chemical classification:* catecholamine

18.4.5.1 Actions and Uses.

At therapeutic doses, dobutamine (formerly available as Dobutrex) causes selective activation of β_1 -adrenergic receptors. The only indication for the drug is *heart failure*.

18.4.5.2 Adverse Effects.

The major adverse effect is *tachycardia*. Blood pressure and the electrocardiogram (ECG) should be monitored closely.

18.4.5.3 Drug Interactions.

Effects of dobutamine on the heart and blood vessels are intensified greatly by MAO inhibitors. Accordingly, in patients receiving an MAO inhibitor, dobutamine dosage must be reduced at least 90%. Concurrent use of tricyclic antidepressants may cause a moderate increase in the cardiovascular effects. Certain general anesthetics can sensitize the myocardium to stimulation by dobutamine, thereby increasing the risk of dysrhythmias.

18.4.5.4 Preparations, Dosage, and Administration.

Dobutamine hydrochloride is supplied in a concentrated solution (12.5 mg/mL in 20-mL vials), which must be diluted to at least 50 mL prior to use. Because of rapid inactivation by MAO and COMT, dobutamine is administered by continuous IV infusion. The usual rate is 2.5 to 10 mcg/kg/min.

18.4.6 Phenylephrine

- *Receptor specificity:* α_1
- *Chemical classification:* noncatecholamine

Phenylephrine [Neo-Synephrine, others] is a selective α_1 agonist. The drug can be administered locally to reduce nasal congestion and parenterally to elevate blood pressure. In addition, phenylephrine eye drops can be used to dilate the pupil. Also, phenylephrine can be coadministered with local anesthetics to retard anesthetic absorption.

18.4.7 Terbutaline

- *Receptor specificity:* β_2
- *Chemical classification:* noncatecholamine

18.4.7.1 Therapeutic Uses

18.4.7.1.1 Asthma.

Terbutaline [Brethine] can reduce airway resistance in asthma by causing β_2 -mediated bronchodilation. Because terbutaline is “selective” for β_2 receptors, it produces much less activation of cardiac β_1 receptors than does isoproterenol. As a result, terbutaline and other β_2 -selective agents have replaced isoproterenol for therapy of asthma. Remember, however, that receptor selectivity is only relative: If administered in large doses, terbutaline will lose selectivity and activate β_1 receptors as well as β_2 receptors. Accordingly, patients should be warned not to exceed recommended doses, since doing so may cause undesired cardiac stimulation. Preparations and dosages for asthma are presented in [Chapter 75](#).

18.4.7.1.2 Delay of Preterm Labor.

By activating beta₂ receptors in the uterus, terbutaline can relax uterine smooth muscle, thereby delaying labor. However, other drugs are preferred (see [Chapter 63](#)).

18.4.7.2 Adverse Effects

Adverse effects are minimal at therapeutic doses. *Tremor* is most common. If dosage is excessive, terbutaline can cause *tachycardia* by activating beta₁ receptors in the heart.

18.4.8 Ephedrine

- *Receptor specificity:* alpha₁, alpha₂, beta₁, beta₂
- *Chemical classification:* noncatecholamine

Ephedrine is referred to as a *mixed-acting drug*, because it activates adrenergic receptors by direct and indirect mechanisms. *Direct* activation results from binding of the drug to alpha and beta receptors. *Indirect* activation results from release of NE from adrenergic neurons.

Owing to the development of more selective adrenergic agonists, uses for ephedrine are limited. By promoting beta₂-mediated bronchodilation, ephedrine can benefit patients with *asthma*. By activating a combination of alpha and beta receptors, ephedrine can improve hemodynamic status in patients with *shock*. In the past, the drug was used for nasal decongestion.

Because ephedrine activates the same receptors as epinephrine, both drugs share the same adverse effects: hypertension, dysrhythmias, angina, and hyperglycemia. In addition, because ephedrine can cross the blood-brain barrier, it can act in the CNS to cause insomnia.

18.5 DISCUSSION OF ADRENERGIC AGONISTS IN OTHER CHAPTERS

All of the drugs presented in this chapter are discussed again in chapters that address specific applications. For example, the use of alpha₁ agonists to relieve nasal congestion is discussed in [Chapter 76](#). [Table 17-4](#) summarizes the chapters in which adrenergic agonists are discussed again.

TABLE 17-4 Discussion of Adrenergic Agonists In Other Chapters

Drug Class	Discussion Topic	Chapter
Alpha₁ Agonists	Nasal congestion	76
	Ophthalmology	103
Alpha₂ Agonists	Cardiovascular effects	19
	Pain relief	28
	Hypertension	46
	Ophthalmology	103
Beta₁ Agonists	Heart failure	47
Beta₂ Agonists	Asthma	75
	Preterm labor	63
Amphetamines	Basic pharmacology	36
	Attention-deficit/hyperactivity disorder	36
	Drug abuse	39
	Appetite suppression	81

158

159

18.5.1

KEY POINTS

- Adrenergic agonists are also known as sympathomimetics. Why? Because their effects mimic those caused by the sympathetic nervous system.
- Most adrenergic agonists act by direct activation of adrenergic receptors. A few act by indirect mechanisms: promotion of norepinephrine release, blockade of norepinephrine uptake, and inhibition of norepinephrine breakdown.
- Adrenergic agonists fall into two chemical classes: catecholamines and noncatecholamines.
- Agents in the catecholamine family cannot be taken orally (because of destruction by MAO and COMT), have a brief duration of action (because of destruction by MAO and COMT), and cannot cross the blood-brain barrier (because they are polar molecules).
- Adrenergic agonists that are noncatecholamines can be taken orally, have a longer duration than the catecholamines, and can cross the blood-brain barrier.
- Activation of alpha₁ receptors causes vasoconstriction and mydriasis.

- Alpha₁ agonists are used for hemostasis, nasal decongestion, and elevation of blood pressure, and as adjuncts to local anesthetics.
- Major adverse effects that can result from alpha₁ activation are hypertension and local necrosis (if extravasation occurs).
- Activation of alpha₂ receptors in the periphery is of minimal clinical significance. In contrast, drugs that activate alpha₂ receptors in the CNS produce useful effects (see [Chapters 19](#) and [28](#)).
- All of the clinically relevant responses to activation of beta₁ receptors result from activating beta₁ receptors in the heart.
- Activation of cardiac beta₁ receptors increases heart rate, force of contraction, and conduction through the AV node.
- Drugs that activate beta₁ receptors can be used to treat heart failure, AV block, and cardiac arrest.
- Potential adverse effects from beta₁ activation are tachycardia, dysrhythmias, and angina.
- Drugs that activate beta₂ receptors are used primarily for asthma.
- Principal adverse effects from beta₂ activation are hyperglycemia (mainly in diabetic patients) and tremor.
- Activation of dopamine receptors dilates renal blood vessels, which helps maintain renal perfusion in shock.
- Epinephrine is a catecholamine that activates alpha₁, alpha₂, beta₁, and beta₂ receptors.
- Epinephrine is the drug of choice for treating anaphylactic shock: By activating alpha₁, beta₁, and beta₂ receptors, epinephrine can elevate blood pressure, suppress glottal edema, and counteract bronchoconstriction.
- Epinephrine can also be used to control superficial bleeding, restart the heart after cardiac arrest, and delay absorption of local anesthetics.
- Epinephrine should not be combined with MAO inhibitors, and should be used cautiously in patients taking tricyclic antidepressants.

- Isoproterenol is a catecholamine that activates beta₁ and beta₂ receptors.
- Isoproterenol can be used to enhance cardiac performance (by activating beta₁ receptors) and to treat bronchospasm (by activating beta₂ receptors).
- Dopamine is a catecholamine whose receptor specificity is highly dose dependent: at low therapeutic doses, dopamine acts on dopamine receptors only; at moderate doses, dopamine activates beta₁ receptors in addition to dopamine receptors; and at high doses, dopamine activates alpha₁ receptors along with beta₁ receptors and dopamine receptors.
- Terbutaline is a noncatecholamine that produces selective activation of beta₂ receptors.
- Terbutaline can be used to treat asthma and delay preterm labor.
- Because terbutaline is “selective” for beta₂ receptors, it produces much less stimulation of the heart than does isoproterenol. Accordingly, terbutaline and related drugs have replaced isoproterenol for therapy of asthma.

18.5.2 Summary of Major Nursing Implications

18.5.... EPINEPHRINE

18.5.... Preadministration Assessment

18.5.... Therapeutic Goal

Epinephrine has multiple indications. Major uses include treatment of *anaphylaxis* and *cardiac arrest*. Other uses include *control of superficial bleeding* and *delay of local anesthetic absorption*.

18.5.... Identifying High-Risk Patients

Epinephrine must be used with *great caution* in patients with hyperthyroidism, cardiac dysrhythmias, organic heart disease, or hypertension. *Caution* is also needed in patients with angina pectoris or diabetes and in those receiving MAO inhibitors, tricyclic antidepressants, or general anesthetics.

18.5... Implementation: Administration

18.5... Routes

Topical, oral inhalation, and parenteral (IV, IM, subQ, intracardiac, intraspinal). Rapid inactivation by MAO and COMT prohibits oral use.

18.5... Administration

The concentration of epinephrine solutions varies according to the route of administration (see [Table 17-3](#)). To avoid serious injury, check solution strength to ensure that the concentration is appropriate for the intended route. Aspirate prior to IM and subQ administration to avoid inadvertent injection into a vein.

Epinephrine solutions oxidize over time, causing them to turn pink or brown. Discard discolored solutions.

18.5... Ongoing Evaluation and Interventions

18.5... Evaluating Therapeutic Effects

In patients receiving IV epinephrine, monitor cardiovascular status continuously.

18.5... Minimizing Adverse Effects

18.5... Cardiovascular Effects.

By stimulating the heart, epinephrine can cause *anginal pain*, *tachycardia*, and *dysrhythmias*. These responses can be reduced with a beta-adrenergic blocking agent (eg, propranolol).

By activating α_1 receptors on blood vessels, epinephrine can cause intense vasoconstriction, which can result in *severe hypertension*. Blood pressure can be lowered with an alpha-adrenergic blocking agent (eg, phentolamine).

18.5... Necrosis.

If an IV line delivering epinephrine becomes extravasated, necrosis may result. Exercise care to avoid extravasation. If extravasation occurs, infiltrate the region with phentolamine to minimize injury.

159

160

18.5....

Hyperglycemia.

Epinephrine may cause hyperglycemia in diabetic patients. If hyperglycemia develops, insulin dosage should be increased.

18.5....

Minimizing Adverse Interactions

18.5....

MAO Inhibitors and Tricyclic Antidepressants.

These drugs prolong and intensify the actions of epinephrine. Patients taking these antidepressants require a reduction in epinephrine dosage.

18.5....

General Anesthetics.

When combined with certain general anesthetics, epinephrine can induce cardiac dysrhythmias. Dysrhythmias may respond to a β_1 -adrenergic blocker.

18.5....

DOPAMINE

18.5....

Preadministration Assessment

18.5....

Therapeutic Goal

Dopamine is used to improve hemodynamic status in patients with *shock* or *heart failure*. Benefits derive from enhanced cardiac performance and increased renal perfusion.

18.5....

Baseline Data

Full assessment of cardiac, hemodynamic, and renal status is needed.

18.5....

Identifying High-Risk Patients

Dopamine is *contraindicated* for patients with tachydysrhythmias or ventricular fibrillation. Use with *extreme caution* in patients with organic heart disease, hyperthyroidism, or hypertension, and in patients receiving MAO inhibitors. *Caution* is also needed in patients with angina pectoris and in those receiving tricyclic antidepressants or general anesthetics.

Implementation: Administration

Route

Intravenous.

Administration

Administer by continuous infusion, employing a metering device to control flow rate.

If extravasation occurs, stop the infusion immediately and infiltrate the region with an alpha-adrenergic antagonist (eg, phentolamine).

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Monitor cardiovascular status continuously. Increased urine output is one index of success. Diuretics may complement the beneficial effects of dopamine on the kidney.

Minimizing Adverse Effects

Cardiovascular Effects.

By stimulating the heart, dopamine may cause *anginal pain*, *tachycardia*, or *dysrhythmias*. These reactions can be decreased with a beta-adrenergic blocking agent (eg, propranolol).

Necrosis.

If the IV line delivering dopamine becomes extravasated, necrosis may result. Exercise care to avoid extravasation. If extravasation occurs, infiltrate the region with phentolamine.

Minimizing Adverse Interactions

MAO Inhibitors.

Concurrent use of MAO inhibitors and dopamine can result in severe cardiovascular toxicity. If a patient is taking an MAO inhibitor, dopamine dosage must be reduced by at least 90%.

18.5....	Tricyclic Antidepressants. These drugs prolong and intensify the actions of dopamine. Patients receiving them may require a reduction in dopamine dosage.	
18.5....	General Anesthetics. When combined with certain general anesthetics, dopamine can induce dysrhythmias. These may respond to a beta ₁ -adrenergic blocker.	
18.5....	DOBUTAMINE	
18.5....	Preadministration Assessment	
18.5....	Therapeutic Goal Improvement of hemodynamic status in patients with heart failure.	
18.5....	Baseline Data Full assessment of cardiac, renal, and hemodynamic status is needed.	
18.5....	Identifying High-Risk Patients Use with <i>great caution</i> in patients with organic heart disease, hyperthyroidism, tachydysrhythmias, or hypertension and in those taking an MAO inhibitor. <i>Caution</i> is also needed in patients with angina pectoris and in those receiving tricyclic antidepressants or general anesthetics.	160
18.5....	Implementation: Administration	161
18.5....	Route Intravenous.	
18.5....	Administration Administer by continuous IV infusion. Dilute concentrated solutions prior to use. Infusion rates usually range from 2.5 to 10 mcg/kg/min. Adjust the infusion rate on the basis of the cardiovascular response.	

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Monitor cardiac function (heart rate, ECG), blood pressure, and urine output. When possible, monitor central venous pressure and pulmonary wedge pressure.

Minimizing Adverse Effects

Major adverse effects are *tachycardia* and *dysrhythmias*. Monitor the ECG and blood pressure closely. Adverse cardiac effects can be reduced with a beta-adrenergic antagonist.

Minimizing Adverse Interactions

MAO Inhibitors.

Concurrent use of an MAO inhibitor with dobutamine can cause severe cardiovascular toxicity. If a patient is taking an MAO inhibitor, dobutamine dosage must be reduced by at least 90%.

Tricyclic Antidepressants.

These drugs can prolong and intensify the actions of dobutamine. Patients receiving them may require a reduction in dobutamine dosage.

General Anesthetics.

When combined with certain general anesthetics, dobutamine can cause cardiac dysrhythmias. These may respond to a beta₁-adrenergic antagonist.

¹⁹CHAPTER 18 Adrenergic Antagonists

The adrenergic antagonists cause direct blockade of adrenergic receptors. With one exception, all of the adrenergic antagonists produce *reversible* (competitive) blockade.

Unlike many adrenergic agonists, which act at alpha- *and* beta-adrenergic receptors, most adrenergic antagonists are more selective. As a result, the adrenergic antagonists can be neatly divided into two major groups: (1) *alpha-adrenergic blocking agents* (drugs that produce selective blockade of alpha-adrenergic receptors); and (2) *beta-adrenergic blocking agents* (drugs that produce selective blockade of beta receptors).^{*} Members of these two groups are listed in [Table 18-1](#).

Our approach to the adrenergic antagonists mirrors the approach we took with the adrenergic agonists. That is, we begin by discussing the therapeutic and adverse effects that can result from alpha- and beta-adrenergic blockade, after which we discuss the individual drugs that produce receptor blockade.

Remember that it is much easier to understand responses to the adrenergic drugs if you first understand the responses to activation of adrenergic receptors. Accordingly, if you have not yet mastered (memorized) [Table 13-3](#), you should do so now (or at least be prepared to consult the table as we proceed).

TABLE 18-1 Receptor Specificity of Adrenergic Antagonists

Category	Drugs	Receptors Blocked
Alpha-Adrenergic Blocking Agents	Phenoxybenzamine	alpha ₁ , alpha ₂
	Phentolamine	alpha ₁ , alpha ₂
	Alfuzosin	alpha ₁
	Doxazosin	alpha ₁
	Prazosin	alpha ₁
	Silodosin	alpha ₁
	Terazosin	alpha ₁
	Tamsulosin	alpha ₁
Beta-Adrenergic Blocking Agents	Carteolol	beta ₁ , beta ₂
	Nadolol	beta ₁ , beta ₂
	Penbutolol	beta ₁ , beta ₂
	Pindolol	beta ₁ , beta ₂
	Propranolol	beta ₁ , beta ₂
	Sotalol	beta ₁ , beta ₂
	Timolol	beta ₁ , beta ₂
	Carvedilol	beta ₁ , beta ₂ , alpha ₁
	Labetalol	beta ₁ , beta ₂ , alpha ₁
	Acebutolol	beta ₁
	Atenolol	beta ₁
	Betaxolol	beta ₁
	Bisoprolol	beta ₁
	Esmolol	beta ₁
	Metoprolol	beta ₁
	Nebivolol	beta ₁

19.1 ALPHA-ADRENERGIC ANTAGONISTS I: THERAPEUTIC AND ADVERSE RESPONSES TO ALPHA BLOCKADE

In this section we discuss the beneficial and adverse responses that can result from blockade of alpha-adrenergic receptors. Properties of individual alpha-blocking agents are discussed later.

19.1.1 Therapeutic Applications of Alpha Blockade

Most of the clinically useful responses to alpha-adrenergic antagonists result from blockade of α_1 receptors on blood vessels. Blockade of α_1 receptors in the bladder and prostate can help men with benign prostatic hyperplasia (BPH). Blockade of α_1 receptors in the eye and blockade of α_2 receptors have no recognized therapeutic applications.

19.1.1.1 Essential Hypertension.

Hypertension (high blood pressure) can be treated with a variety of drugs, including the alpha-adrenergic antagonists. Alpha antagonists lower blood pressure by blocking α_1 receptors on arterioles and veins, causing vasodilation. Dilation of arterioles reduces arterial pressure directly. Dilation of veins lowers arterial pressure by an indirect process: In response to venous dilation, return of blood to the heart decreases, thereby decreasing cardiac output, which in turn reduces arterial pressure. The role of alpha-adrenergic blockers in essential hypertension is discussed further in [Chapter 46](#) (Drugs for Hypertension).

* Only two adrenergic antagonists—carvedilol and labetalol—act at alpha and beta receptors.

19.1.1.2 Reversal of Toxicity from Alpha₁ Agonists.

Overdose with an alpha-adrenergic agonist (eg, epinephrine) can produce *hypertension* secondary to excessive activation of α_1 receptors on blood vessels. When this occurs, blood pressure can be lowered by reversing the vasoconstriction with an alpha-blocking agent.

If an IV line containing an alpha agonist becomes extravasated, necrosis can occur secondary to intense local vasoconstriction. By infiltrating the region with phentolamine (an alpha-adrenergic antagonist), we can block the vasoconstriction and thereby prevent injury.

19.1.1.3 Benign Prostatic Hyperplasia.

BPH results from proliferation of cells in the prostate gland. Symptoms include dysuria, increased frequency of daytime urination, nocturia, urinary hesitance and intermittence, urinary

urgency, a sensation of incomplete voiding, and a reduction in the size and force of the urinary stream. All of these symptoms can be improved with drugs that block α_1 receptors. Benefits derive from reduced contraction of smooth muscle in the bladder neck (trigone and sphincter) and prostatic capsule. BPH is discussed at length in [Chapter 65](#).

19.1.1.4 Pheochromocytoma.

A pheochromocytoma is a catecholamine-secreting tumor derived from cells of the sympathetic nervous system. These tumors are usually located in the adrenal medulla. If secretion of catecholamines (epinephrine, norepinephrine) is sufficiently great, persistent hypertension can result. The principal cause of hypertension is activation of α_1 receptors on blood vessels, although activation of β_1 receptors on the heart can also contribute. The preferred treatment is surgical removal of the tumor, but alpha-adrenergic blockers may also be employed.

Alpha-blocking agents have two roles in managing pheochromocytoma. First, in patients with inoperable tumors, alpha blockers are given chronically to suppress hypertension. Second, when surgery is indicated, alpha blockers are administered preoperatively to reduce the risk of acute hypertension during the procedure. (The surgical patient is at risk because manipulation of the tumor can cause massive catecholamine release.)

19.1.1.5 Raynaud's Disease.

Raynaud's disease is a peripheral vascular disorder characterized by vasospasm in the toes and fingers. Prominent symptoms are local sensations of pain and cold. Alpha blockers can suppress symptoms by preventing alpha-mediated vasoconstriction. It should be noted, however, that although alpha blockers can relieve symptoms of Raynaud's disease, they are generally ineffective against other peripheral vascular disorders that involve inappropriate vasoconstriction.

19.1.2 Adverse Effects of Alpha Blockade

The most significant adverse effects of the alpha-adrenergic antagonists result from blockade of α_1 receptors. Detrimental effects associated with α_2 blockade are minor.

19.1.2.1 Adverse Effects of Alpha₁ Blockade

19.1.2.1.1 Orthostatic Hypotension.

This is the most serious adverse response to alpha-adrenergic blockade. Orthostatic hypotension can reduce blood flow to the brain, thereby causing dizziness, lightheadedness, and even syncope (fainting).

The cause of hypotension is blockade of alpha receptors on *veins*, which reduces muscle tone in the venous wall. Because of reduced venous tone, blood tends to pool (accumulate) in veins when the patient assumes an erect posture. As a result, return of blood to the heart is reduced, which decreases cardiac output, which in turn causes blood pressure to fall.

Patients should be informed about symptoms of hypotension (lightheadedness, dizziness) and advised to sit or lie down if these occur. In addition, patients should be informed that orthostatic hypotension can be minimized by avoiding abrupt transitions from a supine or sitting position to an erect posture.

19.1.2.1.2 Reflex Tachycardia.

Alpha-adrenergic antagonists can increase heart rate by triggering the baroreceptor reflex. The mechanism is this: (1) blockade of vascular alpha₁ receptors causes vasodilation; (2) vasodilation reduces blood pressure; and (3) baroreceptors sense the reduction in blood pressure and, in an attempt to restore normal pressure, initiate a reflex increase in heart rate via the autonomic nervous system. If necessary, reflex tachycardia can be suppressed with a beta-adrenergic blocking agent.

19.1.2.1.3 Nasal Congestion.

Alpha blockade can dilate the blood vessels of the nasal mucosa, producing nasal congestion.

19.1.2.1.4 Inhibition of Ejaculation.

Since activation of alpha₁ receptors is required for ejaculation (see [Table 13-3](#)), blockade of these receptors can cause impotence. This form of drug-induced impotence is reversible and resolves when the alpha blocker is withdrawn.

The ability of alpha blockers to inhibit ejaculation can be a major reason for nonadherence to the prescribed regimen. If a patient deems the adverse sexual effects of alpha blockade unacceptable, a change in medication will be required. Because males may be reluctant to

discuss such concerns, a tactful interview may be needed to discern if drug-induced impotence is discouraging drug use.

19.1.2.1.5 Sodium Retention and Increased Blood Volume.

By reducing blood pressure, alpha blockers can promote renal retention of sodium and water, thereby causing blood volume to increase. The steps in this process are as follows: (1) by reducing blood pressure, alpha₁ blockers decrease renal blood flow; (2) in response to reduced perfusion, the kidney excretes less sodium and water; and (3) the resultant retention of sodium and water increases blood volume. As a result, blood pressure is elevated, blood flow to the kidney is increased, and, as far as the kidney is concerned, all is well. Unfortunately, when alpha blockers are used to treat hypertension (which they often are), this compensatory elevation in blood pressure can negate beneficial effects. In order to prevent the kidney from “neutralizing” hypotensive actions, alpha-blocking agents are usually combined with a diuretic when used in patients with hypertension.

19.1.2.2 Adverse Effects of Alpha₂ Blockade

The most significant adverse effect associated with alpha₂ blockade is *potentiation of the reflex tachycardia that can occur in response to blockade of alpha₁ receptors*. Why does alpha₂ blockade intensify reflex tachycardia? Recall that peripheral alpha₂ receptors are located presynaptically and that activation of these receptors inhibits norepinephrine release. Hence, if alpha₂ receptors are blocked, release of norepinephrine will increase. Since the reflex tachycardia caused by alpha₁ blockade is ultimately the result of increased firing of the sympathetic nerves to the heart, and since alpha₂ blockade will cause each nerve impulse to release a greater amount of norepinephrine, alpha₂ blockade will po

tentiate reflex tachycardia initiated by blockade of alpha₁ receptors. Accordingly, drugs such as phentolamine, which block alpha₂ as well as alpha₁ receptors, cause greater reflex tachycardia than do drugs that block alpha₁ receptors only.

163

164

19.2 ALPHA-ADRENERGIC ANTAGONISTS II: PROPERTIES OF INDIVIDUAL ALPHA BLOCKERS

Only seven alpha-adrenergic antagonists are employed clinically. Because the alpha blockers often cause postural hypotension, therapeutic uses are limited.

As indicated in [Table 18-1](#), the alpha-adrenergic blocking agents can be subdivided into two major groups. One group—the *nonselective* alpha-blocking agents—contains drugs that block alpha₁ and

Pharmacology for Nursing Care, 7th Edition

alpha₂ receptors. Phentolamine is the prototype. The second group, represented by *prazosin*, contains drugs that produce *selective alpha₁ blockade*.

19.2.1 Prazosin

19.2.1.1 Actions and Uses.

Prazosin [Minipress] is a competitive antagonist that produces selective blockade of alpha₁-adrenergic receptors. The result is dilation of arterioles and veins, and relaxation of smooth muscle in the bladder neck (trigone and sphincter) and prostatic capsule. Prazosin is approved only for hypertension. However, it can also benefit men with BPH.

19.2.1.2 Pharmacokinetics.

Prazosin is administered orally. Antihypertensive effects peak in 1 to 3 hours and persist for 10 hours. The drug undergoes extensive hepatic metabolism followed by excretion in the bile. Only 10% is eliminated in the urine. The half-life is 2 to 3 hours.

19.2.1.3 Adverse Effects.

Blockade of alpha₁ receptors can cause *orthostatic hypotension*, *reflex tachycardia*, *inhibition of ejaculation*, and *nasal congestion*. The most serious of these is hypotension. Patients should be educated about the symptoms of hypotension (dizziness, lightheadedness) and advised to sit or lie down if they occur. Also, patients should be informed that orthostatic hypotension can be minimized by moving slowly when changing from a supine or sitting position to an upright position.

About 1% of patients lose consciousness 30 to 60 minutes after receiving their initial prazosin dose. This “first-dose” effect is the result of severe postural hypotension. To minimize the first-dose effect, the initial dose should be small (1 mg or less). Subsequent doses can be gradually increased with little risk of fainting. Patients who are starting treatment should be forewarned about the first-dose effect and advised to avoid driving and other hazardous activities for 12 to 24 hours. Administering the initial dose at bedtime eliminates the risk of a first-dose effect.

19.2.1.4 Preparations, Dosage, and Administration.

Prazosin hydrochloride [Minipress] is available in capsules (1, 2, and 5 mg) for oral use. The initial adult dosage for hypertension is 1 mg 2 or 3 times a day. The maintenance dosage is 6 to 15 mg/day taken in divided doses.

19.2.2 Terazosin

19.2.2.1 Actions and Uses.

Like prazosin, terazosin [Hytrin] is a selective, competitive antagonist at α_1 -adrenergic receptors. The drug is approved for hypertension and BPH.

19.2.2.2 Pharmacokinetics.

Peak effects develop 1 to 2 hours after oral dosing. The drug's half-life is prolonged (9 to 12 hours), allowing benefits to be maintained with just one dose a day. Terazosin undergoes hepatic metabolism followed by excretion in the bile and urine.

19.2.2.3 Adverse Effects.

Like other α -blocking agents, terazosin can cause *orthostatic hypotension*, *reflex tachycardia*, and *nasal congestion*. In addition, terazosin is associated with a high incidence (16%) of *headache*. As with prazosin, the first dose can cause profound hypotension. To minimize this first-dose effect, the initial dose should be administered at bedtime.

19.2.2.4 Preparations, Dosage, and Administration.

Terazosin [Hytrin] is available in tablets and capsules (1, 2, 5, and 10 mg). *Antihypertensive* therapy is initiated with a 1-mg dose, administered at bedtime to minimize the first-dose effect. Dosage can be gradually increased as needed and tolerated. The recommended dosage range for maintenance therapy is 1 to 5 mg once daily. Dosing for *benign prostatic hyperplasia* is similar to that for hypertension, except that the maintenance dosage is 10 mg/day for most men.

19.2.3 Doxazosin

19.2.3.1 Actions and Uses.

Doxazosin [Cardura] is a selective, competitive inhibitor of α_1 -adrenergic receptors. The drug is indicated for hypertension and BPH.

19.2.3.2 Pharmacokinetics.

Doxazosin is administered orally, and peak effects develop in 2 to 3 hours. The drug has a prolonged half-life (22 hours), so once-a-day dosing is adequate. In the blood, most (98%) of the drug is protein bound. Doxazosin undergoes extensive hepatic metabolism followed by biliary excretion.

19.2.3.3 Adverse Effects.

Like prazosin and terazosin, doxazosin can cause *orthostatic hypotension*, *reflex tachycardia*, and *nasal congestion*. As with prazosin and terazosin, the first dose can cause profound hypotension, which can be minimized by giving the initial dose at bedtime.

19.2.3.4 Preparations, Dosage, and Administration.

Doxazosin is available in two oral formulations: standard tablets (1, 2, 4, and 8 mg), marketed as Cardura, and sustained-release tablets (4 and 8 mg), marketed as Cardura XL. Cardura is approved for hypertension and BPH, whereas Cardura XL is approved for BPH only.

19.2.3.5 Dosage Using Cardura.

The initial dosage for hypertension or BPH is 1 mg once a day. The dosage may be gradually increased as needed, up to a maximum of 16 mg once daily for hypertension or 8 mg once daily for BPH.

19.2.3.6 Dosage Using Cardura XL.

The initial dosage (for BPH) is 4 mg once a day administered with breakfast. If needed, the dosage may be increased to 8 mg once daily 3 to 4 weeks later.

19.2.4 Tamsulosin

19.2.4.1 Actions and Uses.

Tamsulosin [Flomax] is an α_1 -adrenergic antagonist that causes “selective” blockade of α_1 receptors on smooth muscle of the bladder neck (trigone and sphincter), prostatic capsule, and prostatic urethra; blockade of vascular α_1 receptors is weak. The drug is approved only for BPH; it is not useful for hypertension. In men with BPH, tamsulosin increases urine flow rate and decreases residual urine volume. Maximum benefits develop within 2 weeks.

19.2.4.2 Pharmacokinetics.

Tamsulosin is administered orally, and absorption is slow. Food further decreases the rate and extent of absorption. The drug is metabolized in the liver and excreted in the urine.

19.2.4.3 Adverse Effects.

The most common adverse effects are *headache* (20%) and *dizziness* (15%). Between 8% and 18% of patients experience *abnormal ejaculation* (ejaculation failure, ejaculation decrease, retrograde ejaculation). In addition, the drug is associated with increased incidence of *infection*. Because relaxation of vascular smooth muscle is relatively weak, the risk of orthostatic hypotension is much lower than with most other alpha blockers.

19.2.4.4 Drug Interactions.

Combined use with cimetidine increases tamsulosin serum levels, which may cause toxicity. Combined use with hypotensive drugs—including sildenafil [Viagra] and related agents—may cause a significant reduction in blood pressure.

19.2.4.5 Preparations, Dosage, and Administration.

Tamsulosin [Flomax] is available in 0.4-mg capsules. The usual dosage is 0.4 mg once a day, administered 30 minutes after the same meal each day.

19.2.5 Alfuzosin

19.2.5.1 Actions and Uses.

Like tamsulosin, alfuzosin [Uroxatral] is an α_1 blocker with selectivity for α_1 receptors in the prostate and urinary tract. At recommended doses, blockade of α_1 receptors on blood vessels is weak. Alfuzosin is indicated only for BPH. The drug is not useful in hypertension.

19.2.5.2 Pharmacokinetics.

Alfuzosin is formulated in extended-release tablets, and hence absorption is slow. Plasma levels peak 8 hours after dosing. Bioavailability is 49%. Alfuzosin undergoes extensive hepatic metabolism, primarily by CYP3A4, an isozyme of cytochrome P450. Most (70%) of each dose is eliminated in the feces as inactive metabolites. A small fraction leaves unchanged in the urine. The drug's half-life is 10 hours.

In patients with moderate to severe hepatic impairment, alfuzosin levels increase three- to fourfold. Accordingly, the drug is contraindicated for these patients.

164

165

19.2.5.3 Adverse Effects.

Alfuzosin is generally well tolerated. The most common adverse effect is *dizziness* (5%). Syncope and clinically significant hypotension are rare. Unlike tamsulosin, alfuzosin does not interfere with ejaculation. Doses 4 times greater than recommended can prolong the QT interval, and might thereby pose a risk of ventricular dysrhythmias.

19.2.5.4 Drug Interactions.

Levels of alfuzosin are markedly raised by powerful inhibitors of CYP3A4. Among these are erythromycin, clarithromycin, itraconazole, ketoconazole, nefazodone, and the HIV protease inhibitors, such as ritonavir. Concurrent use of alfuzosin with these drugs is contraindicated.

Although alfuzosin does not lower blood pressure much by itself, combining it with other hypotensive agents could produce a more dramatic reduction. Accordingly, such combinations should be used with caution. Drugs of concern include organic nitrates, antihypertensive agents, and the type 5 phosphodiesterase inhibitors used for impotence (eg, sildenafil [Viagra]).

19.2.5.5 Preparations, Dosage, and Administration.

Alfuzosin [Uroxatral] is available in 10-mg extended-release tablets. The recommended dosage is 10 mg once a day, taken immediately after the same meal each day.

19.2.6 Silodosin

19.2.6.1 Actions and Uses.

Silodosin [Rapaflo], approved in October 2008, is an alpha-adrenergic antagonist that selectively blocks α_1 receptors in the prostate, bladder, and urethra. Blockade of vascular alpha receptors is weak. The drug is indicated only for BPH.

19.2.6.2 Adverse Effects.

Silodosin is generally well tolerated. However, like tamsulosin, silodosin can greatly reduce or eliminate release of semen during orgasm. Fortunately, this effect reverses when the drug is discontinued. Although blockade of vascular alpha receptors is usually minimal, silodosin *can* produce dizziness, light-headedness, and nasal congestion.

19.2.6.3 Preparations Dosage, and Administration.

When silodosin becomes commercially available (sometime in 1009), the expected formulations are 4- and 8-mg capsules. The usual dosage is 8 mg once daily, but should be reduced to 4 mg once daily in men with moderate renal or hepatic impairment. Men with severe renal or hepatic impairment should not use the drug.

19.2.7 Phentolamine

19.2.7.1 Actions and Uses.

Like prazosin, phentolamine (formerly available as Regitine) is a competitive adrenergic antagonist. However, in contrast to prazosin, phentolamine blocks α_2 receptors as well as α_1 receptors. Phentolamine has two approved applications: (1) treatment of pheochromocytoma and (2) prevention of tissue necrosis following extravasation of drugs that produce α_1 -mediated vasoconstriction (eg, norepinephrine).

19.2.7.2 Adverse Effects.

Like prazosin, phentolamine can produce the typical adverse effects associated with alpha-adrenergic blockade: *orthostatic hypotension, reflex tachycardia, nasal congestion, and inhibition of ejaculation*. Because it blocks α_2 receptors, *phentolamine produces greater reflex tachycardia than prazosin*. If reflex tachycardia is especially severe, heart rate can be reduced with a beta blocker. Since tachycardia can aggravate angina pectoris and myocardial infarction (MI), phentolamine is contraindicated for patients with either disorder.

Overdose can produce profound hypotension. If necessary, blood pressure can be elevated with *norepinephrine*. *Epinephrine* should *not* be used, because the drug can cause blood pressure to drop even further! Why? Because in the presence of α_1 blockade, the ability of epinephrine to promote vasodilation (via activation of vascular β_2 receptors) may outweigh the ability of epinephrine to cause vasoconstriction (via activation of vascular α_1 receptors). Further lowering of blood pressure is not a problem with norepinephrine because norepinephrine does not activate β_2 receptors.

19.2.7.3 Preparations, Dosage, and Administration.

Phentolamine is supplied in solution (5 mg/2 mL) for IM and IV administration. The dose for preventing hypertension during surgical excision of a *pheochromocytoma* is 5 mg (IM or IV) given 1 to 2 hours before surgery. To prevent *necrosis following extravasation* of IV

norepinephrine, the region should be infiltrated with 5 to 10 mg of phentolamine diluted in 10 mL of saline.

19.2.8 Phenoxybenzamine

19.2.8.1 Actions and Uses.

Phenoxybenzamine [Dibenzylamine] is an old drug that, like phentolamine, blocks α_1 and α_2 receptors. However, unlike all of the other alpha-adrenergic antagonists, phenoxybenzamine is a *noncompetitive* receptor antagonist. Hence, receptor blockade is *not reversible*. As a result, the effects of phenoxybenzamine are long lasting. (Responses to a single dose can persist for several days.) Effects subside as newly synthesized receptors replace the ones that have been irreversibly blocked. Phenoxybenzamine is approved only for *pheochromocytoma*.

19.2.8.2 Adverse Effects.

Like the other alpha-adrenergic antagonists, phenoxybenzamine can produce *orthostatic hypotension*, *reflex tachycardia*, *nasal congestion*, and *inhibition of ejaculation*. Reflex tachycardia is greater than that caused by prazosin and about equal to that caused by phentolamine.

If dosage is excessive, phenoxybenzamine, like phentolamine, will cause profound hypotension. Furthermore, since hypotension is the result of *irreversible* α_1 blockade, it cannot be corrected with an α_1 agonist. To restore blood pressure, patients must be given IV fluids, which elevate blood pressure by increasing blood volume.

19.2.8.3 Preparations, Dosage, and Administration.

Phenoxybenzamine hydrochloride [Dibenzylamine] is available in 10-mg tablets for oral use. The initial adult dosage is 10 mg twice a day. The dosage can be increased every other day until the desired level of alpha blockade (blood pressure control) has been achieved. The usual adult maintenance dosage is 20 to 40 mg given 2 or 3 times a day.

19.3 BETA-ADRENERGIC ANTAGONISTS I: THERAPEUTIC AND ADVERSE RESPONSES TO BETA BLOCKADE

In this section we consider the beneficial and adverse responses that can result from blockade of beta-adrenergic receptors. Properties of individual beta blockers are discussed later.

19.3.1 Therapeutic Applications of Beta Blockade

Practically all of the therapeutic effects of the beta-adrenergic antagonists result from blockade of β_1 receptors in the heart. The major consequences of blocking these receptors are (1) reduced heart rate, (2) reduced force of contraction, and (3) reduced velocity of impulse conduction through the atrioventricular (AV) node. Because of these effects, beta blockers are useful in a variety of cardiovascular disorders.

19.3.1.1 Angina Pectoris.

Angina pectoris (paroxysmal pain in the region of the heart) occurs when oxygen supply (blood flow) to the heart is insufficient to meet cardiac oxygen demand. Anginal attacks can be precipitated by exertion, intense emotion, and other factors. Beta-adrenergic blockers are a mainstay of antianginal therapy. By blocking β_1 receptors in the heart, these drugs decrease cardiac work. This brings oxygen demand back into balance with oxygen supply, and thereby prevents pain. Angina pectoris and its treatment are the subject of [Chapter 50](#).

19.3.1.2 Hypertension.

For years, beta blockers were considered drugs of choice for hypertension. However, recent data indicate they are less beneficial than previously believed.

The exact mechanism by which beta blockers reduce blood pressure is not known. Older proposed mechanisms include reduction of cardiac output through blockade of β_1 receptors in the heart and suppression of renin release through blockade of β_1 receptors in the kidney (see [Chapter 43](#) for a discussion of the role of renin in blood pressure control). More recently, we have learned that, with long-term use, beta blockers reduce peripheral vascular resistance, which could account for much of their antihypertensive effects. The role of beta-adrenergic blocking agents in hypertension is discussed further in [Chapter 46](#).

19.3.1.3 Cardiac Dysrhythmias.

Beta-adrenergic blocking agents are especially useful for treating dysrhythmias that involve excessive electrical activity in the sinus node and atria. By blocking cardiac β_1 receptors, these drugs can (1) decrease the rate of sinus nodal discharge and (2) suppress conduction of atrial impulses through the AV node, thereby preventing the ventricles from being driven at an excessive rate. The use of beta-adrenergic blockers to treat dysrhythmias is discussed at length in [Chapter 48](#).

165

166

19.3.1.4 Myocardial Infarction.

An MI is a region of myocardial necrosis caused by localized interruption of blood flow to the heart wall. Treatment with a beta blocker can reduce pain, infarct size, mortality, and the risk of reinfarction. To be effective, therapy with a beta blocker must commence soon after an MI has occurred, and should be continued for several years. The role of beta blockers in treating MI is discussed further in [Chapter 52](#).

19.3.1.5 Heart Failure.

Beta blockers are now considered standard therapy for heart failure. This application is relatively new and may come as a surprise to some readers. Why? Because, until recently, heart failure was considered an absolute *contraindication* to beta blockers. At this time, only three beta blockers—carvedilol, bisoprolol, and metoprolol—have been shown effective for heart failure. Use of beta blockers for heart failure is discussed at length in [Chapter 47](#).

19.3.1.6 Hyperthyroidism.

Hyperthyroidism (excessive production of thyroid hormone) is associated with an increase in the sensitivity of the heart to catecholamines (eg, norepinephrine, epinephrine). As a result, normal levels of sympathetic activity to the heart can generate tachydysrhythmias and angina pectoris. Blockade of cardiac beta₁ receptors suppresses these responses.

19.3.1.7 Migraine.

When taken prophylactically, beta-adrenergic blocking agents can reduce the frequency of migraine attacks. However, although beta blockers are effective as prophylaxis, these drugs are not able to abort a migraine headache once it has begun. The mechanism by which beta blockers prevent migraine is not known. Treatment of migraine and other headaches is the subject of [Chapter 30](#).

19.3.1.8 Stage Fright.

Public speakers and other performers sometimes experience “stage fright.” Prominent symptoms are tachycardia and sweating brought on by generalized discharge of the sympathetic nervous system. Beta blockers help by preventing beta₁-mediated tachycardia.

19.3.1.9 Pheochromocytoma.

As discussed above, a pheochromocytoma secretes large amounts of catecholamines, which can cause excessive stimulation of the heart. Cardiac stimulation can be prevented by beta₁ blockade.

19.3.1.10 Glaucoma.

Beta blockers are important drugs for treating glaucoma, a condition characterized by elevated intraocular pressure with subsequent injury to the optic nerve. The group of beta blockers used in glaucoma (see [Table 103-2](#)) is different from the group of beta blockers discussed in this chapter. Glaucoma and its treatment are addressed in [Chapter 103](#) (Drugs for the Eye).

19.3.2 Adverse Effects of Beta Blockade

Although therapeutic responses to beta blockers are due almost entirely to blockade of beta₁ receptors, adverse effects involve both beta₁ and beta₂ blockade. Consequently, the nonselective beta-adrenergic blocking agents (drugs that block beta₁ *and* beta₂ receptors) produce a broader spectrum of adverse effects than do the “cardioselective” beta-adrenergic antagonists (drugs that selectively block beta₁ receptors at usual therapeutic doses).

19.3.2.1 Adverse Effects of Beta₁ Blockade

All of the adverse effects of beta₁ blockade are the result of blocking beta₁ receptors in the heart. Blockade of renal beta₁ receptors is not a concern.

19.3.2.1.1 Bradycardia.

Blockade of cardiac beta₁ receptors can produce bradycardia (excessively slow heart rate). If necessary, heart rate can be increased using a combination of isoproterenol (a beta-adrenergic agonist) and atropine (a muscarinic antagonist). Isoproterenol competes with the beta blocker for cardiac beta₁ receptors, thereby promoting cardiac stimulation. By blocking muscarinic receptors on the heart, atropine prevents slowing of the heart by the parasympathetic nervous system.

19.3.2.1.2 Reduced Cardiac Output.

Beta₁ blockade can reduce cardiac output by decreasing heart rate and the force of myocardial contraction. Because they can decrease cardiac output, *beta blockers must be used with great*

caution in patients with heart failure or reduced cardiac reserve. In both cases, any further decrease in cardiac output could result in insufficient tissue perfusion.

19.3.2.1.3 Precipitation of Heart Failure.

In some patients, suppression of cardiac function with a beta blocker can be so great as to cause heart failure. Patients should be informed about the early signs of heart failure (shortness of breath, night coughs, swelling of the extremities) and instructed to notify the prescriber if these occur. It is important to appreciate that, although beta blockers can precipitate heart failure, they are also used to *treat* heart failure.

19.3.2.1.4 AV Heart Block.

Atrioventricular heart block is defined as suppression of impulse conduction through the AV node. In its most severe form, AV block prevents *all* atrial impulses from reaching the ventricles. Because blockade of cardiac β_1 receptors can suppress AV conduction, production of AV block is a potential complication of beta-blocker therapy. These drugs are contraindicated for patients with pre-existing AV block.

19.3.2.1.5 Rebound Cardiac Excitation.

Long-term use of beta blockers can sensitize the heart to catecholamines. As a result, if a beta blocker is withdrawn *abruptly*, anginal pain or ventricular dysrhythmias may develop. This phenomenon of increased cardiac activity in response to abrupt cessation of beta-blocker therapy is referred to as *rebound excitation*. The risk of rebound excitation can be minimized by withdrawing these drugs gradually (eg, by tapering the dosage over a period of 1 to 2 weeks). If rebound excitation occurs, dosing should be temporarily resumed. Patients should be warned against abrupt cessation of treatment. Also, they should be advised to carry an adequate supply of their beta blocker when traveling.

19.3.2.2 Adverse Effects of β_2 Blockade

19.3.2.2.1 Bronchoconstriction.

Blockade of β_2 receptors in the lung can cause constriction of the bronchi. (Recall that activation of these receptors promotes bronchodilation.) For most people, the degree of bronchoconstriction is insignificant. However, when bronchial β_2 receptors are blocked in patients with asthma, the resulting increase in airway resistance can be life threatening. Accordingly, *drugs that block β_2 receptors* are contraindicated for people with asthma. If

these individuals must use a beta blocker, they should use an agent that is beta₁ selective (eg, metoprolol).

19.3.2.2.2 Inhibition of Glycogenolysis.

As noted in [Chapter 13](#), epinephrine, acting at beta₂ receptors in skeletal muscle and the liver, can stimulate glycogenolysis (breakdown of glycogen into glucose). Beta₂ blockade will inhibit this process. Although suppression of beta₂-mediated glycogenolysis is inconsequential for most people, interference with this process can be detrimental to patients with *diabetes*. Why? Because these people are especially dependent on beta₂-mediated glycogenolysis as a way to overcome severe reductions in blood glucose levels (caused by overdosing with insulin). If the diabetic patient requires a beta blocker, a beta₁-selective agent should be chosen.

19.4 BETA-ADRENERGIC ANTAGONISTS II: PROPERTIES OF INDIVIDUAL BETA BLOCKERS

The beta-adrenergic antagonists can be subdivided into three groups:

- *First-generation (nonselective) beta blockers* (eg, propranolol), which block beta₁ and beta₂ receptors
- *Second-generation (cardioselective) beta blockers* (eg, metoprolol), which produce selective blockade of beta₁ receptors (at usual doses)
- *Third-generation (vasodilating) beta blockers* (eg, carvedilol), which act on blood vessels to cause dilation, but may produce nonselective or cardioselective beta blockade

Our discussion of the individual beta blockers focuses on two prototypes: propranolol and metoprolol. Properties of these and other beta blockers are summarized in [Tables 18-2](#) and [18-3](#).

19.4.1 Propranolol

Propranolol [Inderal, InnoPran], our prototype of the first-generation beta blockers, produces *nonselective* beta blockade. That is, it blocks both beta₁- and beta₂-adrenergic receptors.

Propranolol was the first beta blocker to receive widespread clinical use and remains one of our most important beta-blocking agents.

19.4.1.1 Pharmacologic Effects

By blocking *cardiac* β_1 receptors, propranolol can *reduce heart rate, decrease the force of ventricular contraction, and suppress impulse conduction through the AV node*. The net effect is a reduction in cardiac output.

TABLE 18-2 Clinical Pharmacology of the Beta-Adrenergic Blocking Agents

Generic Name	Trade Name	Receptors Blocked	ISA	Lipid Solubility	Half-Life (hr)	Route*	Maintenance Dosage in Hypertension†
First-Generation: Nonselective Beta Blockers							
Carteolol	Cartrol	Beta ₁ , Beta ₂	++	Low	6	PO	2.5 mg once/day
Nadolol	Corgard	Beta ₁ , Beta ₂	0	Low	20–24	PO	40 mg once/day
Penbutolol	Levatol	Beta ₁ , Beta ₂	+	Moderate	5	PO	20 mg once/day
Pindolol	Visken	Beta ₁ , Beta ₂	+++	Moderate	3–4	PO	10 mg twice/day
Propranolol (IR)	Inderal	Beta ₁ , Beta ₂	0	High	3–5	PO, IV	60 mg twice/day
Propranolol (SR)	Inderal LA, InnoPran XL					PO	80 mg once/day
Sotalol	Betapace	Beta ₁ , Beta ₂	0	High	12	PO	Not for hypertension
Timolol	Blocadren	Beta ₁ , Beta ₂	0	Low	4	PO	20 mg twice/day
Second-Generation: Cardioslective Beta Blockers							
Acebutolol	Sectral	Beta ₁	+	Moderate	3–4	PO	400 mg once/day
Atenolol	Tenormin	Beta ₁	0	Low	6–9	PO, IV	50 mg once/day
Betaxolol	Kerlone	Beta ₁	0	Low	14–22	PO	10 mg once/day
Bisoprolol	Zebeta	Beta ₁	0	Moderate	9–12	PO	5 mg once/day
Esmolol	Brevibloc	Beta ₁	0	Low	0.15	IV	Not for hypertension
Metoprolol (IR)	Lopressor	Beta ₁	0	High	3–7	PO, IV	100 mg once/day
Metoprolol (SR)	Toprol XL					PO	100 mg once/day

Third-Generation: Beta Blockers with Vasodilating Actions							
Nebivolol	Bystolic	Beta ₁	0	High	12–19	PO	20 mg once/day
Carvedilol (IR)	Coreg	Beta ₁ , Beta ₂ , Alpha ₁	0	Moderate	5–11	PO	12.5 mg twice/day
Carvedilol (SR)	Coreg CR					PO	40 mg once/day
Labetalol	Normodyne, Trandate	Beta ₁ , Beta ₂ , Alpha ₁	0	Low	6–8	PO, IV	300 mg twice/day

IR = immediate release, ISA = intrinsic sympathomimetic activity (partial agonist activity), SR = sustained release.

* Oral administration is used for essential hypertension. Intravenous administration is reserved for acute myocardial infarction (atenolol, metoprolol), cardiac dysrhythmias (esmolol, propranolol), and severe hypertension (labetalol).

† These are the lowest doses normally used for maintenance in hypertension.

TABLE 18-3 Beta-Adrenergic Blocking Agents: Summary of Therapeutic Uses*

	Hypertension	Angina Pectoris	Cardiac Dysrhythmias	Myocardial Infarction	Migraine Prophylaxis	Stage Fright	Heart Failure
Acebutolol	A	I	A				
Atenolol	A	A	I	A	I	I	
Betaxolol	A						
Bisoprolol	A	I	I				I
Carteolol	A	I					
Carvedilol	A	I		A			A
Esmolol		I	A

Timolol	A		I	A	A	I	

A = FDA-approved use, I = investigational use.

* Beta blockers used for glaucoma are discussed in [Chapter 103](#) (Drugs for the Eye).

By blocking *renal* beta₁ receptors, propranolol can *suppress secretion of renin*.

By blocking beta₂ receptors, propranolol can produce three major effects: (1) *bronchoconstriction* (through beta₂ blockade in the lung), (2) *vasoconstriction* (through beta₂ blockade on certain blood vessels), and (3) *reduced glycogenolysis* (through beta₂ blockade in skeletal muscle and liver).

19.4.1.2 Pharmacokinetics

Propranolol is *highly lipid soluble* and therefore can readily cross membranes. The drug is well absorbed following oral administration, but, because of extensive metabolism on its first pass through the liver, less than 30% of each dose reaches the systemic circulation. Because of its

ability to cross membranes, propranolol is widely distributed to all tissues and organs, including the central nervous system (CNS). Propranolol is inactivated by hepatic metabolism, and the metabolites are excreted in the urine.

19.4.1.3 Therapeutic Uses

Practically all of the applications of propranolol are based on blockade of β_1 receptors in the heart. The drug's most important indications are *hypertension*, *angina pectoris*, *cardiac dysrhythmias*, and *myocardial infarction*. The role of propranolol and other beta blockers in these disorders is discussed in [Chapter 46](#) (Drugs for Hypertension), [Chapter 50](#) (Drugs for Angina Pectoris), [Chapter 48](#) (Antidysrhythmic Drugs), and [Chapter 52](#) (Management of ST-Elevation Myocardial Infarction). Additional indications include *migraine headache* and “*stage fright*.”

19.4.1.4 Adverse Effects

The most serious adverse effects result from blockade of β_1 receptors in the heart and blockade of β_2 receptors in the lung.

19.4.1.4.1 Bradycardia.

β_1 blockade in the heart can cause bradycardia. Heart rate should be assessed before each dose. If necessary, heart rate can be increased by administering atropine and isoproterenol.

19.4.1.4.2 AV Heart Block.

By slowing conduction of impulses through the AV node, propranolol can cause AV heart block. The drug is contraindicated for patients with pre-existing AV block (if the block is greater than first degree).

19.4.1.4.3 Heart Failure.

In patients with cardiac disease, suppression of myocardial contractility by propranolol can result in heart failure. Patients should be informed about the early signs of heart failure (shortness of breath, night coughs, swelling of the extremities) and instructed to notify the prescriber if these occur. Propranolol is generally contraindicated for patients with pre-existing heart failure (although other beta blockers are used to *treat* heart failure).

19.4.1.4.4 Rebound Cardiac Excitation.

Abrupt withdrawal of propranolol can cause rebound excitation of the heart, resulting in tachycardia and ventricular dysrhythmias. To avoid rebound excitation, propranolol should be withdrawn slowly (ie, by giving progressively smaller doses over 1 to 2 weeks). Patients should be warned against abrupt cessation of treatment. In addition, they should be advised to carry an adequate supply of propranolol when traveling.

19.4.1.4.5 Bronchoconstriction.

Blockade of β_2 receptors in the lung can cause bronchoconstriction. As a rule, increased airway resistance is hazardous only to patients with asthma and other obstructive pulmonary disorders.

19.4.1.4.6 Inhibition of Glycogenolysis.

Blockade of β_2 receptors in skeletal muscle and the liver can inhibit glycogenolysis. This effect can be dangerous for people with diabetes (see below).

19.4.1.4.7 CNS Effects.

Because of its lipid solubility, propranolol can readily cross the blood-brain barrier, and hence has ready access sites in the CNS. However, although propranolol is reputed to cause a variety of CNS reactions—depression, insomnia, nightmares, and hallucinations—recent evidence indicates that such reactions are very rare. Because of the possible risk of depression, prudence dictates avoiding propranolol in patients who already have this disorder.

19.4.1.5 Precautions, Warnings, and Contraindications

19.4.1.5.1 Severe Allergy.

Propranolol should be avoided in patients with a history of severe allergic reactions (anaphylaxis). Why? Recall that epinephrine, the drug of choice for anaphylaxis, relieves symptoms in large part by activating β_1 receptors in the heart and β_2 receptors in the lung. If these receptors are blocked by propranolol, the ability of epinephrine to act will be dangerously impaired.

19.4.1.5.2 Diabetes.

Propranolol can be detrimental to diabetic patients in two ways. First, by blocking beta₂ receptors in muscle and liver, propranolol can suppress glycogenolysis, thereby eliminating an important mechanism for correcting hypoglycemia (which can occur when insulin dosage is excessive). Second, by blocking beta₁ receptors, propranolol can suppress tachycardia, which normally serves as an early warning signal that blood glucose levels are falling too low. (When glucose drops below a safe level, the sympathetic nervous system is activated, causing an increase in heart rate.) By “masking” tachycardia, propranolol can delay awareness of hypoglycemia, thereby compromising the patient's ability to correct the problem in a timely fashion. Diabetic patients who are taking propranolol should be warned that tachycardia may no longer be a reliable indicator of hypoglycemia. In addition, they should be taught to recognize alternative signs (sweating, hunger, fatigue, poor concentration) that blood glucose is falling perilously low. Because of its ability to suppress glycogenolysis and mask tachycardia, propranolol must be used with caution by diabetic patients.

19.4.1.5.3 Cardiac, Respiratory, and Psychiatric Disorders.

Propranolol can exacerbate *heart failure*, *AV heart block*, *sinus bradycardia*, *asthma*, and *bronchospasm*. Accordingly, the drug is contraindicated for patients with these disorders. In addition, propranolol should be used with caution in patients with a history of *depression*.

19.4.1.6 Drug Interactions

19.4.1.6.1 Calcium Channel Blockers.

The cardiac effects of two calcium channel blockers—verapamil and diltiazem—are identical to those of propranolol: reduction of heart rate, suppression of AV conduction, and suppression of myocardial contractility. When propranolol and these drugs are used concurrently, there is a risk of excessive cardiac suppression.

19.4.1.6.2 Insulin.

As discussed above, propranolol can impede early recognition of insulin-induced hypoglycemia. In addition, propranolol can block glycogenolysis, the body's mechanism for correcting hypoglycemia.

19.4.1.7 Preparations, Dosage, and Administration

19.4.1.7.1 General Dosing Considerations.

Establishing an effective propranolol dosage is difficult for two reasons: (1) patients vary widely in their requirements for propranolol and (2) there is a poor correlation between blood levels of propranolol and therapeutic responses. The explanation for these observations is that responses to propranolol are dependent on the activity of the sympathetic nervous system. If sympathetic activity is high, then the dose needed to reduce receptor activation will be high too. Conversely, if sympathetic activity is low, then low doses will be sufficient to produce receptor blockade. Since sympathetic activity varies among patients, propranolol requirements vary also. Accordingly, the dosage must be adjusted by monitoring the patient's response, and not by relying on dosing information in a drug reference.

19.4.1.7.2 Preparations.

Propranolol hydrochloride [Inderal, InnoPran] is available in three oral formulations: (1) standard tablets (10 to 90 mg), (2) extended-release (ER) capsules (60 to 160 mg), and (3) solution (4 and 8 mg/mL). The drug is also available in solution (1 mg/mL) for IV administration.

19.4.1.7.3 Dosage.

For treatment of *hypertension*, the initial dosage is 40 mg twice a day (using standard tablets) or 80 mg once a day (using ER capsules). Usual maintenance dosages are 120 to 240 mg/day in two, three, or four divided doses (using standard tablets) or 80 to 160 mg once a day (using ER capsules).

For *angina pectoris*, the initial dosage is 80 mg once a day (using ER capsules). The usual maintenance dosage is 160 mg once a day (using ER capsules) or 80 to 320 mg/day in two, three, or four divided doses (using standard tablets).

19.4.2 Metoprolol

Metoprolol [Lopressor, Toprol XL], our prototype of the second-generation beta blockers, produce selective blockade of beta₁ receptors in the heart. At usual therapeutic doses, the drug does not cause beta₂ blockade. Please note, however, that selectivity for beta₁ receptors is not absolute: At higher doses, metoprolol and the other “cardioselective” agents will block beta₂ receptors as well. Because their effects on beta₂ receptors are normally minimal, the

cardioselective agents are not likely to cause bronchoconstriction or suppression of glycogenolysis. Accordingly, these drugs are preferred to the nonselective beta blockers for patients with asthma or diabetes.

19.4.2.1 Pharmacologic Effects.

By blocking cardiac beta₁ receptors, metoprolol has the same impact on the heart as propranolol: it reduces heart rate, force of contraction, and conduction velocity through the AV node. Also like propranolol, metoprolol reduces secretion of renin by the kidney. In contrast to propranolol, metoprolol does not block bronchial beta₂ receptors (at usual doses), and therefore does not increase airway resistance.

19.4.2.2 Pharmacokinetics.

Metoprolol is very lipid soluble and well absorbed following oral administration. Like propranolol, metoprolol undergoes extensive metabolism on its first pass through the liver. As a result, only 40% of an oral dose reaches the systemic circulation. Elimination is by hepatic metabolism and renal excretion.

19.4.2.3 Therapeutic Uses.

The primary indication for metoprolol is *hypertension*. The drug is also approved for *angina pectoris*, *heart failure*, and *myocardial infarction*.

19.4.2.4 Adverse Effects.

Major adverse effects involve the heart. Like propranolol, metoprolol can cause *bradycardia*, *reduced cardiac output*, *AV heart block*, and *rebound cardiac excitation following abrupt withdrawal*. Also, even though metoprolol is approved for *treating* heart failure, it can *cause* heart failure if used incautiously. In contrast to propranolol, metoprolol causes minimal bronchoconstriction and does not interfere with beta₂-mediated glycogenolysis.

19.4.2.5 Precautions, Warnings, and Contraindications.

Like propranolol, metoprolol is contraindicated for patients with *sinus bradycardia* and *AV block greater than first degree*. In addition, it should be used with great care in patients with *heart failure*. Because metoprolol produces only minimal blockade of beta₂ receptors, the drug is safer than propranolol for patients with asthma or a history of severe allergic reactions. In addition, since metoprolol does not suppress beta₂-mediated glycogenolysis, it can be used more safely than propranolol by patients with diabetes. Please note, however, that metoprolol, like

169

170

propranolol, will “mask” tachycardia, thereby depriving the diabetic patient of an early indication that hypoglycemia is developing.

19.4.2.6 Preparations, Dosage, and Administration.

Metoprolol is available in standard tablets (50 and 100 mg) under the trade name Lopressor and in sustained-release tablets (25, 50, 100, and 200 mg) under the trade name Toprol XL. The drug is also available in solution (1 mg/mL) for IV administration. The initial dosage for *hypertension* is 100 mg/day in single or divided doses. Dosages for maintenance therapy range from 100 to 450 mg/day in divided doses. Intravenous administration is reserved for *myocardial infarction*.

19.4.3 Other Beta-Adrenergic Blockers

In the United States, 16 beta blockers are approved for cardiovascular disorders (hypertension, angina pectoris, cardiac dysrhythmias, MI). Principal differences among these drugs concern receptor specificity, pharmacokinetics, indications, side effects, intrinsic sympathomimetic activity, and the ability to cause vasodilation.

In addition to the agents used for cardiovascular disorders, there is a group of beta blockers used for glaucoma (see [Chapter 103](#), Drugs for the Eye).

Properties of the beta blockers employed for cardiovascular disorders are discussed below.

19.4.3.1 Receptor Specificity.

With regard to receptor specificity, beta blockers fall into two groups: nonselective agents and cardioselective agents. The nonselective agents block beta₁ *and* beta₂ receptors, whereas the cardioselective agents block beta₁ receptors only (at usual doses). Because of their limited side effects, the cardioselective agents are preferred for patients with asthma or diabetes. Two beta blockers—*labetalol* and *carvedilol*—differ from all the others in that they block *alpha*-adrenergic receptors in addition to beta receptors. The receptor specificity of individual beta blockers is indicated in [Tables 18-1](#) and [18-2](#).

19.4.3.2 Pharmacokinetics.

Pharmacokinetic properties of the beta blockers are summarized in [Table 18-2](#). The relative lipid solubility of these agents is of particular importance. The drugs with high solubility (eg, propranolol, metoprolol) have two prominent features: (1) they penetrate the blood-brain barrier with ease and (2) they are eliminated primarily by hepatic metabolism. Conversely, the drugs

with low lipid solubility (eg, nadolol, atenolol) penetrate the blood-brain barrier poorly and are eliminated primarily by renal excretion.

19.4.3.3 Therapeutic Uses.

Principal indications for the betaadrenergic blockers are *hypertension*, *angina pectoris*, and *cardiac dysrhythmias*. Other uses include prophylaxis of *migraine headache*, treatment of *myocardial infarction*, symptom suppression in individuals with *situational anxiety* (eg, stage fright), and treatment of *heart failure* (see [Chapter 47](#)). Approved and investigational uses of the beta blockers are summarized in [Table 18-3](#).

Esmolol and *sotalol* differ from the other beta blockers in that they are not used for hypertension. Because of its very short half-life (15 minutes), *esmolol* is clearly unsuited for treating hypertension, which requires maintenance of blood levels throughout the day, every day, for an indefinite time. The only approved indication for *esmolol* is emergency IV therapy of *supraventricular tachycardia*. *Sotalol* is approved only for *ventricular dysrhythmias*. *Esmolol* and *sotalol* are discussed further in [Chapter 48](#) (Antidysrhythmic Drugs).

19.4.3.4 Adverse Effects.

By blocking beta₁ receptors in the heart, all of the beta blockers can cause *bradycardia*, *AV heart block*, and, rarely, *heart failure*. By blocking beta₂ receptors in the lung, the nonselective agents can cause significant *bronchoconstriction* in patients with asthma or chronic obstructive pulmonary disease. In addition, by blocking beta₂ receptors in the liver and skeletal muscle, the *nonselective* agents can *inhibit glycogenolysis*, thereby compromising the ability of diabetic patients to compensate for insulin-induced hypoglycemia. Because of their ability to block alpha-adrenergic receptors, *carvedilol* and *labetalol* can cause *postural hypotension*.

Although *CNS effects* (insomnia, depression) can occur with all beta blockers, these effects are rare, and are most likely with the highly lipid-soluble agents. Abrupt discontinuation of any beta blocker can produce *rebound cardiac excitation*. Accordingly, all beta blockers should be withdrawn slowly (by tapering the dosage over 1 to 2 weeks).

19.4.3.5 Intrinsic Sympathomimetic Activity (Partial Agonist Activity).

The term *intrinsic sympathomimetic activity* (ISA) refers to the ability of certain beta blockers—especially *pindolol*—to act as *partial agonists* at beta-adrenergic receptors. (As discussed in [Chapter 5](#), a partial agonist is a drug that, when bound to a receptor, produces a limited degree of receptor activation while preventing strong agonists from binding to that receptor to cause full activation.)

In contrast to other beta blockers, agents with ISA have very little effect on resting heart rate and cardiac output. When patients are at rest, stimulation of the heart by the sympathetic nervous system is low. If an ordinary beta blocker is given, it will block sympathetic stimulation, causing heart rate and cardiac output to decline. However, if a beta blocker has ISA, its own ability to cause limited receptor activation will compensate for blocking receptor activation by the sympathetic nervous system and, consequently, resting heart rate and cardiac output are not reduced.

Because of their ability to provide a low level of cardiac stimulation, beta blockers with ISA are preferred to other beta blockers for use in patients with bradycardia. Conversely, these agents should not be given to patients with myocardial infarction. Why? Because their ability to cause even limited cardiac stimulation can be detrimental.

19.4.3.6 Vasodilation.

The third-generation beta blockers—*carvedilol*, *labetalol*, and *nebivolol*—can dilate blood vessels. Two mechanisms are employed: Carvedilol and labetalol block vascular α_1 receptors; nebivolol promotes synthesis and release of nitric oxide from the vascular epithelium. The exact clinical benefit of vasodilation by these drugs has not been clarified.

19.4.3.7 Dosage and Administration.

With the exception of esmolol, all of the beta blockers discussed in this chapter can be administered orally. Three drugs—*atenolol*, *labetalol*, and *propranolol*—may be given *intravenously* as well as orally. *Esmolol* is administered only by IV injection.

Maintenance dosages for hypertension are summarized in [Table 18-2](#). For most beta blockers, dosing can be done just once a day. For the drugs with especially short half-lives, twice-a-day dosing is required (unless an extended-release formulation is available).

170

19.4.3.7.1

KEY POINTS

- Most beneficial responses to alpha blockers, including reduction of blood pressure in patients with hypertension, result from blockade of α_1 receptors on blood vessels.
- Alpha blockers reduce symptoms of BPH by blocking α_1 receptors in the bladder neck and prostatic capsule, which causes smooth muscle at those sites to relax.
- The major adverse effects of alpha blockers are *orthostatic hypotension* (caused by blocking α_1 receptors on veins); *reflex tachycardia* (caused by blocking α_1

171

receptors on arterioles); *nasal congestion* (caused by blocking α_1 receptors in blood vessels of the nasal mucosa); and *inhibition of ejaculation* (caused by blocking α_1 receptors in male sex organs).

- The first dose of an alpha blocker can cause fainting from profound orthostatic hypotension, the so-called first-dose effect.
- The alpha blockers used most frequently—prazosin, doxazosin, and terazosin—produce selective blockade of α_1 receptors.
- Beta blockers produce most of their beneficial effects by blocking β_1 receptors in the heart, thereby reducing heart rate, force of contraction, and AV conduction.
- Principal indications for the beta blockers are cardiovascular: hypertension, angina pectoris, heart failure, and supraventricular tachydysrhythmias.
- Potential adverse effects from β_1 blockade are bradycardia, reduced cardiac output, AV block, and precipitation of heart failure (even though some beta blockers are used to treat heart failure).
- Potential adverse effects from β_2 blockade are bronchoconstriction (a concern for people with asthma) and reduced glycogenolysis (a concern for people with diabetes).
- Beta blockers can be divided into three groups: (1) first-generation agents (ie, nonselective beta blockers, such as propranolol, which block β_1 and β_2 receptors); (2) second-generation agents (ie, cardioselective beta blockers, such as metoprolol, which block β_1 receptors only at usual doses); and (3) third-generation agents (ie, vasodilating beta blockers, which may be cardioselective or nonselective).
- Beta blockers can be hazardous to patients with severe allergies because they can block beneficial actions of epinephrine, the drug of choice for treating anaphylactic shock.
- Beta blockers can be detrimental to diabetic patients because they suppress glycogenolysis (an important mechanism for correcting insulin-induced hypoglycemia), and they suppress tachycardia (an early warning signal that glucose levels are falling too low).
- Combining a beta blocker with a calcium channel blocker can produce excessive cardiosuppression.

- Cardioselective beta blockers are preferred to nonselective beta blockers for patients with asthma or diabetes.

19.4.3.7.2

Summary of Major Nursing Implications*

19.4.3.7.2.1

ALPHA₁-ADRENERGIC ANTAGONISTS

Alfuzosin

Doxazosin

Prazosin

Silodosin

Tamsulosin

Terazosin

19.4.3.7.2....

Preadministration Assessment

19.4.3.7.2....

Therapeutic Goal

19.4.3.7.2....

Doxazosin, Prazosin, Terazosin.

Reduction of blood pressure in patients with *essential hypertension*.

19.4.3.7.2....

Doxazosin, Terazosin, Alfuzosin, Silodosin, Tamsulosin.

Reduction of symptoms in patients with *benign prostatic hyperplasia*.

19.4.3.7.2....

Baseline Data

19.4.3.7.2....

Essential Hypertension.

Determine blood pressure and heart rate.

19.4.3.7.2....	Benign Prostatic Hyperplasia. Determine the degree of nocturia, daytime frequency, hesitance, intermittency, terminal dribbling (at the end of voiding), urgency, impairment of size and force of urinary stream, dysuria, and sensation of incomplete voiding.	
19.4.3.7.2....	Identifying High-Risk Patients The only contraindication is hypersensitivity to these drugs.	
19.4.3.7.2....	Implementation: Administration	
19.4.3.7.2....	Route Oral.	
19.4.3.7.2....	Administration Instruct patients to take the initial dose at bedtime to minimize the “first-dose” effect. Except for <i>tamsulosin</i>, which is administered <i>after</i> eating, these drugs may be taken with food.	
19.4.3.7.2....	Ongoing Evaluation and Interventions	
19.4.3.7.2....	Evaluating Therapeutic Effects	
19.4.3.7.2....	Essential Hypertension. Evaluate by monitoring blood pressure.

Betaxolol

Bisoprolol

Carteolol

Carvedilol

Labetalol

Metoprolol

Nadolol

Nebivolol

Penbutolol

Pindolol

Propranolol

Timolol

Except where noted, the implications summarized here apply to all beta-adrenergic blocking agents.

Preadministration Assessment

Therapeutic Goal

Principal indications are *hypertension*, *angina pectoris*, *heart failure*, and *cardiac dysrhythmias*. Indications for individual agents are summarized in [Table 18-3](#).

Baseline Data

All Patients.

Determine heart rate.

Hypertension.

Determine standing and supine blood pressure.

Angina Pectoris.

Determine the incidence, severity, and circumstances of anginal attacks.

Cardiac Dysrhythmias.

Obtain a baseline electrocardiogram (ECG).

Identifying High-Risk Patients

All beta blockers are *contraindicated* for patients with sinus bradycardia or AV heart block greater than first degree, and must be used with *great caution* in patients with heart failure. Use with *caution* (especially the nonselective agents) in patients with asthma, bronchospasm, diabetes, or a history of severe allergic reactions. Use all beta blockers with *caution* in patients with a history of depression and in those taking calcium channel blockers.

19.4.3.7.2....

Implementation: Administration

19.4.3.7.2....

Routes

19.4.3.7.2....

Oral.

All beta blockers.

19.4.3.7.2....

Intravenous.

Atenolol, labetalol, metoprolol, and propranolol.

19.4.3.7.2....

Administration

For maintenance therapy of hypertension, administer one or more times daily (see [Table 18-2](#) and text).

Warn patients against abrupt discontinuation of treatment.

19.4.3.7.2....

Ongoing Evaluation and Interventions

19.4.3.7.2....

Evaluating Therapeutic Effects

19.4.3.7.2....

Hypertension.

Monitor blood pressure and heart rate prior to each dose. Advise outpatients to monitor blood pressure and heart rate daily.

19.4.3.7.2....

Angina Pectoris.

Advise patients to record the incidence, circumstances, and severity of anginal attacks.

19.4.3.7.2....

Cardiac Dysrhythmias.

Monitor for improvement in the ECG.

19.4.3.7.2....	Minimizing Adverse Effects	
19.4.3.7.2....	Bradycardia. Beta₁ blockade can reduce heart rate. If bradycardia is severe, withhold medication and notify the physician. If necessary, administer atropine and isoproterenol to restore heart rate.	
19.4.3.7.2....	AV Heart Block. Beta₁ blockade can decrease AV conduction. Do not give beta blockers to patients with AV block greater than first degree.	
19.4.3.7.2....	Heart Failure. Suppression of myocardial contractility can cause heart failure. Inform patients about early signs of heart failure (shortness of breath, night coughs, swelling of the extremities), and instruct them to notify the prescriber if these occur.	
19.4.3.7.2....	Rebound Cardiac Excitation. Abrupt withdrawal of beta blockers can cause tachycardia and ventricular dysrhythmias. Warn patients against abrupt discontinuation of drug use. Also, advise patients, when traveling, to carry an adequate supply of medication plus a copy of their prescription.	
19.4.3.7.2....	Postural Hypotension. By blocking alpha-adrenergic receptors, <i>carvedilol</i> and <i>labetalol</i> can cause postural hypotension. Inform patients about signs of hypotension (lightheadedness, dizziness) and advise them to sit or lie down if these develop. Advise patients to move slowly when changing from a supine or sitting position to an upright posture.	172
19.4.3.7.2....	Bronchoconstriction. Beta₂ blockade can cause substantial airway constriction in patients with asthma. The risk of bronchoconstriction is much lower with the cardioselective agents than with the nonselective agents.	173

19.4.3.7.2....

Effects in Diabetic Patients.

Beta₁ blockade can “mask” tachycardia, an early sign of hypoglycemia. Warn patients that tachycardia cannot be relied on as an indicator of impending hypoglycemia, and teach them to recognize other indicators (sweating, hunger, fatigue, poor concentration) that blood glucose is falling dangerously low. Beta₂ blockade can prevent glycogenolysis, an emergency means of increasing blood glucose. Patients may need to reduce their insulin dosage. Cardioselective beta blockers are preferred to nonselective agents in patients with diabetes.

19.4.3.7.2....

CNS Effects.

Rarely, beta blockers cause depression, insomnia, and nightmares. If these occur, it may be helpful to switch to a beta blocker with low lipid solubility (see [Table 18-2](#)).

19.4.3.7.2....

Minimizing Adverse Interactions

19.4.3.7.2....

Calcium Channel Blockers.

Two calcium channel blockers—verapamil and diltiazem—can intensify the cardiosuppressant effects of the beta blockers. Use the combination with caution.

19.4.3.7.2....

Insulin.

Beta blockers can prevent the compensatory glycogenolysis that normally occurs in response to insulin-induced hypoglycemia. Diabetic patients may need to reduce their insulin dosage.

* Patient education information is highlighted as blue text.

²⁰CHAPTER 19 Indirect-Acting Antiadrenergic Agents

The indirect-acting antiadrenergic agents are drugs that prevent activation of peripheral adrenergic receptors, but they do so by mechanisms that do not involve direct interaction with peripheral receptors. There are two categories of indirect-acting antiadrenergic drugs. The first group—*adrenergic neuron-blocking agents*—consists of drugs that act within the terminals of sympathetic neurons to decrease norepinephrine (NE) release. The second group—*centrally acting α_2 agonists*—consists of drugs that act within the central nervous system (CNS) to reduce the outflow of impulses along sympathetic neurons. With both groups, the net result is reduced activation of peripheral adrenergic receptors. Hence, the pharmacologic effects of the indirect-acting adrenergic blocking agents are very similar to those of drugs that block adrenergic receptors directly.

^{20.1}ADRENERGIC NEURON-BLOCKING AGENTS

The adrenergic neuron-blocking agents act presynaptically to reduce the release of NE from sympathetic neurons. These drugs have very little effect on release of epinephrine from the adrenal medulla. Our discussion focuses on reserpine.

^{20.1.1} Reserpine

Reserpine is a naturally occurring compound prepared from the root of *Rauwolfia serpentina*, a shrub indigenous to India. Because of its source, reserpine is classified as a *Rauwolfia alkaloid*. The primary indication for reserpine is hypertension. The side effect of greatest concern is severe depression.

^{20.1.1.1} Mechanism of Action

Reserpine causes *depletion of NE from postganglionic sympathetic neurons*. By doing so, the drug can decrease activation of practically all adrenergic receptors. Hence, the effects of reserpine closely resemble those produced by a combination of alpha- and beta-adrenergic blockade.

Reserpine depletes NE in two ways. First, the drug acts on vesicles within the nerve terminal to cause displacement of stored NE, thereby exposing the transmitter to destruction by monoamine oxidase. Second, reserpine suppresses NE synthesis. How? By blocking the uptake of dopamine (the immediate precursor of NE) into presynaptic vesicles, which contain the enzymes needed to convert dopamine into NE ([Fig. 19-1](#)). A week or two may be required to produce maximal transmitter depletion.

In addition to its peripheral effects, reserpine can cause depletion of transmitters (serotonin, catecholamines) from neurons in the CNS. Depletion of these CNS transmitters underlies the most serious side effect of reserpine—deep emotional depression—and also explains the occasional use of reserpine in psychiatry.

20.1.1.2 Pharmacologic Effects

20.1.1.2.1 Peripheral Effects.

By depleting sympathetic neurons of NE, reserpine decreases the activation of alpha- and betaadrenergic receptors. Decreased activation of beta receptors slows heart rate and reduces cardiac output. Decreased alpha activation promotes vasodilation. All three effects cause a *decrease in blood pressure*.

20.1.1.2.2 Effects on the CNS.

Reserpine produces sedation and a state of indifference to the environment. In addition, the drug can cause severe depression. These effects are thought to re

Figure 19-1 Mechanism of reserpine action. Reserpine depletes neurons of norepinephrine (NE) by two mechanisms. (1) As indicated in this figure, reserpine blocks the uptake of dopamine (DA) into vesicles, thereby preventing NE synthesis. (2) Reserpine also displaces NE from vesicles, thereby allowing degradation of NE by monoamine oxidase present in the nerve terminal (not shown).

sult from depletion of certain neurotransmitters (catecholamines, serotonin) from neurons in the brain.

20.1.1.3 Therapeutic Uses

20.1.1.3.1 Hypertension.

The principal indication for reserpine is hypertension. Benefits result from vasodilation and reduced cardiac output. Since these effects occur secondary to depletion of NE, and since transmitter depletion occurs slowly, full antihypertensive responses can take a week or more to develop. Conversely, when reserpine is discontinued, effects may persist for several weeks as the NE content of sympathetic neurons becomes replenished. Because its side effects can be severe, and because more desirable drugs are available (see [Chapter 46](#)), reserpine is not a preferred drug for hypertension.

20.1.1.3.2 Psychotic States.

Reserpine can be used to treat agitated psychotic patients, such as those suffering from certain forms of schizophrenia. However, since superior drugs are available, reserpine is rarely employed in psychotherapy.

20.1.1.4 Adverse Effects

20.1.1.4.1 Depression.

Reserpine can produce severe depression that may persist for months after the drug is withdrawn. Suicide has occurred. All patients should be informed about the risk of depression. Also, they should be educated about signs of depression (eg, early morning insomnia, loss of appetite, change in mood) and instructed to notify the prescriber immediately if these develop. Because of the risk of suicide, patients who develop depression may require hospitalization. *Reserpine is contraindicated for patients with a history of depressive disorders.* The risk of depression can be minimized by keeping the dosage low (0.25 mg/day or less).

20.1.1.4.2 Cardiovascular Effects.

Depletion of NE from sympathetic neurons can result in *bradycardia*, *orthostatic hypotension*, and *nasal congestion*. Bradycardia is caused by decreased activation of beta₁ receptors in the heart. Hypotension and nasal congestion result from decreased activation of alpha receptors on blood vessels. Patients should be informed that orthostatic hypotension, the most serious cardiovascular effect, can be minimized by moving slowly when changing from a seated or

supine position to an upright position. In addition, patients should be advised to sit or lie down if lightheadedness or dizziness occurs.

20.1.1.4.3 GI Effects.

By mechanisms that are not understood, reserpine can stimulate several aspects of GI function. The drug can increase secretion of gastric acid, which may result in *ulcer formation*. In addition, reserpine can increase the tone and motility of intestinal smooth muscle, thereby causing *cramps* and *diarrhea*.

20.1.1.5 Preparations, Dosage, and Administration

Reserpine is available in 0.1- and 0.25-mg tablets, which may administered with food if GI upset occurs. The usual initial dosage for hypertension in adults is 0.5 mg/day for 1 to 2 weeks. The usual maintenance dosage is 0.1 to 0.25 mg/day.

20.1.2 Guanadrel and Guanethidine

Guanadrel [Hylorel] and guanethidine [Ismelin] are adrenergic neuron-blocking agents with actions similar to those of reserpine. However, in contrast to reserpine, these drugs cannot cross the blood-brain barrier, and hence do not cause adverse CNS effects. Nonetheless, they do have serious side effects: diarrhea and *severe* orthostatic hypotension. As a result, guanadrel and guanethidine are considered last-choice options for hypertension, their only indication.

Guanadrel is available in 10- and 25-mg tablets. The usual initial adult dosage is 5 mg twice a day. Maintenance dosages range from 20 to 75 mg/day, given in divided doses.

Guanethidine has been voluntarily withdrawn from the U.S. market. For more information on this drug, refer to previous editions of this book.

20.2 CENTRALLY ACTING ALPHA₂ AGONISTS

The drugs discussed in this section act within the CNS to reduce the firing of sympathetic neurons. These drugs are used primarily for hypertension.

Why are we discussing centrally acting drugs in a unit on peripheral nervous system pharmacology? Because the effects of these drugs are ultimately the result of decreased activation of alpha- and beta-adrenergic receptors in the periphery. That is, by inhibiting the firing of sympathetic neurons, the centrally acting agents decrease the release of NE from sympathetic nerves, and thereby decrease activation of peripheral adrenergic receptors. Hence, although these drugs act within the CNS, their effects are like those of the direct-acting adrenergic receptor blockers. Accordingly, it

seems appropriate to discuss these agents in the context of peripheral nervous system pharmacology, rather than presenting them in the context of CNS drugs.

20.2.1 Clonidine

Clonidine [Catapres] is an *antihypertensive drug* that acts within the CNS. Except for rare instances of rebound hypertension, the drug is generally free of serious adverse effects. Because it is both effective and safe, clonidine is widely used. To treat hypertension, the drug is administered by mouth or by transdermal patch.

In addition to its use in hypertension, clonidine is used to relieve *severe pain of cancer*. To provide pain relief, the drug must be administered by epidural infusion. The preparation employed for this purpose is marketed under the trade name *Duraclon*. Because clonidine's analgesic pharmacology differs substantially from its antihypertensive pharmacology, the analgesic pharmacology is discussed separately in [Chapter 28](#).

20.2.1.1 Mechanism of Antihypertensive Action

Clonidine is an α_2 -adrenergic agonist that causes “selective” activation of α_2 receptors in the CNS—specifically, in brainstem areas associated with autonomic regulation of the cardiovascular system. By activating central α_2 receptors, clonidine reduces sympathetic outflow to blood vessels and the heart.

20.2.1.2 Pharmacologic Effects

The most significant effects of clonidine occur in the heart and vascular system. By suppressing the firing of sympathetic nerves to the heart, clonidine can cause *bradycardia* and a *decrease in cardiac output*. By suppressing sympathetic regulation of blood vessels, the drug promotes *vasodilation*. The net result of cardiac suppression and vasodilation is *decreased blood pressure*. Blood pressure is reduced in both supine and standing subjects. (Note that the effect of clonidine on blood pressure is unlike that of the peripheral α -adrenergic blockers, which tend to decrease blood pressure only when the patient is standing.) Because the hypotensive effects of clonidine are not posture dependent, orthostatic hypotension is minimal.

175

20.2.1.3 Pharmacokinetics

176

Clonidine is very lipid soluble. As a result, the drug is readily absorbed following oral administration and is widely distributed throughout the body, including the CNS. Hypotensive responses begin 30 to 60 minutes after dosing and peak in 4 hours. Effects of a single dose may

persist as long as 1 day. Clonidine is eliminated by a combination of hepatic metabolism and renal excretion.

20.2.1.4 Therapeutic Uses

Clonidine has two *approved* applications: treatment of hypertension (its main use) and relief of severe pain (see [Chapter 28](#)). *Investigational* uses include treatment of migraine; menopausal flushing; withdrawal from opioids, alcohol, and tobacco; and Tourette's syndrome, a CNS disease characterized by uncontrollable tics and verbal outbursts that are frequently obscene.

20.2.1.5 Adverse Effects

20.2.1.5.1 Drowsiness.

CNS depression is common. About 35% of patients experience drowsiness; an additional 8% experience outright sedation. These responses become less intense with continued drug use. Patients in their early weeks of treatment should be advised to avoid hazardous activities if alertness is impaired.

20.2.1.5.2 Xerostomia.

Xerostomia (dry mouth) is common, occurring in about 40% of patients. The reaction usually diminishes over the first 2 to 4 weeks of therapy. Although not dangerous, xerostomia can be annoying enough to discourage drug use. Patients should be advised that discomfort can be reduced by chewing gum, sucking on hard candy, and taking frequent sips of fluids.

20.2.1.5.3 Rebound Hypertension.

Rebound hypertension is characterized by a large increase in blood pressure occurring in response to abrupt clonidine withdrawal. This rare but serious reaction is caused by overactivity of the sympathetic nervous system, and can be accompanied by nervousness, tachycardia, and sweating. Left untreated, the reaction may persist for a week or more. If blood pressure climbs dangerously high, it should be lowered with a combination of alpha- and betaadrenergic blocking agents. Rebound effects can be avoided by withdrawing clonidine slowly (over 2 to 4 days). Patients should be informed about rebound hypertension and warned not to discontinue clonidine without consulting the prescriber.

20.2.1.5.4 Use in Pregnancy.

Clonidine is embryotoxic in animals. Because of the possibility of fetal harm, clonidine is not recommended for pregnant women. Pregnancy should be ruled out before clonidine is given.

20.2.1.5.5 Other Adverse Effects.

Clonidine can cause a variety of adverse effects, including *constipation*, *impotence*, *gynecomastia*, and *adverse CNS effects* (eg, vivid dreams, nightmares, anxiety, depression). *Localized skin reactions* are common with transdermal clonidine patches.

20.2.1.6 Preparations, Dosage, and Administration

20.2.1.6.1 Preparations.

Clonidine hydrochloride is available in oral and transdermal formulations. *Oral clonidine* [Catapres] is available in 0.1-, 0.2-, and 0.3-mg tablets. *Transdermal clonidine* [Catapres-TTS] is available in 2.5-, 5-, and 7.5-mg patches that deliver 0.1, 0.2, and 0.3 mg/24 hr, respectively.

20.2.1.6.2 Dosage and Administration

20.2.1.6.3 Oral.

For treatment of hypertension, the initial adult dosage is 0.1 mg twice a day. The usual maintenance dosage is 0.2 to 0.6 mg/day administered in divided doses. By taking the majority of the daily dose at bedtime, daytime sedation can be minimized.

20.2.1.6.4 Transdermal.

Transdermal patches are applied to a region of hairless, intact skin on the upper arm or torso. A new patch is applied every 7 days.

20.2.2 Guanabenz and Guanfacine

The pharmacology of guanabenz [Wyntensin] and guanfacine [Tenex] is very similar to that of clonidine. Like clonidine, both drugs activate brainstem α_2 -adrenergic receptors, and thereby reduce sympathetic outflow to the heart and blood vessels. The result is a reduction in cardiac output and blood pressure. Both drugs also share the major adverse effects of clonidine: sedation and dry mouth. In addition, both can cause rebound hypertension following abrupt withdrawal. Guanabenz is available in 4- and 8-mg tablets. Dosing is begun at 4 mg twice daily and can be increased to 32 mg twice daily. Guanfacine is available in 1- and 2-mg tablets. The usual dosage is 1 mg/day, taken at bedtime to minimize daytime sedation.

20.2.3 Methyldopa and Methyldopate

Methyldopa is an oral antihypertensive agent that lowers blood pressure by acting at sites within the CNS. Two side effects—hemolytic anemia and hepatic necrosis—can be severe.

Methyldopate, an intravenous agent, is nearly identical to methyldopa in structure and pharmacologic effects. In the discussion below, the term *methyldopa* is used in reference to both methyldopate and methyldopa itself.

20.2.3.1 Mechanism of Action

Methyldopa has a mechanism of action similar to that of clonidine. Like clonidine, methyldopa inhibits sympathetic outflow from the CNS by causing α_2 activation in the brain. However, methyldopa differs from clonidine in that methyldopa itself is not an α_2 agonist. Hence, before it can act, methyldopa must first be taken up into brainstem neurons, where it is then converted to methylnorepinephrine, a compound that *is* an effective α_2 agonist. Release of methylnorepinephrine results in α_2 activation.

20.2.3.2 Pharmacologic Effects

The most prominent response to methyldopa is a drop in blood pressure. The principal mechanism is vasodilation, not cardiosuppression. Vasodilation occurs because of reduced sympathetic traffic to blood vessels. At usual therapeutic doses, methyldopa does not decrease heart rate or cardiac output. Hence, hypotensive actions cannot be ascribed to cardiac depression. The hemodynamic effects of methyldopa are very much like those of clonidine: Both drugs lower blood pressure in supine and standing subjects, and both produce relatively little orthostatic hypotension.

20.2.3.3 Therapeutic Use

The only indication for methyldopa is *hypertension*. Methyldopa was one of the earliest antihypertensive agents available and remains in wide use. Methyldopate may be used for hypertensive crisis, but other drugs are preferred.

20.2.3.4 Adverse Effects

20.2.3.4.1 Positive Coombs' Test and Hemolytic Anemia.

A positive Coombs' test^{*} develops in 10% to 20% of patients who take methyldopa chronically. The test usually turns positive between the 6th and 12th month of treatment. Of

the patients who have a positive Coombs' test, only a few (about 5%) develop hemolytic anemia. Coombs-positive patients who do not develop hemolytic anemia may continue methyl-
dopa treatment. However, if hemolytic anemia does develop, methyl-
dopa should be withdrawn immediately. For most patients, hemolytic anemia resolves shortly after drug withdrawal, although the Coombs' test may remain positive for months. A Coombs' test should be performed prior to treatment and 6 to 12 months later. Blood counts (hematocrit, hemoglobin, or red cell count) should be obtained prior to treatment and periodically thereafter.

* The Coombs' test detects the presence of antibodies directed against the patient's own red blood cells. These antibodies can cause hemolysis (ie, red blood cell lysis).

176

177

20.2.3.4.2 Hepatotoxicity.

Methyldopa has been associated with hepatitis, jaundice, and, rarely, fatal hepatic necrosis. All patients should undergo periodic assessment of liver function. If signs of hepatotoxicity appear, methyldopa should be discontinued immediately. Liver function usually normalizes after drug withdrawal.

20.2.3.4.3 Other Adverse Effects.

Methyldopa can cause *xerostomia*, *sexual dysfunction*, *orthostatic hypotension*, and a variety of *CNS effects*, including drowsiness, reduced mental acuity, nightmares, and depression. These responses are not usually dangerous, but they can detract from adherence.

20.2.3.5 Preparations, Dosage, and Administration

20.2.3.5.1 Preparations.

Methyldopa is available in tablets (250 and 500 mg) for oral use. *Methyldopate* is available in solution (50 mg/mL) for IV use.

20.2.3.5.2 Oral Therapy.

For treatment of hypertension, the initial adult dosage is 250 mg 2 to 3 times a day. Daily maintenance dosages usually range from 0.5 to 2 gm administered in two to four divided doses.

20.2.3.5.3 Intravenous Therapy.

Methyldopate, administered by slow IV infusion, is indicated for hypertensive emergencies. However, since faster acting drugs are available, use of methyldopate is rare. Methyldopate

for infusion should be diluted in 5% dextrose to a concentration of 10 mg/mL. The usual adult dose is 250 to 500 mg infused over 30 to 60 minutes. Dosing may be repeated every 6 hours as required.

20.2.3.5.3.1

KEY POINTS

- All of the drugs discussed in this chapter reduce activation of peripheral alpha- and beta-adrenergic receptors, but they do so by mechanisms other than direct receptor blockade.
- The principal indication for these drugs is hypertension.
- Reserpine acts by depleting NE from adrenergic neurons.
- Clonidine and methyldopa reduce sympathetic outflow to the heart and blood vessels by causing activation of alpha₂-adrenergic receptors in the brainstem.
- The principal adverse effect of reserpine is depression.
- The principal adverse effects of clonidine are drowsiness and dry mouth. Rebound hypertension can occur if the drug is abruptly withdrawn.
- The principal adverse effects of methyldopa are hemolytic anemia and liver damage.
- The Coombs' test detects the presence of antibodies directed against the patient's own red blood cells. These antibodies can cause hemolysis (ie, red blood cell lysis).

20.2.3.5.3.2

Summary of Major Nursing Implications*

20.2.3.5.3.2.1

RESERPINE

20.2.3.5.3.2.1.1

Preadministration Assessment

20.2.3.5.3.2.1...

Therapeutic Goal

Reduction of blood pressure in hypertensive patients.

20.2.3.5.3.2.1...

Baseline Data

Determine blood pressure and heart rate.

20.2.3.5.3.2.1...

Identifying High-Risk Patients

Reserpine is *contraindicated* for patients with active peptic ulcer disease or a history of depression.

20.2.3.5.3.2.1.2

Implementation: Administration

20.2.3.5.3.2.1...

Route

Oral.

20.2.3.5.3.2.1...

Administration

Administer with food to reduce gastric upset.

20.2.3.5.3.2.1.3

Ongoing Evaluation and Interventions

20.2.3.5.3.2.1...

Evaluating Therapeutic Effects

Full antihypertensive effects may take a week or more to develop. Monitor blood pressure to evaluate treatment.

20.2.3.5.3.2.1...

Minimizing Adverse Effects

20.2.3.5.3.2.1...

Depression.

Reserpine can cause profound depression. Inform patients about signs of depression (eg, early morning insomnia, loss of appetite, change in mood) and instruct them to notify the prescriber if these develop. Hospitalization may be required. Avoid reserpine in patients with a history of depression. To minimize the risk of depression, keep the dosage low (0.25 mg/day or less).

20.2.3.5.3.2.1...

Orthostatic Hypotension.

Inform patients that orthostatic hypotension can be minimized by moving slowly when changing from a seated or supine position to an upright position. Advise patients to sit or lie down if dizziness or lightheadedness occurs.

20.2.3.5.3.2.3...

Hemolytic Anemia.

If hemolysis occurs, withdraw methyldopa immediately; hemolytic anemia usually resolves soon. Obtain a Coombs' test prior to treatment and 6 to 12 months later. Obtain blood counts (hematocrit, hemoglobin, or red cell count) prior to treatment and periodically thereafter.

20.2.3.5.3.2.3...

Hepatotoxicity.

Methyldopa can cause hepatitis, jaundice, and fatal hepatic necrosis. Assess liver function prior to treatment and periodically thereafter. If liver dysfunction develops, discontinue methyldopa immediately. In most cases, liver function returns to normal soon.

* Patient education information is highlighted as blue text.

²¹CHAPTER 20 Introduction to Central Nervous System Pharmacology

The central nervous system (CNS) drugs—agents that act on the brain and spinal cord—are used widely for medical and nonmedical purposes. Medical applications include treatment of psychiatric disorders, suppression of seizures, relief of pain, and production of anesthesia. CNS drugs are used nonmedically for their stimulant, depressant, euphoriant, and other “mind-altering” abilities.

Despite the widespread use of CNS drugs, knowledge of these agents is limited. Much of our ignorance stems from the anatomic and neurochemical complexity of the brain and spinal cord. (There are more than 50 billion neurons in the cerebral hemispheres alone.) Because of this complexity, we are a long way from fully understanding both the CNS itself and the drugs used to influence it.

^{21.1}TRANSMITTERS OF THE CNS

In contrast to the peripheral nervous system, in which only three compounds—acetylcholine, norepinephrine, and epinephrine—serve as neurotransmitters, the CNS contains at least 21 compounds that serve as neurotransmitters ([Table 20-1](#)). Furthermore, since there are numerous sites within the CNS for which no transmitter has been identified, it is clear that additional compounds, yet to be discovered, also mediate neurotransmission in the brain and spinal cord.

It is important to note that none of the compounds that are thought to be CNS neurotransmitters has actually been proved to serve this function. The reason for uncertainty lies with the technical difficulties involved in CNS research. However, although absolute proof may be lacking, the evidence supporting a neurotransmitter role for several compounds (eg, dopamine, norepinephrine, serotonin, enkephalins) is completely convincing.

Although much is known about the actions of CNS transmitters at various sites in the brain and spinal cord, it is not usually possible to relate these known actions in a precise way to behavioral or psychologic processes. For example, although we know the locations of specific CNS sites at which norepinephrine appears to act as a transmitter, and although we know the effect of norepinephrine at most of these sites (suppression of neuronal excitability), we do not know the precise relationship between suppression of neuronal excitability at each of these sites and the impact of that suppression on the overt function of the organism. This example illustrates the general state of our knowledge of CNS transmitter function: We have a great deal of detailed information about the biochemistry and electrophysiology of CNS transmitters, but we are as yet unable to assemble those details into a completely meaningful picture.

21.2 THE BLOOD-BRAIN BARRIER

As discussed in [Chapter 4](#), the blood-brain barrier impedes the entry of drugs into the brain. Passage across the barrier is limited to lipid-soluble agents and to drugs that are able to cross by way of specific transport systems. Drugs that are protein bound and drugs that are highly ionized cannot cross.

From a therapeutic perspective, the blood-brain barrier is a mixed blessing. On the positive side, the barrier protects the brain from injury by potentially toxic substances. On the negative side, the barrier can be a significant obstacle to entry of therapeutic agents.

The blood-brain barrier is not fully developed at birth. Accordingly, infants are much more sensitive to CNS drugs than are older children and adults.

21.3 HOW DO CNS DRUGS PRODUCE THERAPEUTIC EFFECTS?

Although much is known about the biochemical and electrophysiologic effects of CNS drugs, in most cases we cannot state with certainty the relationship between these effects and production of beneficial responses. Why? In order to fully understand how a drug alters symptoms, we need to understand, at a biochemical and physiologic level, the pathophysiology of the disorder being treated. In the case of most CNS disorders, our knowledge is limited. That is, we do not fully understand the brain in either health or disease. Given our incomplete understanding of the CNS itself, we must exercise caution when attempting to assign a precise mechanism for a drug's therapeutic effects.

Although we can't state with certainty how CNS drugs act, we do have sufficient data to permit formulation of plausible hypotheses. Consequently, as we study CNS drugs in the chapters that follow, proposed mechanisms of action are presented. Keep in mind, however, that these mechanisms are tentative, representing our best guess based on data available today. As we learn more, it is almost certain that these concepts will be modified, if not discarded entirely.

21.4 ADAPTATION OF THE CNS TO PROLONGED DRUG EXPOSURE

When CNS drugs are taken chronically, their effects may differ from those produced during initial use. These altered effects are the result of adaptive changes that occur in the brain in response to prolonged drug exposure. The brain's ability to adapt to drugs can produce alterations in therapeutic effects and side effects. Adaptive changes are often beneficial, although they can also be detrimental.

21.4.1 Increased Therapeutic Effects.

Certain drugs used in psychiatry—antipsychotics and antidepressants—must be taken for several weeks before full therapeutic effects develop. It would appear that beneficial responses are delayed because they result from adaptive changes—and not from the direct effects of drugs on synaptic function. Hence, full therapeutic effects are not seen until the CNS has had time to modify itself in response to prolonged drug exposure.

21.4.2 Decreased Side Effects.

When CNS drugs are taken chronically, the intensity of side effects may decrease (while therapeutic effects remain undiminished). For example, phenobarbital (an antiseizure drug) produces sedation during the initial phase of therapy; however, with continued treatment, sedation declines while full protection from seizures is retained. Similarly, when morphine is given to control pain, nausea is a common side effect early on; however, as treatment continues, nausea diminishes while analgesic effects persist. Adaptations within the brain are believed to underlie these phenomena.

21.4.3 Tolerance and Physical Dependence.

Tolerance and physical dependence are special manifestations of CNS adaptation. *Tolerance* is defined as a decreased response occurring in the course of prolonged drug use. *Physical dependence* is defined as a state in which abrupt discontinuation of drug use will precipitate a withdrawal syndrome. Research indicates that the kinds of adaptive changes that underlie tolerance and dependence are such that, once they have taken place, continued drug use is required for the brain to function “normally.” If drug use is stopped, the drug-adapted brain can no longer function properly, and hence a withdrawal syndrome ensues. The withdrawal reaction

continues until the adaptive changes have had time to revert, thereby restoring the CNS to its pretreatment state.

21.5 DEVELOPMENT OF NEW PSYCHOTHERAPEUTIC DRUGS

Because of deficiencies in our knowledge of the neurochemical and physiologic changes that underlie mental disease, it is impossible to take a rational approach to the development of truly new (nonderivative) psychotherapeutic agents. History bears this out: Virtually all of the major advances in psychopharmacology have been happy accidents.

In addition to our relative ignorance about the neurochemical and physiologic correlates of mental illness, two other factors contribute to the difficulty in generating truly new psychotherapeutic agents. First, in contrast to many other diseases, we lack adequate animal models of mental illness. Accordingly, animal research is not likely to reveal new types of psychotherapeutic agents. Second, mentally healthy individuals cannot be used as subjects to assess potential psychotherapeutic agents. Why? Because most psychotherapeutic drugs either have no effect on healthy individuals or produce paradoxical effects.

Once a new drug has been stumbled upon, variations on that agent can be developed systematically. The following process can be employed: (1) structural analogs of the new agent are synthesized, (2) these analogs are run through biochemical and physiologic screening tests to determine whether or not they possess activity similar to that of the parent compound, and (3) after serious toxicity has been ruled out, promising agents are tested in humans for possible psychotherapeutic activity. By following this procedure, it is possible to develop drugs that have fewer side effects than the original drug and perhaps even superior therapeutic effects. However, although this procedure may produce small advances, it is not likely to yield a major therapeutic breakthrough.

21.6 APPROACHING THE STUDY OF CNS DRUGS

Because our understanding of the CNS is less complete than our understanding of the peripheral nervous system, our approach to studying CNS drugs differs from the approach we took with peripheral nervous system agents. When we studied the pharmacology of the peripheral nervous system, we emphasized the importance of understanding transmitters and their receptors prior to embarking on a study of drugs. Since our knowledge of CNS transmitters is insufficient to allow this approach, rather than making a detailed examination of CNS transmitters before we study CNS drugs, we will discuss drugs and transmitters concurrently. Hence, for now, all that you need to know about CNS transmitters is that (1) there are a lot of them, (2) their precise functional roles are

not clear, and (3) their complexity makes it difficult for us to know with certainty just how CNS drugs produce their effects.

180

181

21.6.1

KEY POINTS

- In the CNS, many compounds appear to act as neurotransmitters, whereas in the periphery, only three compounds act as neurotransmitters.
- As a rule, we do not understand with precision how CNS drugs produce their effects.
- The blood-brain barrier can protect the CNS from toxic substances, but can also block entry of medicines into the CNS.
- The CNS often undergoes adaptive changes during prolonged drug exposure. The result can be increased therapeutic effects, decreased side effects, tolerance, and physical dependence.

²²CHAPTER 21 Drugs for Parkinson's Disease

Parkinson's disease (PD) is a slowly progressive neurodegenerative disorder first described in 1817 by Dr. James Parkinson, a London physician. The disease afflicts over 1 million Americans, making it second only to Alzheimer's disease as the most common degenerative disease of neurons. Cardinal symptoms are tremor, rigidity, postural instability, and slowed movement. In addition to these motor symptoms, most patients also experience nonmotor symptoms, especially autonomic disturbances, depression, psychosis, and dementia. As a rule, symptoms first appear in middle age and progress relentlessly. The underlying cause of motor symptoms is loss of dopaminergic neurons in the substantia nigra. Although there is no cure for motor symptoms, drug therapy can maintain functional mobility for years, and can thereby substantially prolong quality of life and life expectancy. The most effective drug for PD is levodopa, almost always given in combination with carbidopa. Unfortunately, as neurodegeneration progresses, levodopa eventually becomes ineffective.

^{22.1} PATHOPHYSIOLOGY THAT UNDERLIES MOTOR SYMPTOMS

Motor symptoms result from damage to the *extrapyramidal system*, a complex neuronal network that helps regulate movement. When extrapyramidal function is disrupted, *dyskinesias* (disorders of movement) result. The dyskinesias that characterize PD are tremor at rest, rigidity, postural instability, and bradykinesia (slowed movement). In severe PD, bradykinesia may progress to *akinesia*—complete absence of movement.

In people with PD, neurotransmission is disrupted primarily in the *striatum*, an important component of the extrapyramidal system. A simplified model of striatal neurotransmission is depicted in [Figure 21-1A](#). As indicated, proper function of the striatum requires a balance between two neurotransmitters: *dopamine* and *acetylcholine* (ACh). Dopamine is an *inhibitory* transmitter; ACh is *excitatory*. According to the model, the neurons that release dopamine inhibit neurons that release gamma-aminobutyric acid (GABA, another inhibitory transmitter). In contrast, the neurons that release ACh excite the neurons that release GABA. Movement is normal when the inhibitory influence of dopamine and the excitatory influence of ACh are in balance. Note that the neurons that supply dopamine to the striatum originate in the *substantia nigra*. Between 70% and 80% of these neurons must be lost before PD becomes clinically recognizable. This loss takes place over 5 to 20 years. Put another way, neuronal degeneration begins long before overt symptoms appear.

In PD, there is an imbalance between dopamine and ACh in the striatum ([Fig. 21-1B](#)). As noted, the imbalance results from *degeneration of the neurons that supply dopamine to the striatum*. In the absence of dopamine, the excitatory influence of ACh goes unopposed, causing excessive stimulation of the neurons that release GABA. Overactivity of these GABAergic neurons contributes to the motor symptoms that characterize PD.

What causes degeneration of dopaminergic neurons? No one knows for sure. However, some evidence strongly implicates *alpha-synuclein*—a potentially toxic protein synthesized by dopaminergic neurons. Under normal conditions, alpha-synuclein is rapidly degraded. As a result, it doesn't accumulate and no harm occurs. Degradation of alpha-synuclein requires two other proteins: *parkin* and *ubiquitin*. (Parkin is an enzyme that catalyzes the binding of alpha-synuclein to ubiquitin. Once bound to ubiquitin, alpha-synuclein can be degraded.) If any of these proteins—alpha-synuclein, parkin, or ubiquitin—is defective, degradation of alpha-synuclein cannot take place. When this occurs, alpha-synuclein accumulates inside the cell, forming neurotoxic fibrils. At autopsy, these fibrils are visible as so-called Lewy bodies, which are characteristic of PD pathology. Failure to degrade alpha-synuclein appears to result from two causes: genetic vulnerability and toxins in the environment. Defective genes coding for all three proteins have been found in families with inherited forms of PD. In people with PD that is not inherited, environmental toxins may explain the inability to degrade alpha-synuclein.

As discussed in [Chapter 31](#), movement disorders similar to those of PD can occur as side effects of antipsychotic drugs. These dyskinesias, which are referred to as *extrapyramidal side effects*, result from blockade of dopamine receptors in the striatum. This drug-induced parkinsonism can be managed with some of the drugs used to treat PD.

182

Figure 21-1 **A model of neurotransmission in the healthy striatum and parkinsonian striatum.** **A**, In the healthy striatum, dopamine (DA) released from neurons originating in the substantia nigra *inhibits* the firing of neurons in the striatum that release gamma-aminobutyric acid (GABA). Conversely, neurons located within the striatum, which release acetylcholine (ACh), *excite* the GABAergic neurons. Hence, under normal conditions, the inhibitory actions of DA are balanced by the excitatory actions of ACh, and controlled movement results. **B**, In Parkinson's disease, the neurons that supply DA to the striatum degenerate. In the absence of sufficient DA, the excitatory effects of ACh go unopposed, and disturbed movement results.

B Parkinson's Disease

22.2 OVERVIEW OF MOTOR SYMPTOM MANAGEMENT

22.2.1 Therapeutic Goal

Ideally, treatment would reverse neuronal degeneration, or at least prevent further degeneration, and control symptoms. Unfortunately, the ideal treatment doesn't exist. Hence, the goal with current drugs is simply to improve the patient's ability to carry out activities of daily life. Drug selection and dosage are determined by the extent to which PD interferes with work, walking, dressing, eating, bathing, and other activities. Drugs benefit the patient primarily by improving bradykinesia, gait disturbance, and postural instability. Tremor and rigidity, although disturbing, are less disabling. It is important to note that drugs only provide symptomatic relief; they do not cure PD. Furthermore, there is no convincing proof that any current drug can delay disease progression.

22.2.2 Drugs Employed

Given the neurochemical basis of parkinsonism—too little striatal dopamine and too much ACh—the approach to treatment is obvious: give drugs that can restore the functional balance between dopamine and ACh. To accomplish this, two types of drugs are used: (1) *dopaminergic agents* (ie, drugs that directly or indirectly cause activation of dopamine receptors); and (2) *anticholinergic agents* (ie, drugs that block receptors for ACh). Of the two groups, dopaminergic agents are by far the more widely employed.

As shown in [Table 21-1](#), dopaminergic drugs act by several mechanisms: levodopa promotes dopamine synthesis; the dopamine agonists activate dopamine receptors directly; inhibitors of monoamine oxidase-B (MAO-B) prevent dopamine breakdown; amantadine promotes dopamine release (and may also block dopamine reuptake); and the inhibitors of catechol-*O*-methyltransferase (COMT) enhance the effects of levodopa by blocking its degradation.

In contrast to the dopaminergic drugs, which act by multiple mechanisms, all of the anticholinergic agents share the same mechanism: blockade of muscarinic receptors in the striatum.

22.2.3 Clinical Guidelines

The American Academy of Neurology (AAN) has developed evidence-based guidelines for the treatment of Parkinson's disease. These guidelines were published in *Neurology* as five separate articles, released in 2002 and 2006. Their titles and release years are as follows:

- Initiation and Treatment for Parkinson Disease (Updated), 2002

- Diagnosis and Prognosis for New Onset Parkinson Disease, 2006

183

TABLE 21-1 Dopaminergic Agents for Parkinson's Disease

184

Drug	Mechanism of Action	Therapeutic Role
Dopamine Replacement		
Levodopa	Levodopa undergoes conversion to DA in the brain and then activates DA receptors (carbidopa blocks destruction of levodopa in the periphery)	First-line drug, or supplement to a dopamine agonist
Levodopa/carbidopa		
Dopamine Agonists		
Nonergot Derivatives	Directly activate DA receptors	First-line drugs, or supplements to levodopa; the oral nonergot derivatives—pramipexole and ropinirole—are preferred
Apomorphine		
Pramipexole		
Ropinirole		
Ergot Derivatives		Apomorphine—a subQ nonergot agent—is reserved for rescue therapy during “off” times
Bromocriptine		
Cabergoline		
COMT Inhibitors		
Entacapone	Inhibit breakdown of levodopa by COMT	Adjunct to levodopa to decrease “wearing off”; entacapone is more effective and safer than tolcapone
Tolcapone		
Dopamine Releaser		
Amantadine	Promotes release of DA from remaining dopaminergic neurons; may also block DA reuptake	Second- or third-line drug. May help reduce levodopa-induced dyskinesias
MAO-B Inhibitors		
Selegiline	Inhibit breakdown of DA by MAO-B	Used in newly diagnosed patients and for managing “off” times during levodopa therapy
Rasagiline		
COMT = catechol-O-methyltransferase, DA = dopamine, MAO-B = type B monoamine oxidase.		

- Neuroprotective Strategies and Alternative Therapies for New Onset Parkinson Disease, 2006

- Evaluation and Treatment of Depression, Psychosis and Dementia in Parkinson Disease, 2006
- Medical and Surgical Treatment of Parkinson Disease with Motor Fluctuations and Dyskinesia, 2006

The recommendations below are based on this set of guidelines.

22.2.4 Drug Selection

22.2.4.1 Initial Treatment.

For patients with mild symptoms, treatment can be begin with selegiline, an MAO-B inhibitor that confers mild, symptomatic benefit. Rasagiline, an MAO-B inhibitor that was not available when the guidelines were published, would probably work just as well.

For patients with more severe symptoms, treatment should begin with either levodopa (combined with carbidopa) or a dopamine agonist. Levodopa is more effective than the dopamine agonists, but long-term use carries a higher risk of disabling dyskinesias. Hence, the choice must be tailored to the patient: If improving motor function is the primary objective, then levodopa is preferred; however, if drug-induced dyskinesias are a primary concern, then a dopamine agonist would be preferred.

22.2.4.2 Management of Motor Fluctuations.

Long-term treatment with levodopa or dopamine agonists is associated with two types of motor fluctuations: “*off*” times (loss of symptom relief) and *drug-induced dyskinesias* (involuntary movements). “Off” times can be reduced with three types of drugs: dopamine agonists, COMT inhibitors, and MAO-B inhibitors. Evidence of efficacy is strongest for entacapone (a COMT inhibitor) and rasagiline (an MAO-B inhibitor). The only drug recommended for dyskinesias is amantadine.

22.2.4.3 Neuroprotection.

To date, there is no definitive proof that any drug can protect dopaminergic neurons from progressive degeneration. According to the 2006 guidelines, there is insufficient evidence to support or refute the use of riluzole, coenzyme Q-10, pramipexole, ropinirole, rasagiline, or amantadine for neuroprotection. As for vitamin E, there is good evidence that the compound does *not* confer protection, and hence should not be taken for this purpose. Early treatment with two MAO-B inhibitors—rasagiline and selegiline—can delay *symptom* progression. However,

we don't know if the delay is the result of protecting dopaminergic neurons, or simply the result of preventing dopamine destruction.

22.3 PHARMACOLOGY OF THE DRUGS USED FOR MOTOR SYMPTOMS

22.3.1 Levodopa

Levodopa was introduced in the 1960s, and has been a cornerstone of PD treatment ever since. Unfortunately, although the drug is highly effective, beneficial effects diminish over time. The most troubling adverse effects are dyskinesias. To enhance effects, levodopa is almost always combined with carbidopa.

22.3.1.1 Use in Parkinson's Disease

22.3.1.1.1 Beneficial Effects.

Levodopa [Dopar, Larodopa] is the most effective drug for PD. At the beginning of treatment, about 75% of patients experience a 50% reduction in symptom severity. Levodopa is so effective, in fact, that a diagnosis of PD should be questioned if the patient fails to respond.

Full therapeutic responses may take several months to develop. Consequently, although the effects of levodopa can be significant, patients should not expect immediate improvement.

184

185

Rather, they should be informed that beneficial effects are likely to increase steadily over the first few months.

In contrast to the dramatic improvements seen during initial therapy, long-term therapy with levodopa has been disappointing. Although symptoms may be well controlled during the first 2 years of treatment, by the end of 5 years the patient's ability to function may deteriorate to pretreatment levels. This probably reflects progression of the disease and not development of tolerance to levodopa.

22.3.1.1.2 Acute Loss of Effect.

Acute loss of effect occurs in two patterns: gradual loss and abrupt loss. Gradual loss —“wearing off”—develops near the end of the dosing interval, and simply indicates that drug levels have declined to a subtherapeutic value. Wearing off can be minimized in three ways: (1) shortening the dosing interval, (2) giving a drug that prolongs levodopa's plasma half-life (eg, entacapone), and (3) giving a direct-acting dopamine agonist.

Abrupt loss of effect, often referred to as the “on-off” phenomenon, can occur at any time during the dosing interval—even while drug levels are high. “Off” times may last from

minutes to hours. Over the course of treatment, “off” periods are likely to increase in both intensity and frequency. Drugs that can help reduce “off” times are listed in [Table 21-2](#). As discussed below, avoidance of high-protein meals may also help.

22.3.1.2 Mechanism of Action

Levodopa reduces symptoms by promoting synthesis of dopamine in the striatum ([Fig. 21-2](#)). Levodopa enters the brain via an active transport system that carries it across the blood-brain barrier. Once in the brain, the drug undergoes uptake into the few dopaminergic nerve terminals that remain in the striatum. Following uptake, levodopa, which has no direct effects of its own, is converted to dopamine, its active form. As dopamine, levodopa helps restore a proper balance between dopamine and ACh.

Conversion of levodopa to dopamine is depicted in [Figure 21-3](#). As indicated, the enzyme that catalyzes the reaction is called a *decarboxylase* (because it removes a carboxyl group from levodopa). The activity of decarboxylases is enhanced by *pyridoxine* (vitamin B₆).

Why is PD treated with levodopa and not with dopamine itself? There are two reasons. First, dopamine cannot cross the blood-brain barrier (see [Fig. 21-2](#)). As noted, levodopa crosses the barrier by means of an active transport system; this system does not transport dopamine. Second, dopamine has such a short half-life in the blood that it would be impractical to use even if it could cross the blood-brain barrier.

22.3.1.3 Pharmacokinetics

Levodopa is administered orally and undergoes rapid absorption from the small intestine. Food delays absorption by slowing gastric emptying. Furthermore, since neutral amino acids compete with levodopa for intestinal absorption (and for transport across the blood-brain barrier as well), high-protein foods will reduce therapeutic effects.

Only a small fraction of each dose reaches the brain. The majority is metabolized in the periphery, primarily by *decarboxylase enzymes* and to a lesser extent by COMT. Peripheral decarboxylases convert levodopa into dopamine, an active metabolite. In contrast, COMT converts levodopa into an inactive metabolite. Like the enzymes that decarboxylate levodopa within the brain, peripheral decarboxylases work faster in the presence of pyridoxine. Because of peripheral metabolism, less than 2% of each dose enters the brain.

TABLE 21-2 Drugs for Motor Complications of Levodopa Therapy

Drug	Drug Class
Drugs for “Off” Times	
Definitely Effective	
Entacapone	COMT inhibitor
Rasagiline	MAO-B inhibitor
Probably Effective	
Pramipexole	DA agonist
Ropinirole	DA agonist
Tolcapone	COMT inhibitor
Possibly Effective	
Apomorphine	DA agonist
Cabergoline	DA agonist
Selegiline	MAO-B inhibitor
Drug for Levodopa-Induced Dyskinesias	
Amantadine	DA-releasing agent
COMT = catechol-O-methyltransferase, DA = dopamine, MAO-B = type B monoamine oxidase.	

22.3.1.4 Adverse Effects

Most side effects of levodopa are dose dependent. The elderly, who are the primary users of levodopa, are especially sensitive to adverse effects.

22.3.1.4.1 Nausea and Vomiting.

Most patients experience nausea and vomiting early in treatment. The cause is activation of dopamine receptors in the chemoreceptor trigger zone (CTZ) of the medulla. Nausea and vomiting can be reduced by administering levodopa in low initial doses and with meals. (Food retards levodopa absorption, causing a decrease in peak plasma drug levels and a corresponding decrease in stimulation of the CTZ.) However, since administration with food can reduce therapeutic effects (by decreasing levodopa absorption), administration with meals should be avoided if possible. Giving additional carbidopa (without levodopa) can help reduce nausea and vomiting. Why carbidopa helps is unknown.

22.3.1.4.2 Dyskinesias.

Ironically, levodopa, which is given to *alleviate* movement disorders, actually *causes* movement disorders in many patients. About 80% develop involuntary movements within the first year. Some dyskinesias are just annoying (eg, head bobbing, tics, grimacing), whereas others can be disabling (eg, ballismus, choreoathetosis). These dyskinesias develop just before or soon after optimal levodopa dosage has been achieved. Dyskinesias can be managed in three ways. First, the dosage of levodopa can be reduced. However, dosage reduction may allow PD symptoms to re-emerge. Second, we can give amantadine (see below), which can reduce dyskinesias in some patients. If these measures fail, the only remaining options are surgery and electrical stimulation (see [Box 21-1](#)).

22.3.1.4.3 Cardiovascular Effects.

Postural hypotension is common early in treatment. The underlying mechanism is unknown. Hypotension can be reduced by increasing intake of salt and water. An alpha-adrenergic agonist can also help.

Conversion of levodopa to dopamine in the periphery can produce excessive activation of beta₁ receptors in the heart. *Dysrhythmias* can result, especially in patients with heart disease.

185

Figure 21-2 **Steps leading to alteration of CNS function by levodopa.** To produce its beneficial effects in PD, levodopa must be (1) transported across the blood-brain barrier; (2) taken up by dopaminergic nerve terminals in the striatum; (3) converted into dopamine; (4) released into the synaptic space; and (5) bound to dopamine receptors on striatal GABAergic neurons, causing them to fire at a slower rate. Note that dopamine itself is unable to cross the blood-brain barrier, and hence cannot be used to treat PD.

Figure 21-3 Conversion of levodopa to dopamine.

Decarboxylases present in the brain, liver, and intestine convert levodopa into dopamine. Pyridoxine (vitamin B₆) accelerates the reaction.

22.3.1.4.4 Psychosis.

Psychosis develops in about 20% of patients. Prominent symptoms are visual hallucinations, vivid dreams or nightmares, and paranoid ideation (fears of personal endangerment, sense of persecution, feelings of being followed or spied on). Activation of dopamine receptors is in some way involved. Symptoms can be reduced by lowering levodopa dosage, but this will reduce beneficial effects too.

Treatment of levodopa-induced psychosis with first-generation antipsychotics is problematic. Yes, these agents can decrease psychologic symptoms. However, they will also *intensify* symptoms of PD. Why? Because they block receptors for dopamine in the striatum. In fact, when first-generation antipsychotic agents are used for schizophrenia, the biggest problem is parkinsonian side effects, referred to as extrapyramidal symptoms (EPS).

Two second-generation antipsychotics—*clozapine* and *quetiapine*—have been used successfully to manage levodopa-induced psychosis. Unlike the first-generation antipsychotic drugs, clozapine and quetiapine cause little or no blockade of dopamine receptors in the striatum, and hence do not cause EPS. In patients taking levodopa, these drugs can reduce psychotic symptoms without intensifying symptoms of PD. Interestingly, the dosage of clozapine is only 25 mg/day, about 20 times lower than the dosage used for schizophrenia. Clozapine and quetiapine are discussed at length in [Chapter 31](#).

22.3.1.4.5 Other Adverse Effects.

Levodopa may *darken sweat and urine*; patients should be informed about this harmless effect. The drug can *activate malignant melanoma* and consequently should be avoided in patients with undiagnosed skin lesions.

186
187

22.3.1.4.5.1 BOX 21-1 Special Interest Topic

22.3.1.4.5.1.1 SURGICAL AND ELECTRICAL TREATMENTS FOR PARKINSON'S DISEASE

For patients with advanced Parkinson's disease (PD), levodopa therapy is far from ideal. Over time, the drug becomes less and less effective. Patients typically experience “off” times as well as drug-induced dyskinesias. For these patients, nondrug therapies may help. Potential options are deep brain stimulation, pallidotomy, and cell implants. Brain stimulation and pallidotomy have been very successful; cell implants have not.

22.3.1.4.5.1.1.1 Deep Brain Stimulation

Electrical stimulation of specific brain areas can improve motor symptoms in patients with PD. Three areas have been targeted: the subthalamic nucleus (STN), the globus pallidus internus, and the ventralis intermedius nucleus of the thalamus. Stimulation of the STN has produced the best results. Compared with pallidotomy, electrical stimulation has several advantages: it's reversible and adjustable, and, because brain tissue is not permanently damaged, it can be done bilaterally with low risk. On the other hand, electrical stimulation is very expensive. Several studies on STN stimulation have been conducted. One is described below.

In 1998, researchers reported that continuous, long-term electrical stimulation of the STN can improve symptoms in patients with advanced PD. This work was based on animal models of PD in which (1) motor symptoms were associated with abnormal

neuronal activity in the STN and (2) electrical stimulation of the STN improved the symptoms. In patients with PD, electrodes were implanted *bilaterally* in the STN and then connected by a subcutaneous lead to a pulse generator implanted in the subclavicular region, much like a cardiac pacemaker. The pulse generator was then programmed by telemetry to adjust stimulation parameters (eg, voltage, frequency). All patients in the study had advanced PD and all were experiencing “off” periods with levodopa.

Electrical stimulation produced substantial benefits during “off” times but only modest benefits during “on” times. During “off” times, there was a 60% improvement in motor function; bradykinesia, rigidity, tremor, and gait all improved. During “on” times, improvement was only 10%. Stimulation allowed all patients to become independent in most activities of daily living. On average, stimulation permitted a 50% reduction in levodopa dosage.

Adverse effects were generally mild, but serious sequelae of the neurosurgery are possible. Of the 20 patients in this study, 8 experienced transient CNS effects, including confusion, hallucinations, temporospatial disorientation, and abulia (lack of will; inability to make decisions). All symptoms resolved within 2 weeks of the surgery. Of much greater concern, the procedure carries a 2% to 8% risk of intracerebral hematoma. Accordingly, the procedure should be reserved for patients with advanced PD who are otherwise good candidates for surgery.

How does STN stimulation improve PD symptoms? The answer is unclear. One theory, based on animal studies, suggests that electrical stimulation may *inhibit* overactivity of neurons in the STN. The net result would be to *increase* excitatory input to the cerebral cortex.

Electrical stimulation is expensive. The surgery costs about \$25,000. The pulse generator costs another \$13,000. And every 3 to 5 years, additional costs arise when the batteries in the pulse generator must be replaced.

Pallidotomy

Posteroventral medial pallidotomy, or simply pallidotomy, is a neurosurgical procedure for destroying a region of the globus pallidus. As indicated in [Figure 21-1](#), the globus pallidus, which helps regulate movement, receives input from the striatum. In patients with PD, striatal input to the globus pallidus is disrupted, causing the globus pallidus itself to malfunction. It has been argued that altered output from the globus pallidus underlies many of the symptoms of PD, including tremor, rigidity,

22.3.1.4.5.1.1.2

22.3.1.4.5.1.1.3

and bradykinesia. The results of pallidotomy support this argument: For many patients with PD, *unilateral* destruction of the posteroventral medial region of the globus pallidus produces a substantial improvement in symptoms. The most consistent benefit is a reduction in levodopa-induced dyskinesias. Motor control during levodopa “off” times also improves. In contrast, very little improvement is seen during levodopa “on” times. Following pallidotomy, about 50% of patients who previously needed help with activities of daily living are able to live independently. Pallidotomy may also permit a temporary reduction in levodopa dosage. Although complications of the procedure are generally mild, intracerebral hemorrhage is a potential and serious risk.

Because pallidotomy is irreversible, and because complications can be serious, the procedure should be limited to patients with intractable levodopa-induced dyskinesias and to patients who are disabled by levodopa “off” times. Furthermore, because brain tissue is permanently destroyed, pallidotomy is usually performed unilaterally—thereby leaving the other side of the brain intact, just in case something goes wrong.

Cell Implants

The objective with cell implants is to replace degenerated dopaminergic neurons. Implants have been tried with human adrenal cells and with fetal brain cells from humans and pigs. Human brain cells work best, and even then benefits are modest.

In 1995, researchers finally obtained definitive proof that transplanting fetal dopaminergic neurons into the brain can benefit a patient with PD. In this case study, the patient had severe parkinsonism that would no longer respond to drug therapy. Following the transplant, symptoms steadily improved over 3 months, eventually allowing the patient to perform all activities of daily living without assistance. The improvements were sustained for 15 months, at which time the patient died of a massive pulmonary embolism unrelated to the transplant. Autopsy revealed that the grafts not only took but had become seamlessly integrated into the surrounding tissue. This was the first clear demonstration of a correlation between graft survival and improvement of symptoms.

In 1999, a study done with 40 patients showed that fetal tissue transplants are only moderately effective, and then only in patients who are relatively young. In this study, 20 patients received bilateral implants of dopamine-producing cells and 20 control patients received sham implants. Twelve months later, brain scans indicated cell survival in 60% of the treated patients, regardless of age. However, *functional*

187

188

improvement was modest (30%) and occurred only in patients under 60 years old. In patients over 60, there was no motor improvement despite survival of the implants. Furthermore, although motor function improved in some younger patients, it was not enough to permit a reduction in levodopa dosage.

22.3.1.5 Drug Holidays

With long-term use of levodopa, adverse effects tend to increase and therapeutic effects tend to diminish. For some patients, the situation may improve following a “drug holiday,” defined as a brief (eg, 10-day) interruption of treatment. When the holiday is successful, beneficial effects are achieved with lower doses. Because doses are lower, the incidence of dyskinesias and psychosis is lowered as well. Unfortunately, drug holidays do not eliminate “off” times.

Drug holidays are dangerous. Because drug withdrawal will immobilize the patient, the holiday must take place in a hospital. In addition to severe psychologic distress, immobilization presents a risk of deep vein thrombosis, aspiration pneumonitis, and decubitus ulcers.

22.3.1.6 Drug Interactions

Interactions between levodopa and other drugs can (1) increase beneficial effects of levodopa, (2) decrease beneficial effects of levodopa, and (3) increase toxicity from levodopa. Major interactions are summarized in [Table 21-3](#). Several interactions are discussed immediately below; others are discussed later.

22.3.1.6.1 First-Generation Antipsychotic Drugs.

All of the first-generation antipsychotic drugs (eg, chlorpromazine, haloperidol) block receptors for dopamine in the striatum. As a result, they can decrease therapeutic effects of levodopa. Accordingly, concurrent use of levodopa and these drugs should be avoided. As discussed above, two second-generation agents—clozapine and quetiapine—do not block dopamine receptors in the striatum, and hence can be used safely in patients with PD.

22.3.1.6.2 Monoamine Oxidase Inhibitors.

Levodopa can cause a hypertensive crisis if administered to an individual taking a *nonselective* inhibitor of monoamine oxidase (MAO). The mechanism is as follows: (1) Levodopa elevates neuronal stores of dopamine and norepinephrine (NE) by promoting synthesis of both compounds. (2) Because intraneuronal MAO serves to inactivate dopamine and NE, inhibition of MAO allows elevated neuronal stores of these transmitters to grow even larger. (3) Because both dopamine and NE promote vasoconstriction, release of these agents

in supranormal amounts can lead to massive vasoconstriction, thereby causing blood pressure to rise dangerously high. To avoid hypertensive crisis, nonselective MAO inhibitors should be withdrawn at least 2 weeks prior to giving levodopa.

22.3.1.6.3 Anticholinergic Drugs.

As discussed above, excessive stimulation of cholinergic receptors contributes to the dyskinesias of PD. Therefore, by blocking these receptors, anticholinergic agents can enhance responses to levodopa.

22.3.1.6.4 Pyridoxine.

Pyridoxine (vitamin B₆) stimulates decarboxylase activity. By accelerating decarboxylation of levodopa in the periphery, pyridoxine can decrease the amount of levodopa that reaches the central nervous system (CNS). As a result, therapeutic effects of levodopa are reduced. Patients should be informed about this interaction and instructed to avoid multivitamin preparations that contain pyridoxine.

22.3.1.7 Food Interactions

Meals with a high protein content can reduce therapeutic responses to levodopa. Why? Because neutral amino acids compete with levodopa for absorption from the intestine and for transport across the blood-brain barrier. Hence, a high-protein meal can significantly reduce both the amount of levodopa absorbed and the amount transported into the brain. It has been suggested that a high-protein meal could trigger an abrupt loss of effect (ie, an “off” episode).

Accordingly, patients should be advised to spread their protein consumption evenly throughout the day.

188

189

TABLE 21-3 Major Drug Interactions of Levodopa

Drug Category	Drug	Mechanism of Interaction
Drugs that <i>increase</i> beneficial effects of levodopa	Carbidopa	Inhibits peripheral decarboxylation of levodopa
	Entacapone, tolcapone	Inhibit destruction of levodopa by COMT in the intestine and peripheral tissues
	Apomorphine, bromocriptine, cabergoline, pramipexole, ropinirole	Stimulate dopamine receptors directly, and thereby add to the effects of dopamine derived from levodopa
	Amantadine	Promotes release of dopamine
	Anticholinergic drugs	Block cholinergic receptors in the CNS, and thereby help restore the balance between dopamine and ACh
Drugs that <i>decrease</i> beneficial effects of levodopa	Pyridoxine (vitamin B ₆)	Enhances destruction of levodopa by decarboxylases
	Antipsychotic drugs*	Block dopamine receptors in the striatum
Drugs that increase levodopa toxicity	MAO inhibitors	Inhibition of MAO increases the risk of severe levodopa-induced hypertension
ACh = acetylcholine, CNS = central nervous system, COMT = catechol-O-methyltransferase, MAO = monoamine oxidase.		

* First-generation antipsychotic agents block dopamine receptors in the striatum and thereby nullify the therapeutic effects of levodopa. Two second-generation antipsychotics—clozapine and quetiapine—do not block dopamine receptors in the striatum, and hence do not nullify the therapeutic effects of levodopa.

22.3.1.8 Preparations, Dosage, and Administration

Levodopa [Dopar, Larodopa] is available in tablets and capsules (100, 250, and 500 mg). To minimize adverse effects, especially drug-induced dyskinesias, dosage must be individualized. The usual initial dosage is 0.5 to 1.0 gm/day administered in two or more divided doses. The total daily dosage can be increased gradually to a maximum of 8 gm. Full therapeutic responses may take 6 months to develop.

22.3.2 Levodopa/Carbidopa

The combination of levodopa plus carbidopa is our most effective therapy for PD—much more effective than levodopa alone. Levodopa plus carbidopa is available under two trade names: *Sinemet* and *Paracopa*.

22.3.2.1 Mechanism of Action

Carbidopa is used to enhance the effects of levodopa. Carbidopa has no therapeutic effects of its own, and therefore is always used in conjunction with levodopa. Carbidopa inhibits decarboxylation of levodopa in the intestine and peripheral tissues, thereby making more levodopa available to the CNS. Carbidopa does not prevent the conversion of levodopa to dopamine by decarboxylases in the brain. Why? Because carbidopa is unable to cross the blood-brain barrier.

The impact of carbidopa is shown schematically in [Figure 21-4](#), which compares the fate of levodopa in the presence and absence of carbidopa. In the absence of carbidopa, about 98% of levodopa is lost in the periphery, leaving only 2% available to the brain. Why is levodopa lost? Primarily because decarboxylases in the GI tract and peripheral tissues convert it to dopamine. When these decarboxylases are inhibited by carbidopa, only 90% of levodopa is lost in the periphery, leaving 10% for actions in the brain.

22.3.2.2 Advantages of Carbidopa

The combination of carbidopa plus levodopa is superior to levodopa alone in three ways:

- By increasing the fraction of levodopa available for actions in the CNS, carbidopa allows the dosage of levodopa to be reduced by about 75%. In the example in [Figure 21-4](#), in order to provide 2.5 mg of dopamine to the brain, we must administer 125 mg of levodopa if carbidopa is absent, but only 25 mg if carbidopa is present.
- By reducing production of dopamine in the periphery, carbidopa reduces cardiovascular responses to levodopa as well as nausea and vomiting.
- By causing direct inhibition of decarboxylase, carbidopa obviates stimulation of decarboxylase by pyridoxine. As a result, carbidopa eliminates concern about decreasing the effects of levodopa by taking vitamin preparations that contain pyridoxine.

22.3.2.3 Disadvantages of Carbidopa

Carbidopa has no adverse effects of its own. Accordingly, any adverse responses from carbidopa/levodopa are the result of potentiating the effects of levodopa. When levodopa is combined with carbidopa, abnormal movements and psychiatric disturbances may occur sooner and may be more intense than when levodopa is employed alone.

22.3.2.4 Preparations, Dosage, and Administration

Therapy with levodopa plus carbidopa is almost always accomplished using a fixed-dose combination product, marketed as Sinemet or Paracopa. Under special circumstances, levodopa and carbidopa can be taken separately.

22.3.2.4.1 Levodopa/Carbidopa: Sinemet.

The Sinemet brand of levodopa/carbidopa is available in immediate-release (IR) and sustained-release (SR) tablets. The IR tablets are available in three strengths: (1) 10 mg carbidopa/100 mg levodopa, (2) 25 mg carbidopa/100 mg levodopa, and (3) 25 mg carbidopa/250 mg levodopa. The SR tablets [Sinemet CR] are available in two strengths: 25 mg carbidopa/100 mg levodopa, and 50 mg carbidopa/200 mg levodopa. With either the IR or SR formulation, dosage is low initially and then gradually increased. The usual maximum is 800 mg of levodopa a day, administered in divided doses.

22.3.2.4.2 Levodopa/Carbidopa: Paracopa.

The Paracopa brand of levodopa/carbidopa was introduced in 2005. Paracopa products differ from Sinemet products in that Paracopa products are formulated to dissolve on the tongue and then be swallowed with saliva—a potential advantage for patients who, because of their PD, have difficulty swallowing tablets intact. Orally disintegrating Paracopa tablets are available in the same strengths as IR Sinemet tablets: 10 mg carbidopa/100 mg levodopa, 25 mg carbidopa/100 mg levodopa, and 25 mg carbidopa/250 mg levodopa. Dosage is the same as with Sinemet.

22.3.2.4.3 Carbidopa Alone.

Carbidopa without levodopa, available as *Lodosyn*, is available by special request for investigational use. This preparation is employed when dosages of levodopa and carbidopa must be titrated separately. Carbidopa is never used without levodopa.

22.3.2.4.4 Switching from Levodopa Alone to Levodopa/Carbidopa.

When patients who have been taking levodopa alone are switched to the combination of levodopa plus carbidopa, at least 8 hours should elapse between the last dose of levodopa and the first dose of the combination. This delay is needed to prevent excessive potentiation of residual levodopa by carbidopa. Also, when switching from levodopa alone to the combination, the total daily dose of levodopa must be reduced substantially: The dose of levodopa within the combination should be only 25% of the former dose. For patients who are not currently receiving levodopa, therapy can be initiated with either 10 mg carbidopa/100 mg levodopa or 25 mg carbidopa/100 mg levodopa, each taken 3 times a day.

22.3.3 Dopamine Agonists

Dopamine agonists are first-line drugs for PD. Beneficial effects result from direct activation of dopamine receptors in the striatum. For patients with mild or moderate symptoms, dopamine agonists are drugs of first choice. Although dopamine agonists are less effective than levodopa, they still have advantages. Specifically, in contrast to levodopa, they aren't dependent on enzymatic conversion to become active, aren't converted to potentially toxic metabolites, and don't compete with dietary proteins for uptake from the intestine or transport across the blood-brain barrier. In addition, when used long-term, dopamine agonists have a lower incidence of response failures and are less likely to cause disabling dyskinesias. However, dopamine agonists do cause more serious side effects—especially hallucinations, daytime sleepiness, and postural hypotension. As a result, these drugs are usually reserved for younger patients, who tolerate their side effects better than do the elderly.

At this time, five dopamine agonists are available. The dopamine agonists fall into two groups: derivatives of ergot (an alkaloid found in plants) and nonergot derivatives. The nonergot derivatives—*pramipexole*, *ropinirole*, and *apomorphine*—are highly selective for dopamine receptors. In contrast, the ergot derivatives—*bromocriptine* and *cabergoline*—activate serotonergic and alpha-adrenergic receptors as well. Because of their selectivity, the nonergot derivatives cause fewer side effects than the ergot derivatives, and hence are preferred.

189

Figure 21-4 Fate of levodopa in the presence and absence of carbidopa. In the absence of carbidopa, 98% of an administered dose of levodopa is metabolized in intestinal and peripheral tissues—either by decarboxylases or COMT—leaving only 2% for actions in the brain. Hence, in order to deliver 2.5 mg of levodopa to the brain, the dose of levodopa must be large (125 mg). By inhibiting intestinal and peripheral decarboxylases, carbidopa increases the percentage of levodopa available to the brain. Hence, the dose needed to deliver 2.5 mg is greatly reduced (to 25 mg in this example). Since carbidopa cannot cross the blood-brain barrier, it does not suppress conversion of levodopa to dopamine in the brain. Furthermore, since carbidopa reduces peripheral production of dopamine (from 35 mg to 12.5 mg in this example), peripheral toxicity (nausea, cardiovascular effects) is greatly reduced.

(Data in the figure are extrapolated from Nutt JG, Fellman JH: Pharmacokinetics of levodopa. Clin Neuropharmacol 7:35, 1984.)

22.3.3.1 Pramipexole

22.3.3.1.1 Actions and Uses.

Pramipexole [Mirapex] is a nonergot dopamine receptor agonist. The drug is used alone in early-stage PD, and combined with levodopa in advanced-stage PD. Pramipexole binds selectively to dopamine D₂ and D₃ receptor subtypes. Binding to D₂ receptors underlies therapeutic effects. The significance of D₃ binding is unknown. When used as monotherapy in early PD, pramipexole can produce significant improvement in motor performance. When combined with levodopa in advanced PD, the drug can reduce fluctuations in motor control and may permit a reduction in levodopa dosage. In both cases, maximal benefits take several weeks to develop. Compared with levodopa, pramipexole is less effective at controlling motor symptoms of PD, but is also less likely to cause motor fluctuations.

In addition to its use in PD, pramipexole is approved for patients with moderate to severe *restless legs syndrome* (RLS), a sensorimotor disorder characterized by unpleasant leg sensations that create an urge to move the legs in an effort to ease discomfort. Symptoms are usually more intense in the evening and often disrupt sleep. People with severe RLS experience sleep loss, daytime exhaustion, and diminished quality of life.

22.3.3.1.2 Pharmacokinetics.

Pramipexole is rapidly absorbed and reaches peak plasma levels in 1 to 2 hours. Food reduces the speed of absorption but not the extent. Pramipexole undergoes wide distribution, and achieves a high concentration in red blood cells. The drug is eliminated unchanged in the urine.

22.3.3.1.3 Adverse Effects and Interactions.

Pramipexole can produce a variety of adverse effects. Most are the direct result of activating dopamine receptors. The most common effects seen when pramipexole is used *alone* are nausea (28%), dizziness (25%), daytime somnolence (22%), insomnia (17%), constipation (14%), weakness (14%), and hallucinations (9%). When the drug is *combined with levodopa*, many patients experience orthostatic hypotension (54%) and dyskinesias (47%), which are not seen when the drug is used by itself. In addition, the incidence of hallucinations nearly doubles, rising to 17%.

A few patients have experienced *sleep attacks* (overwhelming and irresistible sleepiness that comes on without warning). Sleep attacks can be a real danger for people who are driving

190

191

(and a potential blessing for those in faculty meetings). Sleep attacks should not be equated with the normal sleepiness that occurs with dopaminergic agents. Patients who experience a sleep attack should inform their prescriber.

Rarely, pramipexole has been associated with pathologic gambling and other *compulsive, self-rewarding behaviors*, including binge eating, compulsive shopping, and hypersexuality. These behaviors are dose related, begin about 9 months after starting pramipexole, and reverse when the drug is discontinued. Risk factors include relative youth, a family or personal history of alcohol abuse, and a personality trait called novelty seeking, characterized by impulsivity, a quick temper, and a low threshold for boredom. Before prescribing pramipexole, clinicians should screen patients for compulsive behaviors.

Cimetidine (a drug for peptic ulcer disease) can inhibit renal excretion of pramipexole, thereby increasing its blood level.

22.3.3.1.4 Preparations, Dosage, and Administration.

Pramipexole [Mirapex] is available in tablets (0.125, 0.25, 0.5, 1.0, and 1.5 mg) for oral dosing. Dosing may be done with food to reduce nausea. To minimize other adverse effects, dosage should be low initially and then gradually increased.

For patients with PD, the recommended starting dosage is 0.125 mg 3 times a day. This can be increased over 7 weeks to a maximum of 1.5 mg 3 times a day. In patients with significant renal impairment, dosage should be reduced.

For patients with RLS, dosing is done once daily, 2 to 3 hours before bedtime. The daily dosage is 0.125 mg initially, and can be gradually increased to a maximum of 0.5 mg.

22.3.3.2 Ropinirole

22.3.3.2.1 Actions, Uses, and Adverse Effects.

Ropinirole [Requip], a nonergot dopamine agonist, is similar to pramipexole with respect to receptor specificity, mechanism of action, and adverse effects. Like pramipexole, ropinirole is highly selective for D₂ and D₃ receptors, and both drugs share the same indications: PD and RLS. In patients with PD, ropinirole can be used as monotherapy (in early PD) and as an adjunct to levodopa (in advanced PD). In contrast to pramipexole, which is eliminated entirely by renal excretion, ropinirole is eliminated by hepatic metabolism. Some adverse effects are more common than with pramipexole. When ropinirole is used alone, the most common effects are nausea (60%), dizziness (40%), somnolence (40%), and hallucinations (5%).

Rarely, sleep attacks occur. When ropinirole is combined with levodopa, the most important

side effects are dyskinesias (34%), hallucinations (10%), and postural hypotension (2%). Note that these occur less frequently than when pramipexole is combined with levodopa. Like pramipexole, ropinirole can promote compulsive gambling and other compulsive, self-rewarding behaviors. Animal tests indicate that ropinirole can harm the developing fetus. Accordingly, the drug should not be used during pregnancy.

22.3.3.2.2 Preparations, Dosage, and Administration.

Preparations and Administration. Ropinirole is available in immediate-release (IR) film-coated tablets (0.25, 0.5, 1, 2, 3, 4, and 5 mg), marketed as *Requip*, and in extended-release (ER) tablets (2, 4, and 8 mg), marketed as *Requip XL*. The drug may be taken with food to decrease nausea. Dosage should be low initially and then gradually increased.

22.3.3.2.2.1 Dosage in Parkinson's Disease.

With the IR tablets, dosing is begun at 0.25 mg 3 times a day, and can be increased over several months to a maximum of 8 mg 3 times a day. With the ER tablets, dosing is begun at 2 mg once a day, and can be increased over several months to a maximum of 24 mg once a day.

22.3.3.2.2.2 Dosage in Restless Legs Syndrome.

Dosing is done once daily, 1 to 3 hours before bedtime, using the IR tablets. The daily dosage is 0.25 mg initially, and can be gradually increased to a maximum of 4 mg.

22.3.3.3 Apomorphine

22.3.3.3.1 Actions and Therapeutic Use.

Apomorphine [Apokyn] is a nonergot dopamine agonist approved for acute, subQ treatment of hypomobility during “off” episodes in patients with advanced PD. Unlike other dopamine agonists, the drug is not indicated for routine PD management. When tested in patients experiencing at least 2 hours of “off” time a day, apomorphine produced a 62% improvement in PD rating scores, compared with no improvement in patients receiving placebo. Benefits were sustained during 4 weeks of use. Apomorphine is a derivative of morphine, but is devoid of typical opioid effects (eg, analgesia, euphoria, respiratory depression).

22.3.3.3.2 Pharmacokinetics.

Apomorphine is highly lipophilic but undergoes extensive first-pass metabolism, and hence is ineffective when taken orally. After subQ injection, the drug undergoes rapid, complete

absorption. Effects begin in 10 to 20 minutes and persist about 1 hour. The drug's half-life is about 40 minutes.

22.3.3.3.3 Adverse Effects.

The most common adverse effects are injection-site reactions (26%), hallucinations (14%), yawning (8%), drowsiness (7%), dyskinesias (7%), rhinorrhea (4%), and nausea and vomiting (4%). During clinical trials, there was a 4% incidence of serious cardiovascular events: angina, myocardial infarction, cardiac arrest, and/or sudden death. Postural hypotension and fainting occurred in 2% of patients. Like other dopamine agonists, apomorphine poses a risk of daytime sleep attacks. In addition, apomorphine can promote hypersexuality and enhanced erections (the drug is used in Europe to treat erectile dysfunction); rarely, apomorphine causes priapism (sustained, painful erection), possibly requiring surgical intervention.

22.3.3.3.4 Combined Use with an Antiemetic.

To prevent nausea and vomiting during clinical trials, nearly all patients were treated with an antiemetic, starting 3 days before the first dose of apomorphine. The antiemetic chosen was trimethobenzamide [Tigan, others]. Two classes of antiemetics *cannot* be used: serotonin receptor agonists (eg, ondansetron [Zofran]) and dopamine receptor antagonists (eg, prochlorperazine [Compazine]). Why? Because serotonin receptor agonists will increase the risk of serious postural hypotension, and dopamine receptor antagonists will decrease the effectiveness of apomorphine and most other drugs for PD. About half the trial participants discontinued the antiemetic at some point, but continued taking apomorphine.

22.3.3.3.5 Preparations, Dosage, and Administration.

Apomorphine [Apokyn] is available in 2-mL ampules and 3-mL cartridges, at a concentration of 10 mg/mL. Doses are given subQ. The 3-mL cartridges are used with the multidose injector pen provided. Only one dose is given for each “off” episode. In clinical trials, patients received an average of three doses a day. Doses should be low initially (1 to 2 mg) and then gradually increased (to a 6-mg maximum).

To control nausea and vomiting, package labeling states that all patients should take an antiemetic (eg, trimethobenzamide, 300 mg 3 times a day), starting 3 days before the first apomorphine dose. However, many patients find the antiemetic unnecessary, and discontinue it within a few days.

22.3.3.4 Ergot Derivatives: Bromocriptine and Cabergoline

Two ergot derivatives—bromocriptine and cabergoline—are employed for PD. Compared with the nonergot dopamine agonists, these drugs are much less well tolerated, and hence their use is limited. Of particular concern, the ergot derivatives have been associated with valvular heart injury. Because of this serious complication, a third ergot derivative—pergolide [Permax]—has been withdrawn. The side effect profile of the ergot derivatives differs from that of the nonergot agents because, in addition to activating dopamine receptors, the nonergot drugs activate serotonergic and alpha-adrenergic receptors as well.

22.3.3.4.1 Bromocriptine.

Bromocriptine [Parlodel], a derivative of ergot, is a direct-acting dopamine agonist. Beneficial effects result from activating dopamine receptors in the striatum. Responses are equivalent to those seen with pramipexole and ropinirole. Bromocriptine is used alone in early PD and in combination with levodopa in advanced PD. When combined with levodopa, bromocriptine can prolong therapeutic responses and reduce motor fluctuations. In addition, since bromocriptine allows the dosage of levodopa to be reduced, the incidence of levodopa-induced dyskinesias may be reduced too.

Adverse effects are dose dependent and seen in 30% to 50% of patients. Nausea is most common, occurring in over 50% of those treated. The most common dose-limiting effects are psychologic reactions (confusion, nightmares, agitation, hallucinations, paranoid delusions).

These occur in about 30% of patients and are most likely when the dosage is high. Like levodopa, bromocriptine can cause dyskinesias and postural hypotension. Rarely,

191

192

bromocriptine causes retroperitoneal fibrosis, pulmonary infiltrates, a Raynaud-like phenomenon, and erythromelalgia (vasodilation in the feet, and sometimes hands, resulting in swelling, redness, warmth, and burning pain). In addition, the ergot derivatives have been associated with valvular heart injury. The probable cause is activation of serotonin receptors on heart valves.

Bromocriptine is available in 5-mg capsules [Parlodel] and 2.5-mg tablets [Parlodel SnapTabs]. The initial dosage is 1.25 mg twice daily, administered with meals. Dosage is gradually increased until the desired response has been achieved, or until side effects become intolerable. Maintenance dosages range from 30 to 100 mg/day.

22.3.3.4.2 Cabergoline.

Cabergoline [Dostinex] is used occasionally in PD, although it is not approved by the Food and Drug Administration for this disorder. According to the 2006 AAN guidelines, the drug is “possibly effective” for improving “off” times during levodopa therapy. The pharmacology of cabergoline, as well as its use in hyperprolactinemia, are discussed in [Chapter 62](#) (Drug Therapy of Infertility).

22.3.4 COMT Inhibitors

Two COMT inhibitors are available: entacapone and tolcapone. With both drugs, benefits derive from inhibiting metabolism of levodopa in the periphery; these drugs have no direct therapeutic effects of their own. Entacapone is safer and more effective than tolcapone, and hence is preferred.

22.3.4.1 Entacapone

22.3.4.1.1 Actions and Therapeutic Use.

Entacapone [Comtan] is a selective, reversible inhibitor of COMT indicated only for use with levodopa. Like carbidopa, entacapone inhibits metabolism of levodopa in the intestine and peripheral tissues. However, the drugs inhibit different enzymes: carbidopa inhibits decarboxylases, whereas entacapone inhibits COMT. By inhibiting COMT, entacapone prolongs the half-life of levodopa in blood, and thereby prolongs the time that levodopa is available to the brain. In addition, entacapone increases levodopa availability by a second mechanism: By inhibiting COMT, entacapone decreases production of levodopa metabolites that compete with levodopa for transport across the blood-brain barrier. In clinical trials, entacapone increased the half-life of levodopa by 50% to 75%, and thereby caused levodopa blood levels to be smoother and more sustained. As a result, “wearing off” was delayed and “on” times were extended. Entacapone may also permit a reduction in levodopa dosage.

22.3.4.1.2 Pharmacokinetics.

Entacapone is rapidly absorbed and reaches peak levels in 2 hours. Elimination is by hepatic metabolism followed by excretion in the feces and urine. The plasma half-life is 1.5 to 3.5 hours.

22.3.4.1.3 Adverse Effects.

Most adverse effects result from increasing levodopa levels, and some are caused by entacapone itself. By increasing levodopa levels, entacapone can cause dyskinesias, orthostatic hypotension, nausea, hallucinations, and sleep disturbances. These can be managed by decreasing levodopa dosage. Entacapone itself can cause vomiting, diarrhea, constipation, and yellow-orange discoloration of the urine.

22.3.4.1.4 Drug Interactions.

Because it inhibits COMT, entacapone can, in theory, increase levels of drugs metabolized by COMT. In addition to levodopa, these include methyldopa (an antihypertensive agent), dobutamine (an adrenergic agonist), and isoproterenol (a beta-adrenergic blocker). If entacapone is combined with these drugs, a reduction in their dosages may be needed.

22.3.4.1.5 Preparations, Dosage, and Administration.

Entacapone [Comtan], by itself, is available in 200-mg tablets. The recommended dosage is 200 mg taken with each dose of levodopa/carbidopa—to a maximum of 8 doses (1600 mg) a day.

As discussed below, entacapone is also available in fixed-dose combinations with levodopa/carbidopa, under the trade name *Stalevo*.

22.3.4.2 Tolcapone

22.3.4.2.1 Actions and Therapeutic Use.

Tolcapone [Tasmar] is a COMT inhibitor used only in conjunction with levodopa—and only if safer agents are ineffective or inappropriate. As with entacapone, benefits derive from inhibiting levodopa metabolism in the periphery, which prolongs levodopa availability. When given to patients taking levodopa, tolcapone improves motor function and may allow a reduction in levodopa dosage. For many patients, the drug reduces the “wearing off” effect that can occur with levodopa, thereby extending levodopa “on” times by as much as 2.9 hours a day. Unfortunately, although tolcapone is effective, it is also dangerous: Deaths from liver failure have occurred. Because it carries a serious risk, tolcapone should be reserved for patients who cannot be treated with safer drugs. Also, when tolcapone is used, treatment should be limited to 3 weeks in the absence of a beneficial response.

22.3.4.2.2 Pharmacokinetics.

Tolcapone is well absorbed following oral administration. Plasma levels peak 2 hours after dosing. In the blood, tolcapone is highly bound (over 99.9%) to plasma proteins, primarily albumin. The drug undergoes extensive hepatic metabolism followed by renal excretion. The plasma half-life is 2 to 3 hours.

22.3.4.2.3 Adverse Effects.

Liver Failure. Tolcapone can cause severe hepatocellular injury. At least three patients have died from acute, fulminant liver failure. Prior to treatment, patients should be fully apprised of the risks. Patients with pre-existing liver dysfunction should not take the drug. Patients taking tolcapone should be informed about signs of emergent liver dysfunction (persistent nausea, fatigue, lethargy, anorexia, jaundice, dark urine) and instructed to report these immediately. If liver injury is diagnosed, tolcapone should be discontinued and never used again.

Laboratory monitoring of liver enzymes is required. Tests for serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) should be conducted prior to treatment and then throughout treatment as follows: every 2 weeks for the first year, every 4 weeks for the next 6 months, and every 8 weeks thereafter. If ALT or AST levels exceed the upper limit of normal, tolcapone should be discontinued. Monitoring may not prevent liver injury, but early detection and immediate drug withdrawal can minimize harm.

22.3.4.2.3.1 Other Adverse Effects.

By increasing the availability of levodopa, tolcapone can intensify levodopa-related effects, especially dyskinesias, orthostatic hypotension, nausea, hallucinations, and sleep disturbances; a reduction in levodopa dosage may be required. Tolcapone itself can cause diarrhea, hematuria, and yellow-orange discoloration of the urine. Abrupt withdrawal of tolcapone can produce symptoms that resemble neuroleptic malignant syndrome (fever, muscular rigidity, altered consciousness). In rats, large doses have caused renal tubular necrosis and tumors of the kidneys and uterus.

22.3.4.2.4 Preparations, Dosage, and Administration.

Tolcapone [Tasmar] is available in 100- and 200-mg tablets that may be taken with or without food. The usual dosage is 100 mg 3 times a day. The first dose should be administered in the morning along with levodopa/carbidopa. The next two doses are taken 6 and 12 hours later. If necessary, the dosage can be increased to 200 mg 3 times a day. However, elevations in ALT are more likely at the higher dosage.

22.3.5 Levodopa/Carbidopa/Entacapone

Levodopa, carbidopa, and entacapone are now available in fixed-dose combinations sold as *Stalevo*. As discussed above, both carbidopa and entacapone inhibit the enzymatic degradation of levodopa, and thereby enhance therapeutic effects. The triple combination is more convenient than taking levodopa/carbidopa and entacapone separately, and costs a little less too. Unfortunately, *Stalevo* is available only in immediate-release tablets and only in the following strengths:

- *Stalevo 50*—50 mg levodopa, 12.5 mg carbidopa, and 200 mg entacapone
- *Stalevo 75*—75 mg levodopa, 18.75 mg carbidopa, and 200 mg entacapone
- *Stalevo 100*—100 mg levodopa, 25 mg carbidopa, and 200 mg entacapone
- *Stalevo 150*—150 mg levodopa, 37.5 mg carbidopa, and 200 mg entacapone
- *Stalevo 125*—125 mg levodopa, 31.25 mg carbidopa, and 200 mg entacapone

Patients who need more flexibility in their regimen cannot be treated with *Stalevo*, nor can patients who require a sustained-release formulation. For each dose of *Stalevo*, only 1 tablet is taken. Also, since each tablet contains 200 mg of entacapone, and since patients should take no more than 1600 mg of entacapone a day, the daily limit for *Stalevo* is 8 tablets.

192

193

22.3.6 MAO-B Inhibitors

The MAO-B inhibitors—selegiline and rasagiline—are considered second- or third-line drugs for PD. When combined with levodopa, they can reduce the “wearing-off” effect, but benefits are modest.

22.3.6.1 Selegiline

Selegiline [Eldepryl, Carbox, Zelapar]—also known as deprenyl—was the first MAO inhibitor approved for PD. The drug may be used alone or in combination with levodopa. In both cases, improvement of motor function is modest. There is some evidence suggesting that selegiline may delay neurodegeneration, and hence may delay disease progression. However, conclusive proof of neuroprotection is lacking. Nonetheless, current guidelines suggest trying selegiline in newly diagnosed patients, just in case the drug *does* confer some protection.

22.3.6.1.1 Actions and Use.

Selegiline causes *selective, irreversible* inhibition of type B monoamine oxidase (MAO-B), the enzyme that inactivates dopamine in the striatum. Another form of MAO, known as

MAO-A, inactivates NE and serotonin. As discussed in [Chapter 32](#), nonselective inhibitors of MAO (ie, drugs that inhibit MAO-A *and* MAO-B) are used to treat depression—and pose a risk of hypertensive crisis as a side effect. Because selegiline is a selective inhibitor of MAO-B, the drug is not an antidepressant and, *at recommended doses*, poses little or no risk of hypertensive crisis.

Selegiline appears to benefit patients with PD in two ways. First, when used as an adjunct to levodopa, selegiline can suppress destruction of dopamine derived from levodopa. The mechanism is inhibition of MAO-B. By helping preserve dopamine, selegiline can prolong the effects of levodopa, and can thereby decrease fluctuations in motor control. Unfortunately, these benefits decline dramatically within 12 to 24 months.

In addition to preserving dopamine, there is some hope that selegiline may delay the progression of PD. When used early in the disease, selegiline can delay the need for levodopa. This may reflect a delay in the progression of the disease, or it may simply reflect direct symptomatic relief from selegiline itself.

If selegiline does slow the progression of PD, what might be the mechanism? In experimental animals, selegiline can prevent development of parkinsonism following exposure to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin that causes selective degeneration of dopaminergic neurons. (Humans accidentally exposed to MPTP develop severe parkinsonism.) Neuronal degeneration is not caused by MPTP itself, but rather by a toxic metabolite. Formation of this metabolite is catalyzed by MAO-B. By inhibiting MAO-B, selegiline prevents formation of the toxic metabolite, and thereby protects against neuronal injury. If selegiline does retard progression of PD, this mechanism could explain the effect. That is, just as selegiline protects animals by suppressing formation of a neurotoxic metabolite of MPTP, the drug may retard progression of PD by suppressing formation of a neurotoxic metabolite of an as-yet unidentified compound.

22.3.6.1.2 Pharmacokinetics.

For treatment of PD, selegiline is available in two oral formulations (tablets and capsules) and in orally disintegrating tablets (ODTs).

22.3.6.1.2.1 Tablets and Capsules.

Selegiline in tablets and capsules [Eldepryl, Carbox] undergoes rapid GI absorption, travels to the brain, and quickly penetrates the blood-brain barrier. Irreversible inhibition of MAO-B follows. Selegiline undergoes hepatic metabolism followed by renal excretion. Two metabolites—*l-amphetamine* and *l-methamphetamine*—are CNS stimulants. These

metabolites do not appear to have therapeutic effects, and they can be harmful. Because selegiline causes irreversible inhibition of MAO-B, effects persist until more MAO-B can be synthesized.

22.3.6.1.2.2 Orally Disintegrating Tablets.

Unlike selegiline in tablets and capsules, which is absorbed from the GI tract, selegiline in ODTs [Zelapar] is absorbed through the oral mucosa. As a result, bioavailability is higher than with tablets and capsules, and hence doses can be lower. Otherwise, the pharmacokinetics of selegiline in ODTs, tablets, and capsules are identical.

22.3.6.1.3 Adverse Effects.

When selegiline is used alone, the principal adverse effect is *insomnia*, presumably because of CNS excitation by amphetamine and methamphetamine. Insomnia can be minimized by administering the last daily dose no later than noon. Other adverse effects include orthostatic hypotension, dizziness, and GI symptoms. About 10% of patients taking selegiline ODTs experience irritation of the buccal mucosa.

22.3.6.1.3.1 Hypertensive Crisis.

Although selegiline is selective for MAO-B, high doses can inhibit MAO-A, and hence there is a risk of hypertensive crisis. As discussed in [Chapter 32](#), when a patient is taking an MAO inhibitor, hypertensive crisis can be triggered by ingesting foods that contain tyramine and by taking certain drugs, including sympathomimetics. Accordingly, patients should be instructed to avoid these foods and drugs, both while taking selegiline and for 2 weeks after discontinuing it. For a full list of foods and drugs to avoid, see [Chapter 32](#).

22.3.6.1.4 Drug Interactions.

Levodopa. When used with levodopa, selegiline can intensify adverse responses to levodopa-derived dopamine. These reactions—orthostatic hypotension, dyskinesias, and psychologic disturbances (hallucinations, confusion)—can be reduced by decreasing the dosage of levodopa.

22.3.6.1.4.1 Meperidine.

Like the nonselective MAO inhibitors, selegiline can cause a dangerous interaction with meperidine [Demerol]. Symptoms include stupor, rigidity, agitation, and hyperthermia. The combination should be avoided.

22.3.6.1.4.2 Fluoxetine.

Selegiline should not be combined with fluoxetine [Prozac]. The combination of a nonselective MAO inhibitor plus fluoxetine has been fatal. Although this interaction has not been reported with selegiline, prudence dictates caution. Accordingly, fluoxetine should be withdrawn at least 5 weeks before giving selegiline.

22.3.6.1.5 Preparations, Dosage, and Administration.

Tablets and Capsules. Selegiline [Eldepryl, Carbox] is available in 5-mg tablets and capsules. For treatment of PD, the usual dosage is 5 mg taken with breakfast and lunch, for a total of 10 mg a day. This dosage produces complete inhibition of MAO-B, and hence larger doses are unnecessary.

22.3.6.1.5.1 Orally Disintegrating Tablets.

Selegiline [Zelapar] is available in 1.25-mg ODTs. For patients with PD, treatment begins with 1.25 mg once a day for 6 weeks. If needed and tolerated, the dosage can then be raised to 2.5 mg once a day. Note that the maximum daily dose (2.5 mg) is 4 times lower than the maximum daily dose with tablets and capsules. Dosing should be done in the morning before breakfast, without liquid. Tablets are placed on the tongue, where they dissolve in seconds. Selegiline is then absorbed through the oral mucosa.

22.3.6.1.5.2 Transdermal System.

Selegiline is available in a transdermal system, marketed as *Emsam*, for treatment of major depressive disorder (see [Chapter 32](#)). Transdermal selegiline is not used for PD.

22.3.6.2 Rasagiline

22.3.6.2.1 Actions and Therapeutic Use.

Rasagiline [Azilect] was approved in 2006, making it the second MAO-B inhibitor for PD. Like selegiline, rasagiline is a selective, irreversible inhibitor of MAO-B. Benefits derive from preserving dopamine in the brain. The drug is approved for initial monotherapy of PD and for combined use with levodopa. As with selegiline, benefits are modest. Rasagiline is similar to selegiline in most regards. The drugs differ primarily in that rasagiline is not converted to amphetamine or methamphetamine.

22.3.6.2.2 Pharmacokinetics.

Rasagiline is rapidly absorbed with a bioavailability of 36%. In the liver, the drug undergoes nearly complete metabolism by CYP1A2 (the 1A2 isozyme of cytochrome P450). Hepatic impairment and drugs that inhibit CYP1A2 will delay metabolism of rasagiline, causing blood levels of the drug to rise. In contrast to selegiline, rasagiline is not metabolized to amphetamine derivatives. Excretion is via the urine (62%) and feces (7%). The plasma half-life is 3 hours. However, because rasagiline causes irreversible inhibition of MAO-B, clinical effects persist until new MAO-B is synthesized.

22.3.6.2.3 Adverse Effects.

When used as monotherapy, rasagiline is generally well tolerated. The most common side effects are headache (14%), arthralgia (7%), dyspepsia (7%), depression (5%), flu-like symptoms (5%), and falls (5%). Unlike selegiline, rasagiline does not cause insomnia.

When rasagiline is combined with levodopa, side effects increase. The most common reactions are dyskinesias (18%), accidental injury (12%), nausea (12%), headache (11%), orthostatic hypotension (9%), constipation (9%), weight loss (9%), arthralgia (8%), and hallucinations (4%).

193

194

Like selegiline, rasagiline may pose a risk of hypertensive crisis (owing to inhibition of MAO-A), and hence patients should be instructed to avoid tyramine-containing foods and certain drugs, including sympathomimetic agents.

Rasagiline may increase the risk of malignant melanoma, a deadly cancer of the skin. Periodic monitoring is recommended.

22.3.6.2.4 Drug and Food Interactions.

Rasagiline has the potential to interact adversely with multiple drugs. Drugs that should be used with *caution* include

- *Levodopa*—Like selegiline, rasagiline can intensify adverse responses to levodopa-derived dopamine.
- *CYP1A2 Inhibitors*—Blood levels of rasagiline can be raised by ciprofloxacin and other drugs that inhibit CYP1A2, the hepatic enzyme that inactivates rasagiline.

Drugs and foods that are *contraindicated* include

- *MAO Inhibitors*—Combining rasagiline with another MAO inhibitor increases the risk of hypertensive crisis. At least 2 weeks should separate use of these drugs.
- *Sympathomimetics*—Sympathomimetics (eg, amphetamines, ephedrine, phenylephrine, pseudoephedrine) increase the risk of hypertensive crisis and must be avoided.
- *Tyramine-Containing Foods*—These agents increase the risk of hypertensive crisis and must be avoided.
- *Antidepressants*—Combining rasagiline with mirtazapine, selective serotonin reuptake inhibitors (SSRIs), serotonin/norepinephrine reuptake inhibitors, and tricyclic antidepressants may pose a risk of hyperpyrexia and death. These drugs should be discontinued at least 14 days before starting rasagiline. Fluoxetine (an SSRI) should be discontinued at least 5 weeks before starting rasagiline.
- *Analgesics*—Combining rasagiline with meperidine, methadone, propoxyphene, or tramadol may pose a risk of serious reactions, including coma, respiratory depression, convulsions, hypertension, hypotension, and even death. At least 14 days should separate use of these drugs.
- *Dextromethorphan*—Combining rasagiline with dextromethorphan may pose a risk of brief episodes of psychosis and bizarre behavior.
- *Cyclobenzaprine*—This drug is structurally related to the tricyclic antidepressants, and hence should be avoided.

22.3.6.2.5 Preparations, Dosage, and Administration.

Rasagiline [Azilect] is available in 0.5- and 1-mg oral tablets.

For *monotherapy*, the usual dosage is 1 mg once a day, taken with or without food. For patients taking ciprofloxacin and other drugs that inhibit CYP1A2, the daily dosage should be reduced to 0.5 mg. For patients with mild hepatic impairment, the daily dosage should be reduced to 0.5 mg. Patients with moderate to severe hepatic impairment should not use the drug.

For *adjunctive therapy* with levodopa, the dosage is 0.5 mg once a day initially, and may be increased to 1 mg once a day if needed. If the patient develops dopaminergic side effects, including dyskinesias or hallucinations, reducing the dosage of levodopa—not rasagiline—should be considered.

22.3.7 Amantadine

22.3.7.1 Actions and Uses.

Amantadine [Symmetrel] was developed as an antiviral agent (see [Chapter 92](#)), and was later found effective in PD. Possible mechanisms include inhibition of dopamine uptake, stimulation of dopamine release, blockade of cholinergic receptors, and blockade of glutamate receptors. Responses develop rapidly—often within 2 to 3 days—but are much less profound than with levodopa or the dopamine agonists. Furthermore, responses may begin to diminish within 3 to 6 months. Accordingly, amantadine is not considered a first-line agent. However, this drug may be helpful for managing dyskinesias caused by levodopa.

22.3.7.2 Adverse Effects.

Amantadine can cause adverse CNS effects (confusion, lightheadedness, anxiety) and peripheral effects that are thought to result from muscarinic blockade (blurred vision, urinary retention, dry mouth, constipation). All of these are generally mild when amantadine is used alone. However, if amantadine is combined with an anticholinergic agent, both the CNS and peripheral responses will be intensified.

Patients taking amantadine for 1 month or longer often develop *livedo reticularis*, a condition characterized by mottled discoloration of the skin. Livedo reticularis is a benign condition that gradually subsides following amantadine withdrawal.

22.3.7.3 Preparations, Dosage, and Administration.

Amantadine [Symmetrel] is supplied in 100-mg capsules and a syrup (10 mg/mL). The usual dosage is 100 mg twice daily. Because amantadine is eliminated primarily by the kidneys, dosage must be reduced in patients with renal impairment.

Amantadine often loses effectiveness after several months. If effects diminish, they can be restored by increasing the dosage or by interrupting treatment for several weeks.

Amantadine can enhance responses to levodopa and anticholinergic agents. When combined with these drugs, amantadine is administered in the same doses employed when taken alone.

22.3.8 Centrally Acting Anticholinergic Drugs

Anticholinergic drugs have been used in PD since 1867, making them the oldest medicines for this disease. These drugs alleviate symptoms by blocking muscarinic receptors in the striatum, thereby improving the functional imbalance between dopamine and ACh. Anticholinergic drugs can

reduce tremor and possibly rigidity, but not bradykinesia. These agents are less effective than levodopa or dopamine agonists, but better tolerated. Today, anticholinergics are used as second-line therapy for tremor. They are most appropriate for younger patients with mild symptoms. Anticholinergics are generally avoided in the elderly, who are intolerant of CNS side effects (sedation, confusion, delusions, and hallucinations).

Although the anticholinergic drugs used today are somewhat selective for cholinergic receptors in the CNS, they can also block cholinergic receptors in the periphery. As a result, they can cause dry mouth, blurred vision, photophobia, urinary retention, constipation, and tachycardia. These effects are usually dose limiting. Blockade of cholinergic receptors in the eye may precipitate or aggravate glaucoma. Accordingly, intraocular pressure should be measured periodically. Peripheral anticholinergic effects are discussed fully in [Chapter 14](#).

The anticholinergic agents used most often are *trihexyphenidyl* [Artane] and *benztropine* [Cogentin]. Doses are low initially and then gradually increased—until the desired response is achieved or until side effects become intolerable. For trihexyphenidyl, the initial dosage is 1.0 mg once a day, and the maximum dosage is 2 mg 3 times a day. For benztropine, the initial dosage is 0.5 mg twice a day, and the maximum dosage is 2 mg twice a day. If anticholinergic drugs are discontinued abruptly, symptoms of parkinsonism may be intensified.

22.4 NONMOTOR SYMPTOMS AND THEIR MANAGEMENT

In addition to having characteristic motor symptoms, about 90% of patients with PD develop nonmotor symptoms, notably autonomic disturbances, depression, dementia, and psychosis.

Disruption of autonomic function can produce a variety of symptoms, including constipation, urinary incontinence, drooling, orthostatic hypotension, cold intolerance, and erectile dysfunction. The intensity of these symptoms increases in parallel with the intensity of motor symptoms. Constipation can be managed by getting regular exercise, maintaining adequate intake of fluid and fiber, and using a stool softener, such as docusate (see [Chapter 78](#)). Urinary incontinence can be controlled with oxybutynin and other peripherally acting anticholinergic drugs (see [Chapter 14](#)). Orthostatic hypotension can be managed by increasing intake of salt and fluid, and by treatment with fludrocortisone, a mineralocorticoid (see [Chapter 59](#)). Erectile function can be improved with sildenafil and other inhibitors of type 5 phosphodiesterase (see [Chapter 65](#)).

About 50% of PD patients develop depression, partly in reaction to having a debilitating disease, and partly because of the disease process itself. According to the 2006 AAN guidelines, only one drug—amitriptyline—has been proved effective in these patients. Unfortunately, amitriptyline, a tricyclic antidepressant, has anticholinergic effects that can exacerbate dementia, and antiadrenergic effects that can exacerbate orthostatic hypotension. Data for other antidepressants, including

selective serotonin reuptake inhibitors and bupropion, are insufficient to prove or disprove efficacy in PD.

Dementia occurs in 40% of PD patients. The AAN guidelines recommend considering treatment with two drugs: donepezil and rivastigmine. Both drugs are cholinesterase inhibitors developed for Alzheimer's disease ([Chapter 22](#)). In patients with PD, these drugs can produce a modest improvement in cognitive function, without causing significant worsening of motor symptoms, even though these drugs increase availability of acetylcholine at central synapses.

In patients with PD, psychosis is usually caused by the drugs taken to control motor symptoms.

Most of these drugs—levodopa, dopamine agonists, amantadine, and anticholinergic drugs—can cause hallucinations. Therefore, if psychosis develops, dopamine agonists, amantadine, and anticholinergic drugs should be withdrawn, and the dosage of levodopa should be reduced to the lowest effective amount. If antipsychotic medication is needed, *first-generation* antipsychotics should be *avoided*. Why? Because all of these drugs block receptors for dopamine, and hence can intensify motor symptoms. Accordingly, the AAN guidelines recommend considering two second-generation antipsychotics: clozapine and quetiapine. Since clozapine can cause agranulocytosis, many clinicians prefer quetiapine. The guidelines recommend against routine use of olanzapine, another second-generation agent. The antipsychotic drugs are discussed in [Chapter 31](#).

194

195

22.4.1

KEY POINTS

- Parkinson's disease is a neurodegenerative disorder that produces characteristic motor symptoms: tremor at rest, rigidity, postural instability, and bradykinesia.
- In addition to motor symptoms, PD can cause nonmotor symptoms, including autonomic dysfunction, depression, psychosis, and dementia.
- The primary pathology in PD is degeneration of neurons in the substantia nigra that supply dopamine to the striatum. The result is an imbalance between dopamine and ACh.
- Motor symptoms are treated primarily with drugs that directly or indirectly activate dopamine receptors. Drugs that block cholinergic receptors can also be used.
- Levodopa (combined with carbidopa) is the most effective treatment for motor symptoms.
- Levodopa relieves motor symptoms by undergoing conversion to dopamine in surviving nerve terminals in the striatum.
- The enzyme that converts levodopa to dopamine is called a decarboxylase.

- Acute loss of response to levodopa occurs in two patterns: gradual “wearing off,” which develops at the end of the dosing interval, and abrupt loss of effect (“on-off” phenomenon), which can occur at any time during the dosing interval.
- The principal adverse effects of levodopa are nausea, dyskinesias, hypotension, and psychosis.
- First-generation antipsychotic drugs block dopamine receptors in the striatum, and can thereby negate the effects of levodopa. Two second-generation antipsychotics—clozapine and quetiapine—do not block dopamine receptors in the striatum, and hence can be used safely to treat levodopa-induced psychosis.
- Combining levodopa with a nonselective MAO inhibitor can result in hypertensive crisis.
- Because amino acids compete with levodopa for absorption from the intestine and for transport across the blood-brain barrier, high-protein meals can reduce therapeutic effects.
- Carbidopa enhances the effects of levodopa by preventing decarboxylation of levodopa in the intestine and peripheral tissues. Since carbidopa cannot cross the blood-brain barrier, it does not prevent conversion of levodopa to dopamine in the brain.
- Pramipexole, an oral nonergot dopamine agonist, is a first-line drug for motor symptoms. It can be used alone in early PD and combined with levodopa in advanced PD.
- Pramipexole and other dopamine agonists relieve motor symptoms by causing direct activation of dopamine receptors in the striatum.
- The major adverse effects of pramipexole—nausea, dyskinesia, postural hypotension, and hallucinations—result from excessive activation of dopamine receptors.
- Entacapone, a COMT inhibitor, is combined with levodopa to enhance levodopa's effects. The drug inhibits metabolism of levodopa by COMT in the intestine and peripheral tissues, thereby making more levodopa available to the brain.
- Selegiline and rasagiline enhance responses to levodopa by inhibiting MAO-B, the brain enzyme that inactivates dopamine.
- Anticholinergic drugs relieve symptoms of PD by blocking cholinergic receptors in the striatum.

22.4.2	Summary of Major Nursing Implications*	
22.4....	LEVODOPA/CARBIDOPA [SINEMET, PARACOPA]	
22.4....	Preadministration Assessment	
22.4....	Therapeutic Goal	
	The goal of treatment is to improve the patient's ability to carry out activities of daily living. Levodopa does not cure PD or delay its progression.	
22.4....	Baseline Data	
	Assess motor symptoms—bradykinesia, akinesia, postural instability, tremor, rigidity—and the extent to which they interfere with activities of daily living (ability to work, dress, bathe, walk, etc.).	
22.4....	Identifying High-Risk Patients	
	Levodopa is <i>contraindicated</i> for patients with malignant melanoma (it can activate this neoplasm) and for patients taking MAO inhibitors.	
	Exercise <i>caution</i> in patients with cardiac disease and psychiatric disorders.	195
22.4....	Implementation: Administration	196
22.4....	Route	
	Oral.	
22.4....	Administration	
	Motor symptoms may render self-medication impossible. Assist the patient with dosing when needed. If appropriate, involve family members in medicating outpatients.	
	Inform patients that levodopa may be taken with food to reduce nausea and vomiting. However, high-protein meals should be avoided.	
	If the patient has been taking levodopa alone, allow at least 8 hours between the last dose of levodopa and the first dose of levodopa/carbidopa. The dosage of levodopa in the	

combination should be reduced to no more than 25% of the dosage employed when levodopa was taken alone.

So that expectations may be realistic, **inform patients that benefits of levodopa may be delayed for weeks to months.** This knowledge will facilitate adherence.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Evaluate for improvements in activities of daily living and for reductions in bradykinesia, postural instability, tremor, and rigidity.

Managing Acute Loss of Effect

“Off” times can be reduced by combining levodopa/carbidopa with a dopamine agonist (eg, pramipexole), a COMT inhibitor (eg, entacapone), or an MAO-B inhibitor (eg, rasagiline). **Forewarn patients about possible abrupt loss of therapeutic effects and instruct them to notify the prescriber if this occurs. Avoiding high-protein meals may help.**

Minimizing Adverse Effects

Nausea and Vomiting.

Inform patients that nausea and vomiting can be reduced by taking levodopa with food. Instruct patients to notify the prescriber if nausea and vomiting persist or become severe. Adding more carbidopa (without levodopa) can help reduce nausea and vomiting.

Dyskinesias.

Inform patients about possible levodopa-induced movement disorders (tremor, dystonic movements, twitching) and instruct them to notify the prescriber if these develop. Giving amantadine may help.

If the hospitalized patient develops dyskinesias, withhold levodopa and consult the prescriber about a possible reduction in dosage.

22.4....

Dysrhythmias.

Inform patients about signs of excessive cardiac stimulation (palpitations, tachycardia, irregular heartbeat) and instruct them to notify the prescriber if these occur.

22.4....

Orthostatic Hypotension.

Inform patients about symptoms of hypotension (dizziness, lightheadedness) and advise them to sit or lie down if these occur. Advise patients to move slowly when assuming an erect posture.

22.4....

Psychosis.

Inform patients about possible levodopa-induced psychosis (visual hallucinations, vivid dreams, paranoia) and instruct them to notify the prescriber if these develop. Treatment with clozapine or quetiapine can help.

22.4....

Minimizing Adverse Interactions

22.4....

First-Generation Antipsychotic Drugs.

These can block responses to levodopa and should be avoided. Two second-generation antipsychotics—clozapine and quetiapine—can be used safely.

22.4....

MAO Inhibitors.

Concurrent use of levodopa and a nonselective MAO inhibitor can produce severe hypertension. Withdraw nonselective MAO inhibitors at least 2 weeks before initiating levodopa.

22.4....

Anticholinergic Drugs.

These can enhance therapeutic responses to levodopa, but they also increase the risk of adverse psychiatric effects.

22.4....

High-Protein Meals.

Amino acids compete with levodopa for absorption from the intestine and for transport across the blood-brain barrier. **Instruct patients not to take levodopa/carbidopa with a high-protein meal.**

22.4....

DOPAMINE AGONISTS

Apomorphine

Bromocriptine

Cabergoline

Pramipexole

Ropinirole

22.4....

Preadministration Assessment

22.4....

Therapeutic Goal

The goal of treatment is to improve the patient's ability to carry out activities of daily living. Dopamine agonists do not cure PD or delay its progression.

Apomorphine is reserved for rescue treatment of hypomobility during “off” episodes in patients with advanced PD.

22.4....

Baseline Data

Assess motor symptoms—bradykinesia, akinesia, postural instability, tremor, rigidity—and the extent to which these interfere with activities of daily living (ability to work, dress, bathe, walk, etc.).

22.4....

Identifying High-Risk Patients

Use *all dopamine agonists* with *caution* in elderly patients and in patients with psychiatric disorders. Use *pramipexole* with *caution* in patients with kidney dysfunction. Avoid *ropinirole* during pregnancy. Use *pramipexole* and *ropinirole* with *caution* in patients prone to compulsive behavior.

22.4....	Implementation: Administration	
22.4....	Route	
22.4....	Oral.	
	Cabergoline, bromocriptine, pramipexole, ropinirole.	
22.4....	Subcutaneous.	
	Apomorphine.	
22.4....	Administration	
	Parkinsonism may render self-medication impossible. Assist the patient with dosing when needed. If appropriate, involve family members in medicating outpatients.	
	Inform patients that oral dopamine agonists may be taken with food to reduce nausea and vomiting.	196
	To minimize adverse effects, dosage should be low initially and then gradually increased.	197
	Reduce dosage of pramipexole in patients with significant renal dysfunction.	
22.4....	Ongoing Evaluation and Interventions	
22.4....	Evaluating Therapeutic Effects	
	Evaluate for improvements in activities of daily living and for reductions in bradykinesia, postural instability, tremor, and rigidity.	
22.4....	Minimizing Adverse Effects	
22.4....	Nausea and Vomiting.	
	Inform patients that nausea and vomiting can be reduced by taking oral dopamine agonists with food. Instruct patients to notify the prescriber if nausea and vomiting persist or become severe. Instruct patients taking apomorphine to pretreat with trimethobenzamide [Tigan], an antiemetic.	

22.4....

Orthostatic Hypotension.

Inform patients about symptoms of hypotension (dizziness, lightheadedness) and advise them to sit or lie down if these occur. Advise patients to move slowly when assuming an erect posture.

22.4....

Dyskinesias.

Inform patients about possible movement disorders (tremor, dystonic movements, twitching) and instruct them to notify the prescriber if these develop.

22.4....

Hallucinations.

Forewarn patients that dopamine agonists can cause hallucinations, especially in the elderly, and instruct them to notify the prescriber if these develop.

22.4....

Sleep Attacks.

Warn patients that *pramipexole*, *ropinirole*, and apomorphine may cause sleep attacks. Instruct patients that, if a sleep attack occurs, they should inform the prescriber and avoid potentially hazardous activities (eg, driving).

22.4....

Fetal Injury.

Inform women of child-bearing age that *ropinirole* may harm the developing fetus, and advise them to use effective birth control. If pregnancy occurs, switching to a different dopamine agonist is advised.

22.4....

Compulsive Behaviors.

Rarely, pramipexole and ropinirole may induce compulsive, self-rewarding behaviors, including compulsive gambling, binge eating, compulsive shopping, and hypersexuality. Risk factors include relative youth, a family or personal history of alcohol abuse, and a novelty-seeking personality. Before prescribing these drugs, clinicians should screen patient for compulsive behaviors.

* Patient education information is highlighted as **blue text**.

²⁴CHAPTER 23 Drugs for Multiple Sclerosis

Multiple sclerosis (MS) is a chronic, inflammatory, autoimmune disorder that damages the myelin sheath of neurons in the central nervous system (CNS), causing a wide variety of sensory and motor deficits. Initially, most patients experience periods of acute clinical exacerbations (relapses) alternating with periods of complete or partial recovery (remissions). Over time, symptoms usually grow progressively worse—although the course of the disease is unpredictable and highly variable. Among young adults, MS causes more disability than any other neurologic disease. Nonetheless, most patients manage to lead fairly normal lives, and life expectancy is only slightly reduced.

Drug therapy of MS changed dramatically in 1993, the year the first disease-modifying agent was approved. Prior to this time, treatment was purely symptomatic. We had no drugs that could alter the disease process. By using disease-modifying drugs, we can now slow the progression of MS, decrease the frequency and intensity of relapses, and delay permanent neurologic loss. As a result, we can significantly improve prognosis, especially if treatment is started early.

^{24.1} OVERVIEW OF MS AND ITS TREATMENT

^{24.1.1} Pathophysiology

^{24.1.1.1} What's the Primary Pathology of MS?

The pathologic hallmark of MS is the presence of multifocal regions of inflammation and myelin destruction in the CNS. Because of demyelination, axonal conduction is slowed or blocked, giving rise to a host of neurologic signs and symptoms. As inflammation subsides, damaged tissue is replaced by astrocyte-derived filaments, forming scars known as *scleroses*, hence the disease name. It is important to note that, in addition to stripping off myelin, inflammation may injure the underlying axon, and may also damage oligodendrocytes, the cells that make CNS myelin. Axon injury can also occur in the *absence* of inflammation, and can be seen early in the course of the disease.

206

^{24.1.1.2} How Does Inflammation Occur?

207

The mechanism appears to be autoimmune: Cells of the immune system mistakenly identify components of myelin as being foreign, and hence mount an attack against them. For the attack to occur, circulating lymphocytes (T cells) and monocytes (macrophages) must adhere to the endothelium of CNS blood vessels, migrate across the vessel wall, and then initiate the inflammatory process. The end result is an inflammatory cascade that destroys myelin and may also injure the axonal membrane and nearby oligodendrocytes.

24.1.1.3 What Initiates the Autoimmune Process?

No one knows. The most likely candidates are genetics, environmental factors, and microbial pathogens. We suspect a *genetic link* for two reasons. First, the risk of MS for first-degree relatives of someone with the disease is 10 to 20 times higher than the risk for people in the general population. Second, the risk of MS differs for members of different races. For example, the incidence is highest among Caucasians (especially those of northern European descent), much lower among Asians, and nearly zero among Inuits (the indigenous people of the Arctic). We suspect *environmental factors* because the risk is not the same in all places: In the United States, MS is more common in northern states than in southern states; around the globe, MS is most common in countries that have a moderately cool climate, whether in the northern or southern hemisphere; and, as we move from the equator toward the poles, the incidence of MS increases. *Microbial pathogens* suspected of initiating autoimmunity include Epstein-Barr virus, human herpesvirus 6, and *Chlamydia pneumoniae*. The bottom line? *Multiple sclerosis appears to be a disease that develops in genetically vulnerable people following exposure to an environmental or microbial factor that initiates autoimmune activity.*

24.1.1.4 What Happens When an Acute Attack Is Over?

When inflammation subsides, some degree of recovery occurs, at least in the early stages of the disease. Three mechanisms are involved: (1) partial remyelination, (2) functional axonal compensation (axons redistribute their sodium channels from the nodes of Ranvier to the entire region of demyelination), and (3) development of alternative neuronal circuits that bypass the damaged region. Unfortunately, with recurrent episodes of demyelination, recovery becomes less and less complete. Possible reasons include mounting astrocytic scarring, irreversible axonal injury, and the death of neurons and oligodendrocytes.

24.1.1.5 Does MS Injure the Myelin Sheath of Peripheral Neurons?

No. Myelin in the periphery is made by Schwann cells, whereas myelin in the CNS is made by oligodendrocytes. Although myelin produced by these two cell types is very similar, it is not identical. Because peripheral myelin differs somewhat from CNS myelin, the immune system does not identify peripheral myelin as foreign, and hence this myelin is spared.

24.1.2 Signs and Symptoms

People with MS can experience a wide variety of signs and symptoms. Depending on where CNS demyelination occurs, a patient may experience paresthesias (numbness, tingling, pins and needles), muscle or motor problems (weakness, clumsiness, ataxia, spasms, spasticity, tremors,

cramps), visual impairment (blurred vision, double vision, blindness), bladder and bowel symptoms (incontinence, urinary urgency, urinary hesitancy, constipation), sexual dysfunction, disabling fatigue, emotional lability, depression, cognitive impairment, slurred speech, dysphagia, dizziness, vertigo, neuropathic pain, and more. The intensity of these symptoms is determined by the size of the region of demyelination. To quantify the impact of MS symptoms, most clinicians employ the Kurtzke Expanded Disability Status Scale (EDSS), an instrument that measures the impact of MS on nine different functional systems (eg, visual, sensory, cerebellar). The results are tabulated and reported on a scale from 0 to 10, with 0 representing no disability and 10 representing death. An EDSS of 4 or greater indicates difficulties with ambulation. Symptoms of MS are discussed further under *Drugs Used to Manage MS Symptoms*.

24.1.3 MS Subtypes

There are four subtypes of MS—relapsing-remitting, secondary progressive, primary progressive, and progressive-relapsing—defined by the clinical course the disease follows. Symptom patterns that characterize the MS subtypes are depicted in [Figure 23-1](#).

24.1.3.1 Relapsing-Relmitting MS.

This subtype is characterized by recurrent, clearly defined episodes of neurologic dysfunction (relapses) separated by periods of partial or full recovery (remissions). Between 85% and 90% of patients have this form initially. Symptoms develop over several days, and then typically resolve within weeks. The average patient has two relapses every 3 years. Specific signs and symptoms during an attack depend on the size and location of CNS lesions, and hence vary from one attack to the next, and from one patient to another. The disease usually begins in the second or third decade of life, and affects twice as many women as men.

24.1.3.2 Secondary Progressive MS.

This subtype occurs when a patient with relapsing-remitting MS develops steadily worsening dysfunction—with or without occasional plateaus, acute exacerbations, or minor remissions. Within 10 to 20 years of symptom onset, about 50% of patients with relapsing-remitting MS develop secondary progressive MS.

24.1.3.3 Primary Progressive MS.

In this subtype, symptoms grow progressively more intense from the outset, although some patients may experience occasional plateaus or even temporary improvement. Clear remissions, however, do not occur. Only 10% of patients have this form of MS.

Figure 23-1 Symptom patterns that define the four subtypes of MS.

24.1.3.4 Progressive-Relapsing MS.

This subtype, which is rare, looks like primary progressive MS, but with acute exacerbations superimposed on the steady intensification of symptoms.

24.1.4 Diagnosis

Diagnosis of MS is based on clinical presentation supplemented with laboratory data. As a rule, we cannot diagnose MS on the basis of symptoms or signs or laboratory tests alone—for most patients, all three kinds of information are needed. In addition, because the signs, symptoms, and test results that suggest MS can also suggest other disorders, a positive diagnosis cannot be made until all other possibilities have been ruled out. Diagnosis of MS is confounded by interpatient variability in symptoms and the course the disease follows.

207

208

TABLE 23-1 McDonald Criteria for Diagnosis of MS as Revised in 2005

Clinical Presentation	Additional Data Needed for a Diagnosis of MS
Two or more attacks <i>and</i> objective clinical evidence of 2 or more lesions	None
Two or more attacks <i>and</i> objective clinical evidence of 1 lesion	Proof of <u>dissemination in space</u> shown by <i>either</i> • MRI data indicating dissemination in space • Positive CSF* plus 2 or more MRI lesions consistent with MS • Another clinical attack implicating a different site
One attack <i>and</i> objective clinical evidence of 2 or more lesions	Proof of <u>dissemination in time</u> shown by <i>either</i> MRI or a second clinical attack
One attack <i>and</i> objective clinical evidence of 1 lesion (clinically isolated syndrome)	Proof of <u>dissemination in space</u> shown by <i>either</i> MRI or positive CSF* plus 2 or more MRI lesions consistent with MS <i>and</i> Proof of <u>dissemination in time</u> shown by <i>either</i> MRI or a second clinical attack
Insidious neurologic progression suggestive of MS but with no clear clinical attack	One year of disease progression (retrospectively or prospectively determined) <i>and</i> Two out of three of the following: • Positive brain MRI (9 T2-weighted lesions or 4 or more T2-weighted lesions combined with a positive VEP†) • Positive spinal cord MRI (2 focal T2-weighted lesions) • Positive CSF*
Adapted from Polman H, Reingold SC, Edan G, et al: Diagnostic criteria for multiple sclerosis: 2005 revisions to the “McDonald Criteria.” Ann Neurol 58:840–846, 2005.	

* CSF = cerebrospinal fluid. A positive CSF test shows either oligoclonal bands different from those in serum or a raised IgG index.

† VEP = visual evoked potential. The test is positive if the VEP is delayed.

In 1965, the following diagnostic criteria were introduced:

- There must be objective evidence of *two or more* clinical attacks lasting at least 24 hours each.
- The attacks must be *separated in time* by at least 1 month.
- The attacks must be *separated in space* (that is, the CNS damage underlying clinical symptoms must occur at different sites).
- There must be no better explanation for the attacks.

Since these criteria were introduced, additional diagnostic tools have become available. Important among these are magnetic resonance imaging (MRI), cerebrospinal fluid (CSF) tests, and measurement of the visual evoked potential (VEP). All three tests can help confirm a suspected diagnosis of MS, but neither test, by itself, can provide definitive proof of the disease. Properties of these tests are as follows:

- MRI is the most sensitive way to image the brain. Sensitivity can be made even greater with gadolinium, an IV contrast agent. MRI is especially good for detecting areas of demyelination. However, it is important to note that, in some patients who have clinically definite MS, an MRI scan may fail to detect any lesions. Hence, a negative scan does not necessarily rule out MS. Conversely, because other disorders can produce a positive scan, a positive scan, by itself, does not prove the presence of MS, although it *can* help *confirm* a suspected case.
- Tests of CSF are used to assess immune activity within the CNS. Two tests are employed: measurement of immunoglobulin G (IgG) levels and measurement of oligoclonal IgG bands (OCBs), which indicate intrathecal production of antibodies. More than 90% of patients with MS have OCBs. However, as with MRI scans, other disorders can also produce positive test results—and negative results may be seen in some patients who *do* have MS. Accordingly, CSF analysis, by itself, can neither confirm nor rule out MS.
- The VEP test measures how quickly the brain responds to a visual stimulus, and hence indirectly measures conduction velocity in the optic nerve. In patients with MS, the VEP is delayed, indicating conduction velocity is slowed (owing to demyelination of the optic nerve). However, as with MRI scans and CSF tests, the VEP test is not specific for MS: Other disorders can produce positive results, and some patients with MS may get negative results.

Diagnostic criteria for MS were updated by the McDonald committee in 2001 and revised again in 2005 ([Table 23-1](#)). The latest criteria are still founded on the patient's clinical presentation, but

also incorporate information from MRI scans, CSF tests, and VEP determinations. These criteria were designed to permit the earliest possible diagnosis of MS, and hence permit the earliest possible initiation of disease-modifying therapy.

24.1.5 Drug Therapy Overview

In patients with MS, drugs are employed to (1) modify the disease process, (2) treat an acute relapse, and (3) manage symptoms. At this time, we have no drugs that can cure MS.

24.1.5.1 Disease-Modifying Therapy

Disease-modifying drugs can decrease the frequency and severity of relapses, reduce development of brain lesions, decrease future disability, and help maintain quality of life. In

208

209

addition, they may prevent permanent damage to axons. However, it is important to note that, although these drugs can slow disease progression, they do not cure MS. Also, they do not work for all patients. Those with relapsing-remitting MS benefit most.

TABLE 23-2 Disease-Modifying Drugs for MS

Generic Name	Trade Name	Route	Dose	Dosing Schedule	Annual Cost	Adverse Effects
IMMUNOMODULATORS						
Interferon Beta Preparations						
Interferon beta-1a	[Avonex]	IM	30 mcg	Once a week	\$12,800	<i>All three preparations:</i> • Flu-like symptoms • Liver injury • Myelosuppression • Injection-site reactions
Interferon beta-1a	[Rebif]	subQ	44 mcg	3 times a week	\$17,300	
Interferon beta-1b	[Betaseron]	subQ	250 mcg	Every other day	\$13,100	
Other Immunomodulators						
Glatiramer acetate	[Copaxone]	subQ	20 mg	Once a day	\$14,000	• Injection-site reactions • Postinjection reaction • Progressive multifocal leukoencephalopathy • Liver injury • Allergic reactions
Natalizumab	[Tysabri]	IV	300 mg	Every 4 weeks	\$24,000	
IMMUNOSUPPRESSANT						
Mitoxantrone	[Novantrone]	IV	12 mg/m ² *	Every 3 months	\$18,000	• Myelosuppression • Cardiotoxicity • Fetal harm

* Maximum lifetime dose is 140 mg/m² (because of cardiotoxicity).

There are two main groups of disease-modifying drugs: *immunomodulators* and *immunosuppressants* (Table 23-2). The immunomodulators—interferon beta, glatiramer acetate, and natalizumab—are safer than mitoxantrone (the major immunosuppressant in use), and hence are generally preferred.

24.1.5.1.1

Relapsing-Remitting MS.

All patients with relapsing-remitting MS—regardless of age, frequency of attacks, or level of disability—should receive one of the immunomodulators:

- Interferon beta-1a [Avonex], for IM use
- Interferon beta-1a [Rebif], for subQ use
- Interferon beta-1b [Betaseron], for subQ use
- Glatiramer acetate [Copaxone], for subQ use
- Natalizumab [Tysabri], for IV use

Treatment should begin *as soon as possible* after relapsing-remitting MS has been diagnosed. Why? Because early treatment can help prevent axonal injury, and may thereby prevent permanent neurologic deficits.

Treatment should continue indefinitely. The principal reasons for stopping would be toxicity or a clear lack of effect. Unfortunately, if disease-modifying therapy is stopped, disease progression may return to the pretreatment rate.

If treatment with an immunomodulator fails to prevent severe relapses or disease progression, treatment with mitoxantrone (an immunosuppressant) should be considered. However, keep in mind that mitoxantrone can cause serious toxicity (eg, myelosuppression, heart damage), and hence should be reserved for patients who truly need it.

24.1.5.1.2 Secondary Progressive MS.

Interferon beta can benefit certain patients with secondary progressive MS, specifically, those who still experience acute relapses. For these people, interferon beta can reduce the severity and frequency of attacks, and can reduce development of MRI-detectable brain lesions. Whether *glatiramer* can help these patients is unclear.

Mitoxantrone can decrease clinical attack rate, reduce development of new brain lesions, and slow progression of disability. However, although the drug is effective, cardiotoxicity precludes long-term use.

24.1.5.1.3 Progressive-Relapsing MS.

Mitoxantrone is the only disease-modifying drug approved for this disorder. Unfortunately, benefits are generally modest.

24.1.5.1.4 Primary Progressive MS.

No disease-modifying therapy has been shown effective against this form of MS. However, ongoing studies with immunosuppressants (eg, methotrexate, azathioprine, cyclophosphamide) are encouraging.

24.1.5.2 Treating an Acute Episode (Relapse)

A short course of a *high-dose IV glucocorticoid* (eg, 500 mg to 1 gm of methylprednisolone daily for 3 to 5 days) is the preferred treatment of an acute relapse. Glucocorticoids suppress inflammation and can thereby reduce the severity and duration of a clinical attack. As discussed in [Chapter 71](#), these drugs are very safe when used short term, elevation of blood glucose being the principal concern. By contrast, long-term exposure can cause osteoporosis and other serious adverse effects. Accordingly, frequent use (more than 3 times a year) or prolonged use (longer than 3 weeks at a time) should be avoided.

Acute relapse may also be treated with *IV gamma globulin*. This option can be especially helpful in patients intolerant of or unresponsive to glucocorticoids. Results have been good.

24.1.5.3 Drug Therapy of Symptoms

All four subtypes of MS share the same symptoms (eg, fatigue, spasticity, pain, bladder dysfunction, bowel dysfunction, sexual dysfunction). Accordingly, the drugs used for treatment are the same for all patients, regardless of MS subtype. Specific treatments are discussed below under *Drugs Used to Manage MS Symptoms*.

209

24.2 DISEASE-MODIFYING DRUGS: IMMUNOMODULATORS

210

Five immunomodulators are available: glatiramer acetate [Copaxone], natalizumab [Tysabri], and three preparations of interferon beta [Avonex, Rebif, Betaseron]. With the exception of natalizumab, all of these drugs are recommended as first-line therapy for patients with relapsing-remitting MS and for patients with secondary progressive MS who still experience acute exacerbations. Natalizumab is reserved for patients with relapsing-remitting MS who have not responded to at least one of the other four drugs. Why? Because, very rarely, natalizumab has been associated with a potentially fatal infection of the brain.

All of the *first-line* immunomodulators—glatiramer and the interferon beta preparations—appear equally effective, decreasing the relapse rate by about 30%. Because benefits are very similar, selection among these drugs is based primarily on patient and prescriber preference. If a particular drug is intolerable or ineffective, a different one should be tried. Natalizumab is more effective than

the first-line drugs, decreasing the relapse rate by 68%, but is also more dangerous. As noted, although the immunomodulators can modify the course of MS, they do not cure the disease.

All of the immunomodulators are administered parenterally. The first-line agents are administered by self-injection (IM or subQ). Natalizumab is administered by IV infusion (in an approved infusion center). All five drugs are expensive: One year of treatment costs \$12,000 to \$24,000. Properties of these drugs are summarized in [Table 23-2](#).

24.2.1 Interferon Beta Preparations

24.2.1.1 Description and Mechanism

Interferon beta is a naturally occurring glycoprotein with antiviral, antiproliferative, and immunomodulatory actions. Natural interferon beta is produced in response to viral invasion and other biologic inducers. In patients with MS, benefits are thought to derive primarily from inhibiting the migration of proinflammatory leukocytes across the blood-brain barrier, thereby preventing these cells from reaching neurons of the CNS.

Two forms of interferon beta are used clinically: *interferon beta-1a* [Avonex, Rebif] and *interferon beta-1b* [Betaseron]. Both forms are manufactured using recombinant DNA technology. Interferon beta-1a contains 166 amino acids plus glycoproteins, and is identical to natural human interferon beta with respect to amino acid content. Interferon beta-1b contains only 165 amino acids and has no glycoproteins, and hence differs somewhat from the natural compound. It should be noted that two preparations of interferon beta-1a are available, marketed as Avonex and Rebif. These products differ slightly in their glycoprotein content, and are administered by different routes (see below).

24.2.1.2 Therapeutic Use

All three interferon beta products are approved for relapsing forms of MS. These drugs can decrease the frequency and severity of attacks, reduce the number and size of MRIdetectable lesions, and delay the progression of disability. Benefits with Rebif and Betaseron may be somewhat greater than with Avonex, perhaps because Avonex is given less frequently and in lower dosage (see below).

In addition to its use in relapsing MS, interferon beta-1b [Betaseron] is approved for patients with secondary progressive MS.

24.2.1.3 Adverse Effects and Drug Interactions

Interferon beta is generally well tolerated, although side effects are common.

24.2.1.3.1 Flu-like Reactions.

Flu-like reactions occur often. Symptoms include headache, fever, chills, malaise, muscle aches, and stiffness. Fortunately, these diminish over time, despite continued interferon beta use. Symptoms can be minimized by (1) starting with a low dose and then slowly titrating up to the full dose, and (2) giving an analgesic-antipyretic medication (ie, acetaminophen; ibuprofen or another nonsteroidal anti-inflammatory drug).

24.2.1.3.2 Hepatotoxicity.

Interferon beta can injure the liver, typically causing an asymptomatic increase in circulating liver enzymes. Very rarely, patients develop hepatitis or even liver failure. To monitor for hepatotoxicity, liver function tests (LFTs) should be performed at baseline, 1 month later, then every 3 months for 1 year, and every 6 months thereafter. If LFTs indicate significant liver injury, a temporary reduction in dosage or interruption of treatment is indicated. When liver function returns to normal, treatment can resume, but careful monitoring is required. Interferon beta should be used with caution in patients who abuse alcohol, use hepatotoxic medications, or have active liver disease or a history of liver disease.

24.2.1.3.3 Myelosuppression.

Interferon beta can suppress bone marrow function, thereby decreasing production of all blood cell types. To monitor for myelosuppression, complete blood counts should be obtained at baseline, every 3 months for 1 year, and every 6 months thereafter.

24.2.1.3.4 Injection-Site Reactions.

Subcutaneous injection (of Rebif or Betaseron) can cause pain, erythema (redness), bumps, and itching. Physical measures to reduce discomfort include rotating the injection site, applying ice (briefly) before and after the injection, and applying a warm, moist compress after the injection. Oral diphenhydramine [Benadryl] or topical hydrocortisone can reduce persistent itching and erythema. However, *continuous* use of topical hydrocortisone should be avoided, owing to a risk of skin damage. Very rarely, subQ injections have caused local necrosis. Intramuscular injection (of Avonex) can cause discomfort and bruising.

24.2.1.3.5 Depression.

It is unclear whether interferon beta promotes depression. Early studies showed an increased risk of depression, suicidal ideation, and suicide attempts. However, later studies have not confirmed these observations.

24.2.1.3.6 Neutralizing Antibodies.

Like all other foreign proteins, interferon beta is immunogenic, and hence can stimulate production of antibodies against itself. If present in sufficiently high titers, these neutralizing antibodies can decrease clinical benefits.

24.2.1.3.7 Drug Interactions.

Exercise caution when combining interferon beta with other drugs that can suppress the bone marrow or cause liver injury.

24.2.1.4 Preparations, Dosage, and Administration

24.2.1.4.1 Avonex (Interferon Beta-1a for IM Use).

Avonex is available in pre-filled, single-use syringes (30 mcg/0.5 mL) and as a powder (30 mcg/0.5 mL when reconstituted with sterile water). The dosage is 30 mcg IM once a week. Store *pre-filled syringes* at 36°F to 46°F (2°C to 8°C). Store the *powder* at 36°F to 46°F (2°C

210

to 8°C) or, if refrigeration is unavailable, store at or below 77°F (25°C) for up to 30 days.

211

Injectons are made late in the day so that flu-like symptoms occur during sleep.

24.2.1.4.2 Rebif (Interferon Beta-1a for SubQ Use).

Rebif is available in pre-filled, single-use syringes containing either 8.8 mcg/0.2 mL, 22 mcg/0.5 mL, or 44 mcg/0.5 mL. Injectons are made subQ 3 times a week, preferably in late afternoon or evening, at least 48 hours apart, and on the same days each week (eg, Monday, Wednesday, Friday). Dosage is titrated as follows: 8.8 mcg/dose for weeks 1 and 2; 22 mcg/dose for weeks 3 and 4; and 44 mcg/dose thereafter. Store Rebif refrigerated at 36°F to 46°F (2°C to 8°C) or, if refrigeration is unavailable, at or below 25°C (77°F) for up to 30 days.

24.2.1.4.3 Betaseron (Interferon Beta-1b for SubQ Use).

Betaseron is supplied as a powder (0.3 mg) in single-use vials. Just prior to use, the drug is reconstituted to form a 0.25-mg/mL solution. Doses are given subQ every other day. Dosage is titrated as follows: 0.0625 mg/dose for weeks 1 and 2; 0.125 mg/dose for weeks 3 and 4; 0.1875 mg/dose for weeks 4 and 5; and 0.25 mg/dose thereafter. Store the powder at room temperature. Following reconstitution, the drug solution may be stored up to 3 hours refrigerated.

24.2.2 Glatiramer Acetate

24.2.2.1 Therapeutic Use.

Glatiramer acetate [Copaxone], also known as *copolymer-1*, is used for long-term therapy of relapsing-remitting MS. Like interferon beta, glatiramer can reduce the frequency and severity of relapses, decrease MRI-detectable lesions, and delay the progression of disability. Glatiramer requires more frequent injections than interferon beta, and is less well tolerated.

24.2.2.2 Description and Mechanism.

Glatiramer is a polypeptide composed of a random sequence of four amino acids: L-alanine, L-glutamate, L-lysine, and L-tyrosine. The drug is similar in structure to myelin basic protein, a component of the axonal myelin sheath. In patients with MS, the drug promotes a “T-cell shift.” That is, it decreases production of proinflammatory TH1 cells and increases production of anti-inflammatory TH2 cells. The anti-inflammatory cells migrate across the blood-brain barrier at sites of inflammation, and then suppress the inflammatory attack on myelin.

24.2.2.3 Adverse Effects and Drug Interactions.

Glatiramer is generally well tolerated. *Injection-site* reactions—pain, erythema, pruritus (itching), induration (pitting)—are most common. Unlike interferon beta, glatiramer does *not* cause flu-like symptoms, myelosuppression, or liver toxicity. About 10% of patients experience a self-limited *postinjection reaction*—characterized by flushing, palpitations, severe chest pain, anxiety, laryngeal constriction, and urticaria—that typically lasts 15 to 20 minutes. No specific treatment is indicated. Safety in pregnancy or breast-feeding has not been established. No significant interactions with other MS drugs have been observed.

24.2.2.4 Preparations, Dosage, and Administration.

Glatiramer acetate [Copaxone] is available in single-use, pre-filled syringes that contain 20 mg/mL glatiramer plus 40 mg of mannitol. The recommended dosage is 20 mg (1 mL) once a day, injected subQ into the arm, abdomen, hip, or thigh. Store under refrigeration at 36°F to 46°F (2°C to 8°C).

24.2.3 Natalizumab

Natalizumab [Tysabri], a recombinant monoclonal antibody, was introduced in 2004 and then withdrawn a few months later, in response to three reports of progressive multifocal

leukoencephalopathy (PML), a severe infection of the brain. The drug was re-introduced in 2006, but with protective restrictions on who can prescribe, dispense, administer, and receive it.

24.2.3.1 Therapeutic Uses

Natalizumab is approved for two autoimmune diseases: multiple sclerosis and Crohn's disease (an inflammatory disorder of the bowel). Because of the risk of PML, natalizumab is a second-line choice for both conditions.

24.2.3.1.1 Multiple Sclerosis.

Natalizumab is approved only for *monotherapy of relapsing forms of MS*. In the AFFIRM trial, which compared natalizumab with placebo, natalizumab reduced the annualized rate of relapse by 68%, and reduced the number of new or enlarging brain lesions by 83%. These benefits are superior to those seen with interferon beta or glatiramer. However, owing to the risk of PML, natalizumab should be reserved for patients who have not responded to at least one of the first-line agents, and should not be combined with other disease-modifying drugs. Safety and efficacy beyond 2 years of use has not been established, nor have safety and efficacy in patients with chronic progressive MS.

24.2.3.1.2 Crohn's Disease.

Natalizumab is approved for induction and maintenance therapy of moderate to severe Crohn's disease in patients who have been unresponsive to or intolerant of other therapies, including inhibitors of tumor necrosis factor (TNF)-alpha. In clinical trials, benefits of the drug were modest. Natalizumab must not be combined with TNF-alpha inhibitors or with immunosuppressants (eg, cyclophosphamide, azathioprine, methotrexate). Crohn's disease and its treatment are discussed at length in [Chapter 79](#).

24.2.3.2 Mechanism of Action

In patients with MS and Crohn's disease, natalizumab prevents circulating leukocytes (T cells and monocytes) from leaving the vasculature, and thereby prevents these cells from migrating to sites where they can do harm. In order to exit the vasculature, activated leukocytes must first adhere to the vascular endothelium, a process that requires the interaction of two types of molecules: (1) *integrins* (adhesion molecules) expressed on the surface of leukocytes and (2) *integrin receptors* expressed on cells of the vascular epithelium. Natalizumab binds with integrin molecules on leukocytes, and thereby renders these cells unable to bind with integrin receptors on the capillary wall. As a result, the leukocytes cannot cross the capillary wall, and hence are unable to exit the vasculature to reach their sites of inflammatory action. In patients

with MS, natalizumab prevents activated leukocytes from crossing the blood-brain barrier. In patients with Crohn's disease, the drug prevents leukocytes from crossing capillaries that deliver blood to the GI tract.

24.2.3.3 Adverse Effects

Natalizumab is generally well tolerated. The most common reactions are headache and fatigue. Other common reactions include abdominal discomfort, arthralgia, depression, diarrhea, gastroenteritis, urinary tract infections, and lower respiratory tract infections. The most serious effects are PML, liver injury, and hypersensitivity reactions.

24.2.3.3.1 Progressive Multifocal Leukoencephalopathy.

Shortly after natalizumab was released, there were three reports of PML, a severe infection of the CNS caused by reactivation of the JC virus, an opportunistic pathogen resistant to all available drugs. Two of the infected patients died. All three were taking natalizumab in combination with another immunosuppressant (azathioprine or interferon beta). As of August 2008, more than 25,000 patients had received natalizumab, and only two additional cases of PML had been confirmed. Surprisingly, both new cases were in patients taking natalizumab as monotherapy. (Presumably, PML is made possible by natalizumab-mediated immunosuppression, and hence combining natalizumab with another immunosuppressant increases the risk.) In addition to immunosuppressant drugs, the risk of PML is increased by HIV/AIDS and other conditions that compromise cell-mediated immunity.

211

212

To reduce the risk of PML, natalizumab is available only through the *TOUCH Prescribing Program*. Patients, prescribers, infusion nurses, infusion centers, and pharmacies associated with infusion centers must all register with the program. In addition, prescribers and patients must understand the risks of natalizumab, including PML and other opportunistic infections—and patients must be screened for PML prior to each infusion.

24.2.3.3.2 Hepatotoxicity.

Like interferon beta, natalizumab can injure the liver. Patients should be informed about signs of liver injury—jaundice, nausea, vomiting, fatigue, darkening of the urine—and instructed to report these immediately. If significant liver injury is diagnosed, natalizumab should be discontinued.

24.2.3.3.3 Hypersensitivity Reactions.

Natalizumab can cause a variety of allergic reactions, manifesting as hives, itching, chest pain, dizziness, chills, rash, flushing, and hypotension. Severe reactions (eg, anaphylaxis)

usually develop within 2 hours of infusion onset, but can also develop later. The risk of a severe reaction is increased by the presence of neutralizing antibodies. If a severe reaction develops, natalizumab should be discontinued and never used again.

24.2.3.3.4 Neutralizing Antibodies.

Antibodies against natalizumab develop in about 6% of patients. These antibodies greatly decrease the efficacy of natalizumab and increase the risk of hypersensitivity and infusion reactions.

24.2.3.4 Drug Interactions

As noted, *immunosuppressants* increase the risk of PML and other opportunistic infections. Accordingly, these drugs should be discontinued at least 3 months before natalizumab is started.

24.2.3.5 Preparations, Dosage, and Administration

Natalizumab [Tysabri] is supplied in single-use vials (300 mg/15 mL) for dilution in 100 mL of 0.9% sodium chloride injection. Administration is by IV infusion, done over a 1-hour span. The dosage for MS and Crohn's disease is 300 mg every 4 weeks. Patients should be observed during the infusion and for 1 hour after. If any signs of hypersensitivity develop, the infusion should cease immediately. Before natalizumab can be administered, everyone involved with the drug—patients, physicians, pharmacists, infusion nurses, and infusion centers—must be registered with the TOUCH Prescribing Program. Natalizumab vials should be stored cold (36°F to 46°F [2°C to 8°C]), but not frozen.

24.3 DISEASE-MODIFYING DRUGS: IMMUNOSUPPRESSANTS

At this time, only one immunosuppressant—mitoxantrone—is approved by the Food and Drug Administration (FDA) for treating MS. Mitoxantrone is more toxic than the immunomodulators and produces greater immune suppression. Another immunosuppressant—cyclophosphamide—is also employed, but is not approved for MS.

24.3.1 Mitoxantrone

Mitoxantrone [Novantrone], originally used for cancer (see [Chapter 101](#)), was approved for MS in October 2000. The drug poses a significant risk of toxicity, and hence is generally reserved for patients who cannot be treated with safer agents.

24.3.1.1 Therapeutic Use

Mitoxantrone is approved for decreasing neurologic disability and clinical relapses in patients with

- Worsening relapsing-remitting MS
- Secondary progressive MS
- Progressive-relapsing MS

For these patients, the drug may delay the time to relapse and the time to disability progression. In addition, it may decrease the number of new MRI-detectable lesions. Mitoxantrone is *not* effective against primary progressive MS, and hence should not be used for this disorder.

24.3.1.2 Mechanism of Action

Mitoxantrone is a cytotoxic drug that binds with DNA and inhibits topoisomerase II. These actions inhibit DNA and RNA synthesis, and promote cross-linking and breakage of DNA strands. In cell culture, mitoxantrone is toxic to all cells, whether dividing or not. However, in clinical practice, the drug appears especially toxic to tissues with a high percentage of actively dividing cells (bone marrow, hair follicles, GI mucosa). In patients with MS, mitoxantrone suppresses production of immune system cells (B lymphocytes, T lymphocytes, and macrophages), and thereby decreases autoimmune destruction of myelin. Additional protection may derive from reducing antigen presentation and reducing production of cytokines (eg, interleukin-2, TNF-alpha, interferon gamma) that participate in the immune response.

24.3.1.3 Pharmacokinetics

Following IV infusion, mitoxantrone undergoes rapid, widespread distribution. Elimination occurs slowly, primarily by hepatic metabolism and biliary excretion. In patients with liver dysfunction, clearance of the drug is reduced, thereby increasing the risk of toxicity. Accordingly, mitoxantrone should not be given to patients with liver disease. To assess liver status, LFTs should be performed at baseline and prior to each infusion. If LFTs are abnormal, the drug should be withheld.

24.3.1.4 Adverse Effects

Mitoxantrone can cause a variety of adverse effects. Myelosuppression, cardiotoxicity, and fetal injury are the greatest concerns.

24.3.1.4.1 Myelosuppression.

Toxicity to the bone marrow cells (myelosuppression) can decrease production of platelets and all blood cells. Loss of neutrophils, which is maximal 10 to 14 days after dosing, increases the risk of *severe infection*. Patients should be advised to avoid contact with people who have infections, and should report signs of infection (fever, chills, cough, hoarseness) immediately. Also, patients should not be immunized with a live virus vaccine (because the vaccine itself could cause infection). To guide mitoxantrone use, complete blood counts should be obtained at baseline, before each infusion, 10 to 14 days after each infusion, and whenever signs of infection develop. Dosing should not be done if the neutrophil count is below 1500 cells/mm³.

212

213

24.3.1.4.2 Cardiotoxicity.

Mitoxantrone can cause irreversible injury to the heart, manifesting as a reduced left ventricular ejection fraction (LVEF) or outright heart failure. Injury may become apparent during treatment, or months to years after drug use has ceased. Cardiotoxicity is directly related to the cumulative lifetime dose. Risk increases significantly if the cumulative dose exceeds 140 mg/m², and hence the total should not exceed this amount. Mitoxantrone should not be given to patients with cardiac impairment. Accordingly, LVEF should be determined prior to the first dose, and, if the LVEF is less than 50%, mitoxantrone should be withheld. During treatment, LVEF should be measured before every dose and whenever signs of heart failure develop (eg, peripheral edema, fatigue, shortness of breath).

24.3.1.4.3 Fetal Harm.

Mitoxantrone has the potential for fetal harm, and is classified in FDA Pregnancy Risk Category D. In animal studies, extremely low doses were associated with growth retardation and premature delivery. To date, teratogenicity of mitoxantrone has not been proved. However, since mitoxantrone has the same mechanism as known teratogens, its teratogenicity can be inferred. Women of child-bearing age should avoid becoming pregnant, and pregnancy should be ruled out before each dose. If pregnancy occurs, counseling about possible termination of pregnancy should be offered.

24.3.1.4.4 Other Adverse Effects.

Because mitoxantrone is especially toxic to tissues with a high percentage of dividing cells, it can cause reversible hair loss and injury to the GI mucosa, resulting in stomatitis and GI distress. The drug can also cause nausea, vomiting, menstrual irregularities (eg, amenorrhea),

and symptoms of allergy (itching, rash, hypotension, shortness of breath). In addition, mitoxantrone can impart a harmless, blue-green tint to the urine, skin, and sclera; patients should be forewarned. Very rarely, patients taking mitoxantrone for MS have developed acute myelogenous leukemia, although a cause-and-effect relationship has not been established.

24.3.1.5 Monitoring Summary

To minimize risk, we need to

- Perform complete blood counts at baseline, before each dose, and 10 to 14 days after each dose.
- Perform LFTs at baseline and before each dose.
- Perform a pregnancy test before each dose.
- Determine LVEF before each dose and whenever signs of heart failure develop.

24.3.1.6 Preparations, Dosage, and Administration

Mitoxantrone [Novantrone] is available in solution (2 mg/mL) in 10-, 12.5-, and 15-mL multi-use vials. For patients with MS, the dosage is 12 mg/m² every 3 months, infused IV over 5 to 30 minutes. The maximum lifetime cumulative dose is 140 mg/m². Before infusing, dilute each dose with at least 50 mL of normal saline or 5% dextrose in water; then administer into a free-flowing IV line. Extravasation can cause severe local injury. Accordingly, if extravasation occurs, discontinue the infusion immediately and restart in a different vein. Don't mix mitoxantrone with other drugs.

24.3.2 Cyclophosphamide

Cyclophosphamide [Cytosan, Neosar], originally developed for cancer (see [Chapter 101](#)), is used off-label to treat refractory MS. In one trial, high-dose cyclophosphamide prevented disease progression and, for many patients, produced a marked improvement in EDSS scores.

Furthermore, these improvements persisted at least 15 months. Benefits appear to result from decreasing the number and activity of lymphocytes. Side effects, which can be severe, include bone marrow suppression, acute hemorrhagic cystitis, alopecia, and intense nausea and vomiting.

24.4 DRUGS USED TO MANAGE MS SYMPTOMS

Multiple sclerosis is associated with an array of potentially debilitating symptoms. Accordingly, effective management is essential for maintaining productivity and quality of life. However, despite the importance of symptom management, the discussion below is brief. Why? Because all of the

drugs employed are discussed at length in other chapters. For more details on symptom management, the web site of the National Multiple Sclerosis Society—www.nationalmssociety.org—is a good resource.

24.4.1 Bladder Dysfunction

Bladder dysfunction is very common, occurring in up to 90% of patients. The underlying cause is disruption of nerve traffic in areas of the CNS that control the bladder detrusor muscle and bladder sphincter. (Recall that coordinated contraction of the detrusor and relaxation of the sphincter are required for normal voiding.) Three types of bladder dysfunction may be seen: detrusor hyperreflexia, detrusor-sphincter dyssynergia, and flaccid bladder. All three can be successfully managed.

Detrusor hyperreflexia results from decreased inhibition of the bladder reflex and manifests as urinary frequency, urinary urgency, nocturia, and incontinence. Relief is accomplished with anticholinergic drugs, which relax the detrusor and thereby permit a normal volume of urine to accumulate before bladder emptying. Options include *tolterodine* [Detrol], *oxybutynin* [Ditropan, Oxytrol], *darifenacin* [Enablex], and *solifenacin* [VESIcare].

Detrusor-sphincter dyssynergia is characterized by a lack of synchronization between detrusor contraction and sphincter relaxation. The result is difficulty initiating or stopping urination, and incomplete bladder emptying. Some patients respond to *alpha-adrenergic blocking agents*, such as phenoxybenzamine [Dibenzylin], tamsulosin [Flomax], or terazosin [Hytrin], all of which promote sphincter relaxation. However, most patients require intermittent or continuous catheterization.

In patients with *flaccid bladder*, there is a loss of reflex detrusor contraction, resulting in impaired bladder emptying. In some cases, the condition responds to *bethanechol* [Urecholine], a muscarinic agonist that directly stimulates the detrusor. However, as with detrusor-sphincter dyssynergia, many patients require intermittent or continuous catheterization.

24.4.2 Bowel Dysfunction

Constipation is relatively common, whereas fecal incontinence is relatively rare. Constipation can be managed by increasing dietary fiber and fluids, taking fiber supplements, performing regular exercise, and, if needed, using a bulk-forming laxative, such as *psyllium* [Metamucil]. Rapid relief can be achieved by instilling a mini-enema, sold under the name Enemeez. The product consists of docusate sodium (a stool softener) in a soft-soap base composed of polyethylene glycol and glycerin. Fecal incontinence can be managed by establishing a regular bowel routine and, if needed, using a bulk-forming laxative (to improve stool consistency) and/or using an

anticholinergic agent (eg, hyoscyamine) to reduce bowel motility. Be aware, however, that excessive slowing of bowel motility can result in constipation.

24.4.3 Fatigue

Fatigue develops in up to 90% of patients. The underlying cause is unknown. Regular exercise can help. The most common drug therapies are *amantadine* [Symmetrel] and *modafinil* [Provigil]. Both are generally well tolerated. *Methylphenidate* [Ritalin] and *amphetamine mixture* [Adderall] are the next options. *Selective serotonin reuptake inhibitors (SSRIs)* can reduce fatigue, and hence are a good choice for patients who are also depressed.

24.4.4 Depression

Depression is seen in about 70% of MS patients. In these people, depression may be reactive—that is, it may be an emotional response to having a chronic, progressive, disabling disease—or it may be the result of MS-induced injury to neurons that help regulate mood. Depression can be treated with antidepressant drugs and with counseling. For drug therapy, the *SSRIs*, such as fluoxetine [Prozac] and sertraline [Zoloft], can elevate mood, but often seem to increase fatigue. In contrast, *bupropion* [Wellbutrin], which has stimulant properties, can relieve depression and may help fight fatigue. The *tricyclic antidepressants*, such as amitriptyline (formerly available as Elavil) and nortriptyline [Pamelor], can treat pain, sleep disturbances, and incontinence (owing to detrusor hyperreflexia) in addition to improving mood.

213

214

24.4.5 Spasticity

Spasticity can range in severity from mild muscle tightness to painful muscle spasms, usually in the legs. Clinically significant spasticity occurs in more than 40% of patients. Interestingly, for some patients, spasticity can be beneficial: By making the legs more rigid, spasticity can facilitate standing and walking.

Spasticity can be managed with drug therapy and with nondrug measures (physical therapy, stretching, regular exercise). The drugs used most are *baclofen* [Lioresal] and *tizanidine* [Zanaflex]. However, dosage must be carefully controlled. Why? Because high doses of either agent can exacerbate MS-related muscle weakness. Tizanidine causes less weakness than baclofen, but poses a risk of liver injury, sedation, and dry mouth. Alternatives to baclofen and tizanidine include *diazepam* [Valium] and *botulinum toxin* [Botox]. Intrathecal infusion of baclofen is a very effective option, but is also very invasive.

24.4.6 Sexual Dysfunction

Among MS patients, sexual dysfunction may affect as many as 91% of men and 72% of women. Among men, erectile dysfunction is the most common complaint. Among women, complaints include vaginal dryness, reduced libido, and decreased vaginal and clitoral sensation. Possible causes of sexual dysfunction include depression, side effects of drugs, and injury to neurons of the lower spinal cord. Erectile dysfunction can be treated with *sildenafil* [Viagra], *varденаfil* [Levitra], and other inhibitors of phosphodiesterase type 5 (see [Chapter 65](#)). Vaginal dryness can be managed with a water-soluble personal lubricant (eg, K-Y Jelly); petroleum jelly (Vaseline) should be avoided. There are no drugs proved to enhance vaginal sensation, clitoral sensation, or libido.

24.4.7 Neuropathic Pain

Neuropathic pain results from injury to neurons (in contrast to nociceptive pain, which results from injury to peripheral tissues.) Neuropathic pain responds poorly to traditional analgesics, but often does respond to certain antiepileptic drugs and antidepressants. The antiepileptic drugs employed include *carbamazepine* [Tegretol], *gabapentin* [Neurontin], and *oxcarbazepine* [Trileptal]. The antidepressants employed, all from the tricyclic family, include *nortriptyline* [Pamelor], *imipramine* [Tofranil], and *amitriptyline* (formerly available as Elavil). Please note that pain relief with antidepressants occurs even in patients who are *not* depressed, and hence is not simply the result of elevating mood.

24.4.8 Ataxia and Tremor

Ataxia (loss of coordination) and tremor are relatively common and often disabling. Unfortunately, they are also largely unresponsive to treatment. Drugs that may offer some relief include *clonazepam* [Klonopin], *primidone* [Mysoline], and *propranolol* [Inderal]. A physical therapist can provide gait training, and an occupational therapist can provide equipment to help maintain independence.

24.4.9 Cognitive Dysfunction

About 50% of people with MS experience cognitive dysfunction at some time in the course of the disease. Fortunately, only 5% to 10% experience dysfunction severe enough to significantly interfere with daily living. Memory impairment is the most common problem. Other problems include impaired concentration, reasoning, and problem solving. Cognitive impairment is caused in part by demyelination of CNS neurons, and in part by depression, anxiety, stress, and fatigue. By protecting against demyelination, disease-modifying drugs can decrease the degree of

cognitive loss. *Donepezil* [Aricept], a cholinesterase inhibitor developed for Alzheimer's disease, may offer modest benefits, as may *memantine* [Namenda], an NMDA receptor blocker developed for Alzheimer's disease (see [Chapter 22](#)).

24.4.10 Dizziness and Vertigo

Dizziness and vertigo result from lesions in CNS pathways that provide a sense of equilibrium. Both symptoms are relatively common, and can be reduced with several drugs. Among these are *meclizine* [Antivert, Dramamine] (a drug for motion sickness) and *ondansetron* [Zofran] (a powerful antiemetic).

24.4.10.1 KEY POINTS

- Multiple sclerosis is a chronic, inflammatory, autoimmune disorder that damages the myelin sheath of neurons in the CNS. Because of demyelination, axonal conduction is slowed or blocked, giving rise to a host of sensory and motor deficits. When inflammation subsides, some degree of recovery occurs, at least in the early stage of the disease.
- In addition to stripping off myelin, inflammation may injure the underlying axon, and may also injure nearby oligodendrocytes, the cells that make CNS myelin.
- What causes MS? There is general agreement that MS develops in genetically vulnerable people following exposure to an environmental or microbial factor that initiates autoimmune activity.
- There are four subtypes of MS: relapsing-remitting (the most common form), secondary progressive, primary progressive, and progressive-relapsing.
- Diagnosis of MS is based on clinical presentation supplemented by laboratory data (eg, MRI scans, CSF tests, and VEP determinations). A positive diagnosis requires objective evidence of two or more clinical attacks separated in time and space.
- In patients with MS, drugs are employed to (1) modify the disease process, (2) treat acute relapses, and (3) manage symptoms. We have no drugs to cure MS.
- Disease-modifying drugs can decrease the frequency and severity of relapses, reduce development of brain lesions, decrease future disability, and help maintain quality of life. In addition, they may prevent permanent damage to axons.

- There are two main groups of disease-modifying drugs: immunomodulators and immunosuppressants.
- The immunomodulators—interferon beta, glatiramer acetate, and natalizumab—are much safer than mitoxantrone (the only FDA-approved immunosuppressant for MS), and hence are generally preferred.
- All patients with relapsing-remitting MS should receive an immunomodulator—interferon beta, glatiramer acetate, or natalizumab—beginning as soon as possible after diagnosis and continuing indefinitely.
- Interferon beta and glatiramer are equally effective, but less effective than natalizumab.
- Interferon beta and glatiramer are administered by self-injection (IM or subQ), whereas natalizumab is administered by IV infusion.
- Interferon beta is generally well tolerated, although side effects—flu-like reactions, liver injury, myelosuppression, injection-site reactions—are relatively common.
- Glatiramer is less well tolerated than interferon beta, and requires more frequent injections.
- The most common side effects of glatiramer are injection-site reactions (pain, erythema, pruritus, induration), and the most disturbing side effect is brief but severe chest pain after the injection. Unlike interferon beta, glatiramer does not cause flu-like symptoms, myelosuppression, or liver toxicity.
- Natalizumab can cause progressive multifocal leukoencephalopathy (PML), a severe CNS infection caused by reactivation of the JC virus. To reduce the risk of PML, natalizumab must not be combined with other immunosuppressant drugs, must not be given to patients with HIV/AIDS and other conditions that compromise cell-mediated immunity, and must be used in accord with the TOUCH Prescribing Program.
- Mitoxantrone is the only immunosuppressant currently approved for MS.
- Mitoxantrone suppresses immune function more strongly than the immunomodulators, but is also more toxic. Accordingly, the drug is generally reserved for patients who are unresponsive to or intolerant of an immunomodulator.
- In patients with MS, mitoxantrone suppresses production of immune system cells, and thereby decreases autoimmune destruction of myelin.

214

215

- The major side effects of mitoxantrone are myelosuppression, cardiotoxicity, and fetal injury.
- The risk of cardiotoxicity from mitoxantrone increases significantly if the lifetime cumulative dose exceeds 140 mg/m^2 , and hence the total dose should not exceed this amount.
- A short course of high-dose IV glucocorticoids (eg, methylprednisolone) is the preferred treatment for an acute MS relapse. Intravenous gamma globulin is an option.

24.4.10.2 Summary of Major Nursing Implications*

24.4.10.... INTERFERON BETA

Interferon beta-1a [Avonex, Rebif]

Interferon beta-1b [Betaseron]

24.4.10.... Preadministration Assessment

24.4.10.... Therapeutic Goal

All preparations of beta interferon are used to decrease the frequency and severity of relapses and slow disease progression in patients with relapsing forms of MS. In addition, *interferon beta-1b* [Betaseron] is used to treat secondary progressive MS.

24.4.10.... Baseline Data

Obtain baseline LFTs and complete blood counts.

24.4.10.... Identifying High-Risk Patients

Exercise *caution* in patients who abuse alcohol, in those with active liver disease or a history of liver disease, and in those taking drugs that can cause liver injury or suppress the bone marrow.

Implementation: Administration

Routes

Intramuscular.

Avonex (interferon beta-1a).

Subcutaneous.

Rebif (interferon beta-1a), Betaseron (interferon beta-1b).

Administration

For all three formulations of interferon beta, teach patients how to self-inject, and advise them to rotate the injection site.

Avonex.

Instruct patients to inject Avonex IM once a week.

Rebif.

Instruct patients to inject Rebif subQ 3 times a week, preferably in the late afternoon or evening, at least 48 hours apart, and on the same days each week (eg, Monday, Wednesday, Friday).

Betaseron.

Instruct patients to reconstitute powdered Betaseron just prior to use, and to inject it subQ every other day.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Indices of success include a reduction in the frequency and intensity of relapses, a reduction in new MRI-detectable lesions, and improvement in the EDSS score.

24.4.10....

Minimizing Adverse Effects

24.4.10....

Flu-like Reactions.

Flu-like reactions—headache, fever, chills, malaise, muscle aches, stiffness—are common early in therapy, but later diminish. To minimize symptoms, begin therapy with low doses, and then slowly titrate to full doses. **Inform patients that symptoms can be reduced by taking an analgesic-antipyretic medication (ie, acetaminophen; ibuprofen or another nonsteroidal anti-inflammatory drug).**

24.4.10....

Hepatotoxicity.

Interferon beta can cause liver injury. To monitor for hepatotoxicity, obtain LFTs at baseline, 1 month later, then every 3 months for 1 year, and every 6 months thereafter. If LFTs indicate significant injury, interferon should be given in reduced dosage or discontinued. When liver function returns to normal, treatment can resume with careful monitoring.

24.4.10....

Myelosuppression.

Interferon beta can decrease production of all blood cell types. To monitor for myelosuppression, obtain complete blood counts at baseline, every 3 months for 1 year, and every 6 months thereafter.

24.4.10....

Injection-Site Reactions.

Subcutaneous injection (of Rebif or Betaseron) can cause pain, erythema, bumps, and itching. **Inform patients that they can reduce discomfort by physical measures—rotating the injection site, applying ice (briefly) before and after the injection, and applying a warm moist compress—and that they can reduce persistent itching and erythema with oral diphenhydramine [Benadryl] or topical hydrocortisone. Instruct patients to avoid continuous exposure to topical hydrocortisone owing to a risk of skin damage. Forewarn patients that IM injection (of Avonex) can cause discomfort and bruising.**

215

216

24.4.10.... Minimizing Adverse Interactions

24.4.10.... Hepatotoxic and Myelosuppressant Drugs.

Exercise caution when combining interferon beta with other drugs that can suppress the bone marrow or cause liver injury.

24.4.10.... GLATIRAMER ACETATE

24.4.10.... Preadministration Assessment

24.4.10.... Therapeutic Goal

The goal is to decrease the frequency and severity of relapses and slow disease progression in patients with relapsing-remitting MS.

24.4.10.... Implementation: Administration

24.4.10.... Route

Subcutaneous.

24.4.10.... Administration

Teach patients how to self-inject the drug (subQ) into the arm, abdomen, hip, or thigh. Advise patients to store glatiramer under refrigeration at 36°F to 46°F (2°C to 8°C).

24.4.10.... Ongoing Evaluation and Interventions

24.4.10.... Evaluating Therapeutic Effects

Indices of success include a reduction in the frequency and intensity of relapses, a reduction in new MRI-detectable lesions, and improvement in the EDSS score.

24.4.10.... Minimizing Adverse Effects

24.4.10.... Injection-Site Reactions.

Forewarn patients that glatiramer may cause pain, erythema, pruritus, and induration at the injection site.

24.4.10....

Immediate Postinjection Reaction.

Forewarn patients that glatiramer may cause an uncomfortable and disturbing set of systemic symptoms—flushing, palpitations, chest pain, anxiety, laryngeal constriction, urticaria—that may persist for 15 to 20 minutes after the injection.

No specific intervention is needed.

24.4.10....

NATALIZUMAB

24.4.10....

Preadministration Assessment

24.4.10....

Therapeutic Goal

Natalizumab is used to either (1) decrease the frequency and severity of relapses and slow disease progression in patients with relapsing forms of MS who have failed to respond to at least one other immunomodulating drug or (2) treat patients with moderate to severe Crohn's disease who have been unresponsive to or intolerant of other therapies, including inhibitors of TNF-alpha.

24.4.10....

Baseline Data

Obtain an MRI scan of the brain at baseline and every 6 months thereafter. Obtain a baseline evaluation for PML.

24.4.10....

Identifying High-Risk Patients

Natalizumab is *contraindicated* for patients with PML, for patients taking immunosuppressant drugs, and for patients with HIV/AIDS and other conditions that compromise cell-mediated immunity.

24.4.10....

Implementation: Administration

24.4.10....

Route

Intravenous

24.4.10....

Administration

Dilute concentrated natalizumab in 100 mL of 0.9% sodium chloride injection and infuse over a 1-hour span. If any signs of hypersensitivity develop, stop the infusion immediately.

24.4.10.... Ongoing Evaluation and Interventions

24.4.10.... Evaluating Therapeutic Effects

Indices of success include a reduction in the frequency and intensity of relapses, a reduction in new MRI-detectable lesions, and improvement in the EDSS score.

24.4.10.... Minimizing Adverse Effects

24.4.10.... Progressive Multifocal Leukoencephalopathy.

Natalizumab increases the risk of PML, a severe infection of the CNS with no effective treatment. To reduce the risk of PML, do not give natalizumab to patients taking immunosuppressants or to patients with HIV/AIDS and other conditions that compromise cell-mediated immunity. Screen for PML prior to each infusion. All patients, prescribers, infusion nurses, infusion centers, and pharmacies associated with infusion centers must register with the *TOUCH Prescribing Program* and must comply with its provisions.

24.4.10.... Hepatotoxicity.

Natalizumab can injure the liver. **Inform patients about signs of liver injury—jaundice, nausea, vomiting, fatigue, darkening of the urine—and instruct them to report these immediately.** Discontinue natalizumab if significant liver injury is diagnosed.

24.4.10.... Hypersensitivity Reactions.

Natalizumab can cause severe hypersensitivity reactions (eg, anaphylaxis), usually within 2 hours of starting the infusion. Monitor patients for a reaction during the infusion and for 1 hour after. If a severe reaction develops, discontinue natalizumab and never use it again.

24.4.10.... Drug Interactions

Immunosuppressants increase the risk of PML and other opportunistic infections, and hence should be discontinued at least 3 months before starting natalizumab.

216

MITOXANTRONE

Preadministration Assessment

Therapeutic Goal

The goal is to decrease the frequency and severity of relapses and slow disease progression in patients with secondary progressive MS, progressive-relapsing MS, and worsening relapsing-remitting MS.

Baseline Data

Obtain a pregnancy test, LFTs, complete blood counts, and LVEF determination.

Identifying High-Risk Patients

Mitoxantrone is *contraindicated* during pregnancy and for patients with abnormal LFTs or an LVEF below 50%.

Implementation: Administration

Route

Intravenous.

Administration

Infuse over 5 to 30 minutes through a free-flowing IV line. If extravasation occurs, discontinue the infusion immediately and restart in a different vein. Don't mix mitoxantrone with other drugs.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Indices of success include a reduction in the frequency and intensity of relapses, a reduction in new MRI-detectable lesions, and improvement in the EDSS score.

Monitoring Summary

Perform complete blood counts before each dose, 10 to 14 days after each dose, and whenever signs of infection develop.

Perform liver function tests before each dose.

Perform a pregnancy test before each dose.

Determine LVEF before each dose and whenever signs of heart failure develop.

24.4.10....

Minimizing Adverse Effects

24.4.10....

Myelosuppression.

Mitoxantrone can decrease production of platelets and all blood cells. Neutrophil loss increases the risk of severe infection, and hence the drug should be withheld if the neutrophil count has dropped below 1500 cells/mm³. **Advise patients to avoid contact with people who have infections, and instruct them to report signs of infection (fever, chills, cough, hoarseness) immediately.** Do not give patients a live virus vaccine.

24.4.10....

Cardiotoxicity.

Mitoxantrone can cause irreversible injury to the heart, manifesting as a reduced LVEF or outright heart failure. Cardiotoxicity is directly related to the cumulative lifetime dose, which must not exceed 140 mg/m². Withhold mitoxantrone if the LVEF drops below 50%. **Inform patients about symptoms of heart failure (eg, shortness of breath, fatigue, peripheral edema) and instruct them to report these immediately.**

24.4.10....

Fetal Harm.

Mitoxantrone is classified in FDA Pregnancy Risk Category D, and hence must not be used during pregnancy. Rule out pregnancy before each infusion. **Warn women of child-bearing age to avoid pregnancy. If pregnancy occurs, offer counseling about possible pregnancy termination.**

24.4.10....

Urine and Tissue Discoloration.

Forewarn patients that mitoxantrone can impart a harmless, blue-green tint to the urine, skin, and sclera.

* Patient education information is highlighted as **blue text**.

²⁵CHAPTER 24 Drugs for Epilepsy

The term *epilepsy* refers to a group of disorders characterized by excessive excitability of neurons in the central nervous system (CNS). This abnormal neuronal activity can produce a variety of symptoms, ranging from brief periods of unconsciousness to violent convulsions.

In the United States, about 2.3 million people have epilepsy. Every year, 150,000 new cases are diagnosed. The incidence is highest during the first year of life and in the elderly. Between 60% and 70% of patients can be rendered seizure free with drugs. Unfortunately, this means that 30% to 40% cannot.

The terms *seizure* and *convulsion* are not synonymous. *Seizure* is a general term that applies to all types of epileptic events. In contrast, *convulsion* has a more limited meaning, applying only to abnormal motor phenomena, for example, the jerking movements that occur during a tonic-clonic (grand mal) attack. Accordingly, although all convulsions may be called seizures, it is not correct to call all seizures convulsions. Absence seizures, for example, manifest as brief periods of unconsciousness, which may or may not be accompanied by involuntary movements. Since not all epileptic seizures involve convulsions, we will refer to the agents used to treat epilepsy as *antiepileptic drugs* (AEDs), rather than anticonvulsants.

^{25.1} SEIZURE GENERATION

Seizures are initiated by synchronous, high-frequency discharge from a group of hyperexcitable neurons, called a *focus*. A focus may result from several causes, including congenital defects, hypoxia at birth, head trauma, and cancer. Seizures result when discharge from a focus spreads to other brain areas, thereby recruiting normal neurons to discharge abnormally along with the focus.

The overt manifestations of any particular seizure disorder depend on the location of the seizure focus and the neuronal connections to that focus. (The connections to the focus determine the brain areas to which seizure activity can spread.) If seizure activity invades a very limited part of the brain, a partial or local seizure occurs. In contrast, if seizure activity spreads to a large portion of the brain, a generalized seizure develops.

An experimental procedure referred to as *kindling* may explain how a focal discharge is eventually able to generate a seizure. Experimental kindling is performed by implanting a small electrode into the brain of an animal. The electrode is used to deliver localized stimuli for a brief interval once a day. When stimuli are first administered, no seizures result. However, after repeated once-a-day delivery, these stimuli eventually elicit a seizure. If brief, daily stimulations are continued long enough, spontaneous seizures will begin to occur.

The process of kindling may tell us something about seizure development in humans. For example, kindling may account for the delay that can take place between injury to the head and eventual development of seizures. Furthermore, kindling may explain why the seizures associated with some forms of epilepsy become more frequent as time passes. Also, the progressive nature of kindling suggests that early treatment might prevent seizure disorders from becoming more severe over time.

218

219

25.2 TYPES OF SEIZURES

Seizure can be divided into two broad categories: *partial (focal) seizures* and *generalized seizures*. In partial seizures, seizure activity begins focally in the cerebral cortex and usually undergoes limited spread to adjacent cortical areas. In generalized seizures, focal seizure activity is conducted widely throughout both hemispheres. As a rule, partial seizures and generalized seizures are treated with different drugs ([Table 24-1](#)).

25.2.1 Partial Seizures

Partial seizures fall into three groups: simple partial seizures, complex partial seizures, and partial seizures that evolve into secondarily generalized seizures.

25.2.1.1 Simple Partial Seizures.

These seizures manifest with discrete symptoms that are determined by the brain region involved. Hence, the patient may experience discrete motor symptoms (eg, twitching thumb), sensory symptoms (eg, local numbness; auditory, visual, or olfactory hallucinations), autonomic symptoms (eg, nausea, flushing, salivation, urinary incontinence), or psychoillusive symptoms (eg, feelings of unreality, fear, or depression). Simple partial seizures are distinguished from complex partial seizures in that there is *no loss of consciousness*. These seizures persist for 20 to 60 seconds.

TABLE 24-1 Drugs for Specific Types of Seizures

Seizure Type	Drugs Used for Treatment	
	Traditional AEDs	Newer AEDs
Partial		
Simple partial, complex partial, and secondarily generalized	Carbamazepine	Oxcarbazepine
	Phenytoin	Gabapentin
	Valproic acid	Lamotrigine
	Phenobarbital	Levetiracetam
	Primidone	Pregabalin
		Topiramate
		Tiagabine
		Zonisamide
Primary Generalized		
Tonic-clonic	Carbamazepine	Lamotrigine
	Phenytoin	Levetiracetam
	Valproic acid	Topiramate
	Phenobarbital	
	Primidone	
Absence	Ethosuximide	Lamotrigine
	Valproic acid	
Myoclonic	Valproic acid	Lamotrigine
		Levetiracetam
		Topiramate
AEDs = antiepileptic drugs.		

25.2.1.2 Complex Partial Seizures.

These seizures are characterized by *impaired consciousness* and lack of responsiveness. At seizure onset, the patient becomes motionless and stares with a fixed gaze. This state is followed

by a period of *automatism*, in which the patient performs repetitive, purposeless movements, such as lip smacking or hand wringing. Seizures last 45 to 90 seconds.

25.2.1.3 Secondly Generalized Seizures.

These seizures begin as simple or complex partial seizures, and then evolve into generalized tonic-clonic seizures. Consciousness is lost. These seizures last 1 to 2 minutes.

25.2.2 Generalized Seizures

Generalized seizures may be convulsive or nonconvulsive. As a rule, they produce immediate loss of consciousness. The major generalized seizures are discussed briefly below.

25.2.2.1 Tonic-Clonic Seizures (Grand Mal).

In tonic-clonic seizures, neuronal discharge spreads throughout both hemispheres of the cerebral cortex. These seizures manifest as major convulsions, characterized by a period of muscle rigidity (tonic phase) followed by synchronous muscle jerks (clonic phase). Tonic-clonic seizures often cause urination, but not defecation. Convulsions may be preceded by a loud cry, caused by forceful expiration of air across the vocal cords. Tonic-clonic seizures are accompanied by marked impairment of consciousness and are followed by a period of CNS depression, referred to as the *postictal state*. The seizure itself lasts 90 seconds or less.

25.2.2.2 Absence Seizures (Petit Mal).

Absence seizures are characterized by loss of consciousness for a brief time (10 to 30 seconds). Seizures usually involve mild, symmetric motor activity (eg, eye blinking) but may occur with no motor activity at all. The patient may experience hundreds of absence attacks a day. Absence seizures occur primarily in children and usually cease during the early teens.

25.2.2.3 Atonic Seizures.

These seizures are characterized by sudden loss of muscle tone. If seizure activity is limited to the muscles of the neck, “head drop” occurs. However, if the muscles of the limbs and trunk are involved, a “drop attack” can occur, causing the patient to suddenly collapse. Atonic seizures occur mainly in children.

25.2.2.4 Myoclonic Seizures.

These seizures consist of sudden muscle contractions that last for just 1 second. Seizure activity may be limited to one limb (focal myoclonus) or it may involve the entire body (massive myoclonus).

25.2.2.5 Status Epilepticus.

Status epilepticus (SE) is defined as a seizure that persists for 30 minutes or longer. There are several types of SE, including generalized convulsive SE, absence SE, and myoclonic SE. Generalized convulsive SE, which can be life threatening, is discussed later.

25.2.2.6 Febrile Seizures.

Fever-associated seizures are common among children ages 6 months to 5 years. Febrile seizures typically manifest as generalized tonic-clonic convulsions of short duration. Children who experience these seizures are *not* at high risk of developing epilepsy later in life.

25.2.3 Mixed Seizures: Lennox-Gastaut Syndrome

Lennox-Gastaut syndrome (LGS) is a severe form of epilepsy that usually develops during the preschool years. The syndrome is characterized by developmental delay and a mixture of partial and generalized seizures. Seizure types include partial, atonic, tonic, generalized tonic-clonic, and atypical absence. In children with LGS, seizures are often very difficult to treat.

219

220

25.3 HOW ANTIEPILEPTIC DRUGS WORK

We have long known that AEDs can (1) suppress discharge of neurons within a seizure focus and (2) suppress propagation of seizure activity from the focus to other areas of the brain. However, until recently we did not know how these effects were achieved. It now appears that AEDs act through four basic mechanisms: suppression of sodium influx, suppression of calcium influx, blockade of receptors for glutamate, and potentiation of gamma-aminobutyric acid (GABA).

25.3.1 Suppression of Sodium Influx.

Before discussing AED actions, we need to review sodium channel physiology. Neuronal action potentials are propagated by influx of sodium through sodium channels, which are gated pores in the cell membrane that control sodium entry. For sodium influx to occur, the channel must be in an *activated state*. Immediately following sodium entry, the channel goes into an *inactivated state*, during which further sodium entry is prevented. Under normal circumstances, the inactive channel

very quickly returns to the activated state, thereby permitting more sodium entry and propagation of another action potential.

Several AEDs, including phenytoin, carbamazepine, valproic acid, and lamotrigine, reversibly bind to sodium channels while they are in the inactivated state, and thereby prolong channel inactivation. By delaying return to the active state, these drugs decrease the ability of neurons to fire at high frequency. As a result, seizures that depend on high-frequency discharge are suppressed.

25.3.2 Suppression of Calcium Influx.

In axon terminals, influx of calcium through voltage-gated calcium channels promotes transmitter release. Hence, drugs that block these calcium channels can suppress transmission. Several AEDs, including valproic acid and ethosuximide, act by this mechanism.

25.3.3 Antagonism of Glutamate.

Glutamic acid (glutamate) is the primary excitatory transmitter in the CNS. The compound works through two receptors, known as (1) NMDA receptors (*N*-methyl-D-aspartate receptors) and (2) AMPA receptors (alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors). Two drugs—felbamate and topiramate—block the actions of glutamate at NMDA and AMPA receptors, and thereby suppress neuronal excitation.

25.3.4 Potentiation of GABA.

Several AEDs potentiate the actions of GABA, an inhibitory neurotransmitter that is widely distributed throughout the brain. By augmenting the inhibitory influence of GABA, these drugs decrease neuronal excitability and thereby suppress seizure activity. Drugs increase the influence of GABA by several mechanisms. Benzodiazepines and barbiturates enhance the effects of GABA by mechanisms that involve direct binding to GABA receptors. Gabapentin promotes GABA release. Tiagabine inhibits GABA reuptake, and vigabatrin inhibits the enzyme that degrades GABA, and thereby increases GABA availability.

25.4 BASIC THERAPEUTIC CONSIDERATIONS

25.4.1 Therapeutic Goal and Treatment Options

The goal in treating epilepsy is to reduce seizures to an extent that enables the patient to live a normal or near-normal life. Ideally, treatment should eliminate seizures entirely. However, this may not be possible without causing intolerable side effects. Therefore, we must balance the desire for complete seizure control against the acceptability of side effects.

Epilepsy may be treated with drugs or with nondrug therapies. As noted, drugs can benefit 60% to 70% of patients. This means that, of the 2.3 million Americans with epilepsy, between 690,000 and 920,000 *cannot* be treated successfully with drugs. For these people, nondrug therapy may well help. Three options exist: neurosurgery, vagus nerve stimulation, and the ketogenic diet. Of the three, neurosurgery has the best success rate. All three nondrug therapies are discussed in [Box 24-1](#).

25.4.2 Diagnosis and Drug Selection

Control of seizures requires proper drug selection. As indicated in [Table 24-1](#), many AEDs are selective for specific seizure disorders. Phenytoin, for example, is useful for treating tonic-clonic and partial seizures but not absence seizures. Conversely, ethosuximide is active against absence seizures but does not work against tonic-clonic or partial seizures. Only one drug—valproic acid—appears effective against practically all forms of epilepsy. Since most AEDs are selective for certain seizure disorders, effective treatment requires a proper match between the drug and the seizure. To make this match, the seizure type must be accurately diagnosed.

Making a diagnosis requires physical, neurologic, and laboratory evaluations along with a thorough history. The history should determine the age at which seizures began, the frequency and duration of seizure events, precipitating factors, and times when seizures occur. Physical and neurologic evaluations may reveal signs of head injury or other disorders that could underlie seizure activity, although in many patients the physical and neurologic evaluations may be normal. An electroencephalogram (EEG) is essential for diagnosis. Other diagnostic tests that may be employed include computed tomography (CT), positron emission tomography (PET), and magnetic resonance imaging (MRI).

Very often, patients must try several AEDs before a regimen that is both effective and well tolerated can be established. Initial treatment should be done with just one AED. If this drug fails, it should be discontinued and a different AED should be tried. If this second drug fails, two options are open: (1) treatment with a third AED alone, or (2) treatment with a combination of AEDs.

25.4.3 Drug Evaluation

Once an AED has been selected, a trial period is needed to determine its effectiveness. During this time there is no guarantee that seizures will be controlled. Until seizure control is certain, the patient should be warned not to participate in driving and other activities that could be hazardous should a seizure occur.

During the process of drug evaluation, adjustments in dosage are often needed. No drug should be considered ineffective until it has been tested in sufficiently high dosage and for a reasonable time. Knowledge of plasma drug levels can be a valuable tool for establishing dosage and evaluating the effectiveness of a specific drug.

220

221

25.4.3.1 BOX 24-1 Special Interest Topic

25.4.3.1.1 NONDRUG THERAPIES FOR EPILEPSY: NEUROSURGERY, VAGUS NERVE STIMULATION, AND THE KETOGENIC DIET

25.4.3.1... Neurosurgery: The Cure That's Rarely Used

For patients with temporal lobe epilepsy, surgery is highly effective, yet used only rarely. Despite advances in drug therapy, surgical intervention remains the only *cure* for epilepsy. (Although drugs can control symptoms, they don't offer a cure.) The safety and efficacy of surgery have been documented in literally hundreds of papers. Among patients with forms of epilepsy that can be treated surgically, the procedure can render between 70% and 90% seizure free—and, even when seizures do continue, their frequency is often decreased. This degree of success is all the more remarkable when we consider that, in order to qualify for surgery, candidates must first be proved refractory to drugs. Put another way, surgery is only performed on patients who have epilepsy that is especially hard to treat. Yet, despite its proven efficacy, surgery remains grossly underutilized: Each year, only 500 surgeries are performed, although more than 20,000 patients are eligible. This is especially unfortunate because, among people who are refractory to drugs, surgery can greatly improve seizure control, thereby improving quality of life, along with attendance at work and at school.

Temporal lobe surgery is not without risk. Between 5% and 10% of patients experience adverse effects, including infection, visual field defects, memory loss, and paralysis. The death rate is very low—only 0.2%. Prior to surgery, patients undergo a battery of tests designed to locate the seizure focus as well as nearby areas associated with language and other critical functions. This information allows the surgeon to remove as little tissue as possible, thereby minimizing disruption of normal brain function.

25.4.3.1... Vagus Nerve Stimulation: Fighting Impulses with Impulses

The vagus nerve stimulator (VNS) is the first medical device for reducing seizures. The only commercial VNS available—the VNS Therapy System (formerly known as the NeuroCybernetic Prosthesis System)—received FDA approval in 1997. The system is

intended for use in conjunction with drugs by patients with severe, uncontrolled seizures. Responses to vagal stimulation develop slowly: Initial responses usually occur in 3 months, and full responses take even longer to develop.

The heart of the VNS is a small, programmable pulse generator that is implanted under the collarbone, much like a cardiac pacemaker. Subcutaneous leads connect the generator to the left branch of the vagus nerve in the neck. Stimulation is typically applied for 30 seconds every 5 minutes around the clock. When needed, stimulation parameters (voltage, frequency, duration) can be adjusted externally by the physician. By holding a small magnet over the generator, patients can activate the device manually if they feel a seizure coming on. In addition, patients can use the magnet to turn the generator off. VNS batteries last 3 to 5 years. Replacement is done in an outpatient procedure that takes 30 to 60 minutes.

In clinical trials, some patients responded dramatically and most showed at least some improvement. However, with a few patients, seizures *increased*. Specific results were as follows:

- In 26% of patients, seizure frequency decreased by 25% to 50%.
- In 11% of patients, seizure frequency decreased by more than 75%.
- In one patient, seizures stopped entirely.
- In 6% of patients, seizure frequency increased.

Vagal stimulation does not eliminate the need for drugs—but it can permit a simpler regimen. Up to 50% of patients can decrease the number of drugs they are taking (eg, two instead of three; one instead of two). Please note, however, that stimulation does *not* permit a reduction in dosage of the drugs that remain.

Vagal stimulation is well tolerated by most patients, although side effects occur often. During stimulation, patients experience hoarseness (100%), coughing (50%), voice alteration (73%), and shortness of breath (25%). In addition, there is a 2% to 3% risk of infection at the implant site. Stimulation does not cause cognitive effects and, perhaps surprisingly, does not cause autonomic effects (eg, bradycardia, GI disturbances, hypotension).

How does vagal stimulation decrease seizure frequency? No one knows. What we do know is that vagal fibers project to the brainstem, and from there to areas of the brain

25.4.3.1...

involved in seizure generation. When we stimulate the vagus, the resultant impulses in some way interrupt or prevent abnormal neuronal firing.

In 2005, the VNS Therapy System was approved for treating depression. This application is discussed in [Chapter 32](#).

The Ketogenic Diet: It's Tough but It Works

The ketogenic diet for epilepsy can decrease seizure frequency, but it's hard to implement and potentially dangerous. The diet was introduced in the 1920s, but fell out of use when AEDs became available. Today, the diet is under renewed study as a way to control seizures when drug therapy fails. Because the diet is both difficult and hazardous, close medical supervision is essential.

The ketogenic diet has two cornerstones: high intake of fat and very low intake of carbohydrates. Fats—usually butter or heavy cream—comprise 80% of daily calories. In contrast, the carbohydrate allowance is very low—so low, in fact, that the sugar in a dose of valproic acid [Depakene] syrup would exceed the daily limit. With strict adherence to the diet, ketosis develops in a few days. However, with just a minor deviation from the diet (eg, ingestion of two cookies), ketosis will be lost in hours.

How does a high-fat, low-carbohydrate diet reduce seizures? By causing *ketoacidosis*. Because carbohydrate availability is low, the body burns fat to meet its needs. Burning fat produces large amounts of ketone bodies (beta-hydroxybutyric acid, acetoacetic acid, acetone), whose presence creates a state of ketoacidosis. For reasons that are unclear, ketoacidosis can decrease seizures in some patients.

221
222

The principal candidates for dietary therapy are children under the age of 10 who have not responded to AEDs. Depending on the child, the ketogenic diet may be very effective, moderately effective, or ineffective. In older clinical trials, about one-third of children became seizure free and were able to discontinue AEDs; one-third showed some improvement but still required AEDs; and one-third failed to benefit at all. Results of a more recent trial, released in 2008, indicated that, in treatment-resistant children, the diet can decrease seizure frequency by more than 50%. These results are of special interest in that this was the first randomized controlled trial to evaluate the diet's efficacy.

Adverse effects of the diet are considerable. The most consistent—and obvious—is elevation of blood cholesterol. In one study, cholesterol levels rose from a mean of 170 mg/dL to 245 mg/dL. In another study, five children developed severe hypercholesterolemia, with an average level of 367 mg/dL. Since cholesterol contributes

to coronary artery disease (CAD), and since CAD is known to begin early in life, elevation of cholesterol is a significant drawback. Other adverse effects include poor linear growth, poor weight gain, kidney stones, dehydration, acidosis, constipation, and vomiting.

Maintenance of a seizure frequency chart is important for evaluating treatment. The chart should be kept by the patient or a family member and should contain a complete record of all seizure events. This record will enable the prescriber to determine if treatment has been effective. The nurse should teach the patient how to create and use a seizure frequency chart.

25.4.4 Monitoring Plasma Drug Levels

Monitoring plasma levels of AEDs is common. Safe and effective levels have been firmly established for most AEDs ([Table 24-2](#)). Measurement of these levels can help guide dosage adjustments.

Monitoring plasma drug levels is especially helpful when treating major convulsive disorders (eg, tonic-clonic seizures). Since these seizures can be dangerous, and since delay of therapy may allow the condition to worsen, rapid control of seizures is desirable. However, because these seizures occur infrequently, a long time may be needed to establish control if clinical outcome is relied on as the only means of determining an effective dosage. By adjusting initial doses on the basis of plasma drug levels (rather than on the basis of seizure control), we can readily achieve drug levels that are likely to be effective, thereby increasing our chances of establishing control quickly.

Measurements of plasma drug levels are not especially important for determining effective dosages for absence seizures. Why? Because absence seizures occur very frequently (up to several hundred a day), and hence observation of the patient is the best means for establishing an effective dosage: if seizures stop, dosage is sufficient; if seizures continue, more drug is needed.

In addition to serving as a guide for dosage adjustment, knowledge of plasma drug levels can serve as an aid to (1) monitoring patient adherence, (2) determining the cause of lost seizure control, and (3) identifying causes of toxicity, especially in patients taking more than one drug.

25.4.5 Promoting Patient Adherence

Epilepsy is a chronic condition that requires regular and continuous therapy. As a result, seizure control is highly dependent on patient adherence. In fact, it is estimated that nonadherence accounts for about 50% of all treatment failures. Accordingly, promoting adherence should be a priority for all members of the healthcare team. Measures that can help include

- Educating patients and families about the chronic nature of epilepsy and the importance of adhering to the prescribed regimen.
- Monitoring plasma drug levels so as to encourage and evaluate adherence.
- Deepening patient and family involvement by having them maintain a seizure frequency chart.

25.4.6 Withdrawing Antiepileptic Drugs

Some forms of epilepsy undergo spontaneous remission, and hence discontinuing treatment may at some time be appropriate. Unfortunately, there are no firm guidelines to indicate the most appropriate time to withdraw AEDs. However, once the decision to discontinue treatment has been made, agreement does exist on how drug withdrawal should be accomplished. The most important rule is that *AEDs be withdrawn slowly* (over a period of 6 weeks to several months). Failure to gradually reduce dosage is a frequent cause of SE. If the patient is taking two drugs to control seizures, they should be withdrawn sequentially, not simultaneously.

25.4.7 Suicide Risk with Antiepileptic Drugs

In 2008, the Food and Drug Administration (FDA) warned that AEDs may increase suicidal thoughts and behavior. By analyzing data from 199 placebo-controlled studies involving 11 different AEDs, the FDA found that, compared with patients taking a placebo, patients taking AEDs had *twice* the risk of suicidal thoughts and behaviors (0.43% vs. 0.22%). The reason underlying the increased risk is unknown. Of note, risk was higher among patients taking AEDs for epilepsy than among patients taking these drugs for other conditions, such as migraine, neuropathic pain, or psychiatric illness. Risk may rise within 1 week of starting AEDs and may continue for 24 weeks or more. Although the analysis was limited to 11 drugs, the FDA believes the results probably apply to *all* AEDs. Accordingly, all patients using these drugs should be monitored for increased anxiety, agitation, mania, and hostility—signs that may indicate the emergence or worsening of depression—and an increased risk of suicidal thoughts or behaviors. Patients, families, and caregivers should be alerted to these signs and advised to report them immediately.

222

223

TABLE 24-2 Clinical Pharmacology of the Oral Antiepileptic Drugs (AEDs)

Drug	Product Name	Daily Dosing	Daily Maintenance Dosage		Target Serum Level* (mcg/mL)	Induces Hepatic Drug Metabolism
			Adults (mg)	Children (mg/kg)		
Traditional AEDs						
Carbamazepine	Tegretol	3 times	600–1800	10–35	4–12	Yes
	Tegretol-XR	Twice				
	Carbatrol	Twice				
Ethosuximide	Zarontin	1 or 2 times	750	15–40	40–100	No
Phenobarbital	Generic only	1 or 2 times	60–120	3–6	15–45	Yes
Phenytoin	Phenytoin, prompt	2 or 3 times	200–300	4–8	10–20	Yes
	Dilantin Infatab	2 or 3 times				
	Dilantin Suspension	2 or 3 times				
	Phenytoin, extended	Once				
	Dilantin Kapseals	Once				
Primidone	Phenytek	Once	500–750	10–25	5–15†	Yes
	Mysoline	3 or 4 times				
	Depakene	3 or 4 times				
Valproic acid	Depakote	3 or 4 times	750–3000	15–45	40–100	No
	Depakote ER	Twice				
	Stavzor	2 or 3 times				
	Newer AEDs					
Gabapentin	Neurontin	3 times	1200–3600	25–50	12–20	No
Lamotrigine	Lamictal	Twice	400†§	5†§	3–14	No
Levetiracetam	Keppra	Twice	2000–3000	40–100	10–40	No
Oxcarbazepine	Trileptal	Twice	900–2400	30–46	3–40	No¶
Pregabalin	Lyrica	2 or 3 times	150–600	ND	ND	No

Tiagabine	Gabitril Filmtablets	2 to 4 times	16–32	0.4 [§]	ND	No
Topiramate	Topamax	Twice	100–400	3–9	5–25	No
Zonisamide	Zonegran	1 or 2 times	200–400	4–12	10–40	No

* ND = not determined.

† Target serum level is 5 to 15 mcg/mL for primidone itself, and 15 to 40 mcg/mL for phenobarbital derived from primidone.

‡ Dosage must be decreased in patients taking valproic acid.

§ Dosage must be increased in patients taking drugs that induce hepatic drug-metabolizing enzymes.

¶ Oxcarbazepine does not induce enzymes that metabolize AEDs, but does induce enzymes that metabolize other kinds of drugs.

25.5 CLASSIFICATION OF ANTIEPILEPTIC DRUGS

The AEDs can be grouped into two major categories: *traditional AEDs* and *newer AEDs*. The traditional group has six major members, the last of which—valproic acid—was approved in 1978. The group of newer AEDs has eight major members, all of which were approved in 1993 or later. As summarized in [Table 24-3](#), both groups have their advantages and disadvantages. For example, clinical experience with the older AEDs is more extensive than with the newer ones, and the older drugs cost less. Both facts make the older drugs attractive. However, the older AEDs also have drawbacks, including troublesome side effects and complex drug interactions. Of importance, drugs in both groups appear equally effective—although few direct comparisons have been made. The bottom line? Neither group is clearly superior to the other. Hence, when selecting an AED, drugs in both groups should be considered.

25.6 TRADITIONAL ANTIEPILEPTIC DRUGS

The traditional AEDs have been in use for many years. Antiseizure properties of phenobarbital, the oldest member of the group, were demonstrated in 1912. Even the youngest member—valproic acid—has been in use for over three decades. Because of this extensive clinical experience, the efficacy and therapeutic niche of the traditional AEDs are well established. As a result, these drugs are prescribed more widely than the newer AEDs. In the discussion below, we focus on six of the traditional AEDs: phenytoin, carbamazepine, valproic acid, ethosuximide, phenobarbital, and primidone. The group has other members, but they are less important.

Although familiarity makes the traditional AEDs appealing, these drugs do have drawbacks. In general, they are less well tolerated than the newer AEDs, and they pose a greater risk to the

developing fetus. Furthermore, owing to effects on drug-metabolizing enzymes (either induction or inhibition), they have complex interactions with other drugs, including other AEDs.

TABLE 24-3 Comparison of Traditional and Newer Antiepileptic Drugs

Area of Comparison	Drug Group	
	Traditional AEDs*	Newer AEDs†
Efficacy	Well established	Equally good (probably), but less well established
Clinical experience	Extensive	Less extensive
Therapeutic niche	Well established	Evolving
Tolerability	Less well tolerated	Better tolerated
Pharmacokinetics	Often complex	Less complex
Drug interactions	Extensive, owing to induction of drug-metabolizing enzymes	Limited; no induction of drug-metabolizing enzymes
Safety in pregnancy	Less safe	Safer
Cost	Less expensive	More expensive

* Carbamazepine, ethosuximide, phenobarbital, phenytoin, primidone, and valproic acid.

† Gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, and zonisamide.

25.6.1 Phenytoin

Phenytoin [Dilantin, Phenytek] is our most widely used AED, despite having tricky kinetics and troublesome side effects. The drug is active against partial seizures as well as primary generalized tonic-clonic seizures. Phenytoin is of historic importance in that it was the first drug to suppress seizures without depressing the entire CNS. Hence, phenytoin heralded the development of selective medications that could treat epilepsy while leaving most CNS functions undiminished.

25.6.1.1 Mechanism of Action

At the concentrations achieved clinically, phenytoin causes selective inhibition of sodium channels. Specifically, the drug slows recovery of sodium channels from the inactive state back to the active state. As a result, entry of sodium into neurons is inhibited, and hence action potentials are suppressed. Blockade of sodium entry is limited to neurons that are hyperactive. As a result, the drug suppresses activity of seizure-generating neurons while leaving healthy neurons unaffected.

25.6.1.2 Pharmacokinetics

Phenytoin has unusual pharmacokinetics that must be accounted for in therapy. Absorption varies substantially among patients. In addition, because of saturable kinetics, small changes in dosage can produce disproportionately large changes in serum drug levels. As a result, a dosage that is both effective and safe is difficult to establish.

25.6.1.2.1 Absorption.

Absorption varies between the different oral formulations of phenytoin. With some—Dilantin Infatab, Dilantin Suspension, phenytoin (prompt)—absorption is relatively fast, whereas with others—Dilantin Kapseals, Phenytek, phenytoin (extended)—absorption is delayed and prolonged.

In the past, there was concern that absorption also varied between preparations of phenytoin made by different manufacturers. However, it is now clear that all FDA-approved equivalent products have equivalent bioavailability. As a result, switching from one brand of phenytoin to another produces no more variability than switching between lots of phenytoin produced by the same manufacturer.

25.6.1.2.2 Metabolism.

The capacity of the liver to metabolize phenytoin is very limited. As a result, the relationship between dosage and plasma levels of phenytoin is unusual. Doses of phenytoin needed to produce therapeutic effects are only slightly smaller than the doses needed to saturate the hepatic enzymes that metabolize phenytoin. Consequently, if phenytoin is administered in doses only slightly greater than those needed for therapeutic effects, the liver's capacity to metabolize the drug will be overwhelmed, causing plasma levels of phenytoin to rise dramatically. This unusual relationship between dosage and plasma levels is illustrated in [Figure 24-1A](#). As you can see, once plasma levels have reached the therapeutic range, small changes in dosage produce large changes in drug levels. As a result, small increases in dosage can cause toxicity, and small decreases can cause therapeutic failure. This relationship makes it difficult to establish and maintain a dosage that is both safe and effective.

[Figure 24-1B](#) indicates the relationship between dosage and plasma levels that exists for most drugs. As indicated, this relationship is *linear*, in contrast to the nonlinear relationship that exists for phenytoin. Accordingly, for most drugs, if the patient is taking doses that produce plasma levels that are within the therapeutic range, small deviations from that dosage produce

only small deviations in plasma drug levels. Because of this relationship, for most drugs it is relatively easy to maintain plasma levels that are safe and effective.

Because of saturation kinetics, the half-life of phenytoin varies with dosage. At low doses, the half-life is relatively short—about 8 hours. However, at higher doses, the half-life becomes prolonged—in some cases up to 60 hours. Why? Because, at higher doses, there is more drug present than the liver can process. As a result, metabolism is delayed, causing the half-life to increase.

25.6.1.3 Therapeutic Uses

25.6.1.3.1 Epilepsy.

Phenytoin can be used to treat all major forms of epilepsy except absence seizures. The drug is especially effective against tonic-clonic seizures, and is a drug of choice for treating these seizures in adults and older children. (Carbamazepine is preferred to phenytoin for treating tonic-clonic seizures in young children.) Although phenytoin can be used to treat simple and complex partial seizures, the drug is less effective against these seizures than against tonic-clonic seizures. Phenytoin can be administered IV to treat generalized convulsive SE, but other drugs are preferred.

25.6.1.3.2 Cardiac Dysrhythmias.

Phenytoin is active against certain types of dysrhythmias. Antidysrhythmic applications are discussed in [Chapter 48](#).

25.6.1.4 Adverse Effects

25.6.1.4.1 Effects on the CNS.

Although phenytoin acts on the CNS in a relatively selective fashion to suppress seizures, the drug is not completely devoid of CNS side effects—especially

224

Figure 24-1 **Relationship between dose and plasma level for phenytoin compared with most other drugs.** **A,** Within the therapeutic range, small increments in phenytoin dosage produce sharp increases in plasma drug levels. This relationship makes it difficult to maintain plasma phenytoin levels within the therapeutic range. **B,** Within the therapeutic range, small increments in dosage of most drugs produce small increases in drug levels. With this relationship, moderate fluctuations in dosage are unlikely to result in either toxicity or loss of therapeutic effects.

when dosage is excessive. At therapeutic levels (10 to 20 mcg/mL), sedation and other CNS effects are mild. At plasma levels above 20 mcg/mL, toxicity can occur. Nystagmus (continuous back-and-forth movements of the eyes) is relatively common. Other manifestations of excessive dosage include sedation, ataxia (staggering gait), diplopia (double vision), and cognitive impairment.

25.6.1.4.2

Gingival Hyperplasia.

Gingival hyperplasia (excessive growth of gum tissue) is characterized by swelling, tenderness, and bleeding of the gums. This effect occurs in about 20% of patients. Gingival hyperplasia can be minimized by good oral hygiene, including dental flossing and gum massage. Patients should be taught these techniques and encouraged to practice them. In some cases, gingival hyperplasia is so great as to require gingivectomy (surgical removal of excess gum tissue).

25.6.1.4.3 Skin Rash.

Between 2% and 5% of patients develop a morbilliform (measles-like) rash. Rarely, morbilliform rash progresses to toxic epidermal necrolysis or Stevens-Johnson syndrome, an inflammatory skin disease characterized by red macules, papules, and tubercles. If a rash develops, phenytoin should be stopped.

25.6.1.4.4 Effects in Pregnancy.

Phenytoin is a teratogen in animals and humans. In animals, the drug can cause cleft palate, hydrocephalus, renal defects, and micromelia (small or shortened limbs). In humans, phenytoin can cause cleft palate, heart malformations, and *fetal hydantoin syndrome*, characterized by growth deficiency, motor or mental deficiency, microcephaly, craniofacial distortion, positional deformities of the limbs, hypoplasia of the nails and fingers, and impaired neurodevelopment. Accordingly, phenytoin should be used during pregnancy only if the benefits of seizure control outweigh the risk to the fetus.

Phenytoin can decrease synthesis of vitamin K–dependent clotting factors, and can thereby cause *bleeding tendencies in newborns*. The risk of neonatal bleeding can be decreased by giving the mother prophylactic vitamin K for 1 month prior to and during delivery, and to the infant immediately after delivery.

25.6.1.4.5 Cardiovascular Effects.

When phenytoin is administered by IV injection (to treat SE), cardiac dysrhythmias and hypotension may result. These dangerous responses can be minimized by injecting phenytoin slowly and in dilute solution.

25.6.1.4.6 Other Adverse Effects.

Hirsutism (overgrowth of hair in unusual places) can be a disturbing response, especially in young women. Interference with vitamin D metabolism may cause *rickets* and *osteomalacia* (softening of the bones). Interference with vitamin K metabolism can lower prothrombin levels, thereby causing *bleeding tendencies in newborns*. Very rarely, *liver damage* occurs, probably because of drug allergy.

25.6.1.5 Drug Interactions

Phenytoin interacts with a large number of drugs. The more important interactions are discussed below.

25.6.1.5.1 Interactions Resulting from Induction of Hepatic Drug-Metabolizing Enzymes.

Phenytoin stimulates synthesis of hepatic drug-metabolizing enzymes. As a result, phenytoin can decrease the effects of other drugs, including *oral contraceptives*, *warfarin* (an anticoagulant), and *glucocorticoids* (anti-inflammatory/immunosuppressive drugs). Because avoiding pregnancy is desirable while taking antiseizure medications, and because phenytoin can decrease the effectiveness of oral contraceptives, women should increase the contraceptive dosage, or switch to an alternative form of contraception.

25.6.1.5.2 Drugs That Increase Plasma Levels of Phenytoin.

Since the therapeutic range of phenytoin is narrow, slight increases in phenytoin levels can cause toxicity. Consequently, caution must be exercised when phenytoin is used with drugs that can increase its level. Drugs known to elevate phenytoin levels include *diazepam* (an antianxiety agent and AED), *isoniazid* (a drug for tuberculosis), *cimetidine* (a drug for gastric ulcers), and *alcohol* (when taken acutely). These agents increase phenytoin levels by reducing the rate at which phenytoin is metabolized. *Valproic acid* (an AED) elevates levels of free phenytoin by displacing phenytoin from binding sites on plasma proteins.

25.6.1.5.3 Drugs That Decrease Plasma Levels of Phenytoin.

Carbamazepine, *phenobarbital*, and *alcohol* (when used chronically) can accelerate the metabolism of phenytoin, thereby decreasing its level. Breakthrough seizures can result.

25.6.1.5.4 CNS Depressants.

The depressant effects of *alcohol*, *barbiturates*, and *other CNS depressants* will add with those of phenytoin. Advise patients to avoid alcohol and all other drugs with CNS-depressant actions.

225

25.6.1.6 Preparations, Dosage, and Administration

226

25.6.1.6.1 Preparations.

Phenytoin [Dilantin, Phenytek] is available in solution for injection and in four oral formulations: (1) 50-mg chewable tablets, marketed as *Dilantin Infatab*; (2) a 25-mg/mL oral suspension, marketed as *Dilantin-125*; (3) 100-mg prompt-acting capsules (generic only); and (4) 30- and 100-mg extended-release capsules, marketed as *Dilantin*, *Dilantin Kapseals*, and *Phenytek*. Phenytoin products made by different manufacturers have equivalent

bioavailability. Hence, although switching between products from different manufacturers was a concern in the past, it is not a concern today.

25.6.1.6.2 Dosage.

Dosing is highly individualized. Initial doses are usually given twice daily. Once a maintenance dosage has been established, once-a-day dosing is often possible (using extended-release capsules). For *adults*, a typical initial dosage is 150 mg twice a day; maintenance dosages usually range between 200 and 300 mg/day. For *children*, a typical initial dosage is 2.5 mg/kg twice a day; maintenance dosages usually range between 4 and 8 mg/kg/day.

Plasma drug levels are often monitored as an aid to dosage determination. *The dosing objective is to produce levels between 10 and 20 mcg/mL.* Levels below 10 mcg/mL are too low to control seizures; levels above 20 mcg/mL produce toxicity. Because phenytoin has a relatively narrow therapeutic range (between 10 and 20 mcg/mL), and because of the nonlinear relationship between phenytoin dosage and phenytoin plasma levels, *once a safe and effective dosage has been established, the patient should adhere to it rigidly.*

When treatment is discontinued, dosage should be reduced gradually. Abrupt withdrawal may precipitate seizures.

25.6.1.6.3 Administration.

Oral preparations may cause gastric discomfort. Patients should be informed that gastric upset can be reduced by administering phenytoin with or immediately after a meal. Patients using the oral suspension should shake it well before dispensing, since failure to do so can result in uneven dosing.

Intravenous administration is used to treat generalized convulsive SE. *It is imperative that infusions be performed slowly* (no faster than 50 mg/min). Why? Because rapid administration can cause cardiovascular collapse. Phenytoin should not be added to an existing IV infusion, since mixing phenytoin with other solutions is likely to produce a precipitate. Solutions of phenytoin are highly alkaline and can cause local venous irritation. Irritation can be reduced by flushing the IV needle or catheter with sterile saline immediately after completing the infusion.

25.6.2 Carbamazepine

Carbamazepine [Tegretol, Tegretol-XR, Carbatrol, Epitol, Equitro] is a cornerstone of epilepsy therapy. The drug is active against partial seizures and tonic-clonic seizures but not absence seizures.

25.6.2.1 Mechanism of Action

Carbamazepine suppresses high-frequency neuronal discharge in and around seizure foci. The mechanism appears to be the same as that of phenytoin: delayed recovery of sodium channels from their inactivated state.

25.6.2.2 Pharmacokinetics

Absorption of carbamazepine is delayed and variable. Peak levels are achieved in 4 to 12 hours. Overall bioavailability is about 80%. The drug distributes well to tissues.

Elimination is by hepatic metabolism. Carbamazepine is unusual in that its half-life decreases as therapy progresses. During the initial phase of treatment, the half-life is about 40 hours. The half-life decreases to about 15 hours with continued treatment. Why? Because carbamazepine, like phenytoin and phenobarbital, induces hepatic drug-metabolizing enzymes; by increasing its own metabolism, carbamazepine causes its own half-life to decline.

25.6.2.3 Therapeutic Uses

25.6.2.3.1 Epilepsy.

Carbamazepine is effective against tonic-clonic, simple partial, and complex partial seizures. Because the drug causes fewer adverse effects than phenytoin and phenobarbital, it is often preferred to these agents. Many prescribers consider carbamazepine the drug of first choice for partial seizures. Carbamazepine is not effective against absence, myoclonic, or atonic seizures.

25.6.2.3.2 Bipolar Disorder.

Carbamazepine can provide symptomatic control in patients with bipolar disorder (manicdepressive illness), and is often effective in patients who are refractory to lithium. The role of carbamazepine in bipolar disorder is discussed in [Chapter 33](#).

25.6.2.3.3 Trigeminal and Glossopharyngeal Neuralgias.

A neuralgia is a severe, stabbing pain that occurs along the course of a nerve. Carbamazepine can reduce neuralgia associated with the trigeminal and glossopharyngeal nerves. The mechanism is unknown. It should be noted that, although carbamazepine can reduce pain in these specific neuralgias, it is not generally effective as an analgesic, and is not indicated for other kinds of pain.

25.6.2.4 Adverse Effects

25.6.2.4.1 CNS Effects.

In contrast to phenytoin and phenobarbital, carbamazepine has minimal effects on cognitive function. This is a primary reason for selecting carbamazepine over these other drugs.

Carbamazepine can cause a variety of *neurologic effects*, including visual disturbances (nystagmus, blurred vision, diplopia), ataxia, vertigo, unsteadiness, and headache. These reactions are common during the first weeks of treatment, affecting 35% to 50% of patients. Fortunately, tolerance usually develops with continued use. These effects can be minimized by initiating therapy at low doses and giving the largest portion of the daily dose at bedtime.

25.6.2.4.2 Hematologic Effects.

Carbamazepine-induced bone marrow suppression can cause *leukopenia*, *anemia*, and *thrombocytopenia*. However, serious reactions are rare. Thrombocytopenia and anemia, which have an incidence of 5%, respond to drug discontinuation. Leukopenia, which has an incidence of 10%, is usually transient and subsides even with continued drug use; accordingly, carbamazepine should not be withdrawn unless the white blood cell count drops below 3000/mm³.

Fatal *aplastic anemia* has occurred during carbamazepine therapy. This reaction is extremely rare, having an incidence of 1 in 200,000. Very few cases have been reported since 1964, and in many of these, a direct cause-and-effect relationship could not be established.

To reduce the risk of serious hematologic effects, complete blood counts should be performed before treatment and periodically thereafter. Patients with pre-existing hematologic abnormalities should not use this drug. Patients should be informed about manifestations of hematologic abnormalities (fever, sore throat, pallor, weakness, infection, easy bruising, petechiae) and instructed to notify the prescriber if these occur.

25.6.2.4.3 Birth Defects.

Carbamazepine may be teratogenic. In humans, the drug is associated with an increased risk of neural tube defects. In mice, it has caused cleft palate, dilated cerebral ventricles, and growth retardation. Because it can harm the fetus, carbamazepine is classified in FDA Pregnancy Risk Category D, and hence should be used only if the benefits of seizure control are deemed to outweigh risks to the fetus.

25.6.2.4.4 Hypo-Osmolarity.

Carbamazepine can inhibit renal excretion of water, apparently by promoting secretion of antidiuretic hormone. Water retention can reduce the osmolarity of blood and other body fluids, thereby posing a threat to patients with heart failure. Periodic monitoring of serum sodium content is recommended.

25.6.2.4.5 Dermatologic Effects.

Carbamazepine has been associated with several dermatologic effects, including morbilliform rash (10% incidence), photosensitivity reactions, Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN). Mild reactions can often be treated with prednisone (an anti-inflammatory agent) or an antihistamine. Severe reactions—SJS and TEN—necessitate drug withdrawal.

A major risk factor for severe skin reactions is a genetic variation known as *human leukocyte antigen (HLA)-B*1502*, which occurs primarily in people of Asian descent. Among people with the variant gene, about 5% develop SJS or TEN when taking carbamazepine.

Accordingly, to reduce the risk of severe reactions, the FDA recommends that, before receiving carbamazepine, patients of Asian descent be tested for HLA-B*1502. Of note, this is the first time that the FDA has recommended genetic screening for a major drug.

25.6.2.5 Drug-Drug and Drug-Food Interactions

25.6.2.5.1 Induction of Drug-Metabolizing Enzymes.

Carbamazepine is an effective inducer of hepatic drug-metabolizing enzymes. By promoting synthesis of these enzymes, carbamazepine can increase the rate at which it and other drugs are inactivated. Accelerated inactivation of *oral contraceptives* and *warfarin* is of particular concern.

25.6.2.5.2 Phenytoin and Phenobarbital.

Both phenytoin and phenobarbital are effective inducers of hepatic drug metabolism. Hence, if either drug is taken with carbamazepine, induction of metabolism is likely to be greater than with carbamazepine alone. Accordingly, phenytoin and phenobarbital can further accelerate the metabolism of carbamazepine, thereby decreasing its effects.

TABLE 24-4 Oral Preparations of Valproic Acid and Its Derivatives

Chemical Form	Trade Name	Product Description	Comments
Valproic acid	Depakene	Capsules (250 mg)	Immediate release; GI upset is common.
	Stavzor	Capsule, delayed-release, enteric-coated (125, 250, 500 mg)	Capsule is smaller than Depakote and Depakote ER tablets, and hence easier to swallow. Enteric coating may reduce GI upset, but there are no clinical data to show that Stavzor is better tolerated than Depakene.
Valproate sodium	Depakene	Syrup (250 mg/5 mL)	Immediate release; GI upset is common.
Divalproex sodium	Depakote	Tablets, delayed-release, enteric-coated (125, 250, 500 mg)	Released over 8–12 hr, and hence <i>not</i> for once-daily administration. <i>Not interchangeable with Depakote ER</i> (extended-release tablets) because rate of drug release is different. Less GI upset than Depakene.
	Depakote ER	Tablets, extended-release, enteric-coated (250 and 500 mg)	Released over 18–24 hr, and hence <i>can</i> be administered once daily. <i>Not interchangeable with regular Depakote</i> (delayed-release tablets) because rate of drug release is different. Not approved for epilepsy (but is used anyway). Less GI upset than Depakene.
	Depakote	“Sprinkle” capsules containing enteric-coated granules (125 mg)	Immediate release. Less GI upset than Depakene. May swallow capsule whole or open and sprinkle granules on a small amount (1 tsp) of soft food.

25.6.2.5.3 Grapefruit Juice.

As discussed in [Chapter 6](#), grapefruit juice can inhibit the metabolism of many drugs, thereby causing their plasma levels to rise. Grapefruit juice can increase peak and trough levels of

carbamazepine by 40%. Accordingly, patients taking the drug should be advised to avoid grapefruit juice.

25.6.2.6 Preparations, Dosage, and Administration

Carbamazepine [Tegretol, Tegretol-XR, Carbatrol, Epitol, Equitrol] is available in immediate-release tablets (200 mg), sold as *Tegretol* and *Epitol*; chewable tablets (100 mg), sold as *Tegretol*; extended-release tablets (100, 200, and 400 mg), sold as *Tegretol-XR*; extended-release capsules (200 and 300 mg), sold as *Carbatrol* and *Equitrol*; and an oral suspension (20 mg/mL), sold as *Tegretol*. The drug should be administered with meals to reduce gastric upset. Administering the largest portion of the daily dose at bedtime can help reduce adverse CNS effects. Carbamazepine suspension should not be administered with other liquid-formulation medicines.

Therapy is initiated with small doses (100 to 200 mg twice a day) to minimize side effects. Dosage is then increased gradually (every 1 to 3 weeks) until seizure control is achieved. Maintenance dosages for *adults* range from 600 to 1800 mg/day, administered in divided doses. Maintenance dosages for *children* range from 10 to 35 mg/kg/day, administered in divided doses.

25.6.3 Valproic Acid

Valproic acid [Depakene, Depakote, Depacon, Stavzor] is an important AED used widely to treat all major seizure types. Serious adverse effects are limited to rare cases of severe hepatotoxicity and pancreatitis, both of which can be fatal. In addition to its use in epilepsy, valproic acid is used for bipolar disorder and prevention of migraine.

25.6.3.1 Nomenclature

Valproic acid is available in three closely related chemical forms ([Table 24-4](#)): (1) valproic acid itself, (2) the sodium salt of valproic acid, known as *valproate*, and (3) *divalproex sodium*, a combination of valproic acid plus its sodium salt. All three forms have identical antiseizure actions. In this chapter, the term *valproic acid* is used in reference to all three forms.

227

25.6.3.2 Mechanism of Action

Valproic acid appears to act by three mechanisms. First, it shares the same mechanism as phenytoin and carbamazepine: suppression of high-frequency neuronal firing through blockade of sodium channels. Second, it suppresses calcium influx through T-type calcium channels. Third, it may augment the inhibitory influence of GABA.

228

25.6.3.3 Pharmacokinetics

Valproic acid is readily absorbed from the GI tract and is widely distributed throughout the body. The drug undergoes extensive hepatic metabolism followed by renal excretion.

Therapeutic responses are often seen at plasma levels of 40 to 100 mcg/mL. However, the correlation between plasma levels and therapeutic effects is not very tight.

25.6.3.4 Therapeutic Uses

25.6.3.4.1 Seizure Disorders.

Valproic acid is considered a first-line drug for all partial and generalized seizures.

25.6.3.4.2 Bipolar Disorder.

Like carbamazepine, valproic acid can provide symptomatic control in patients with bipolar disorder (manic-depressive illness). This application is discussed in [Chapter 33](#).

25.6.3.4.3 Migraine.

Valproic acid is approved for prophylaxis of migraine (see [Chapter 30](#)).

25.6.3.5 Adverse Effects

Valproic acid is generally well tolerated and causes minimal sedation and cognitive impairment. Gastrointestinal effects are most common. Hepatotoxicity and pancreatitis are rare but serious.

25.6.3.5.1 Gastrointestinal Effects.

Nausea, vomiting, and indigestion are common but transient. These effects are most intense with formulations that are not enteric coated. Gastrointestinal reactions can be minimized by administering valproic acid with food and by using an enteric-coated product (see [Table 24-4](#)).

25.6.3.5.2 Hepatotoxicity.

Rarely, valproic acid has been associated with fatal liver failure. Most deaths have occurred within the first few months of therapy. The overall incidence of fatal hepatotoxicity is about 1 in 40,000. However, in high-risk patients—children under the age of 2 years receiving multidrug therapy—the incidence is much higher: 1 in 500. To minimize the risk of fatal liver injury, the following guidelines have been established:

- Don't use valproic acid in conjunction with other drugs in children under 2 years old.
- Don't use valproic acid in patients with pre-existing liver dysfunction.
- Evaluate liver function at baseline and periodically thereafter. (Unfortunately, monitoring liver function may fail to provide advance warning of severe hepatotoxicity: Fatal liver failure can develop so rapidly that it is not preceded by an abnormal test result.)
- Inform patients about signs and symptoms of liver injury (reduced appetite, malaise, nausea, abdominal pain, jaundice) and instruct them to notify the prescriber if these develop.
- Use valproic acid in the lowest effective dosage.

25.6.3.5.3 Pancreatitis.

Life-threatening pancreatitis has developed in children and adults. Some cases have been hemorrhagic, progressing rapidly from initial symptoms to death. Pancreatitis can develop soon after starting therapy or after years of drug use. Patients should be informed about signs of pancreatitis (abdominal pain, nausea, vomiting, anorexia) and instructed to obtain immediate evaluation if these develop. If pancreatitis is diagnosed, valproic acid should be withdrawn, and alternative medication should be substituted as indicated.

25.6.3.5.4 Teratogenic Effects.

Like most other AEDs, valproic acid can harm the developing fetus. Neural tube defects (eg, spina bifida) are the greatest concern, with an incidence of 1% to 2%. Women of child-bearing age should use an effective form of contraception, and should take folic acid supplements (5 mg/day), which can help protect against neural tube damage in case pregnancy occurs. Valproic acid is classified in FDA Pregnancy Risk Category D: There is evidence of human fetal risk, but the drug may be used during pregnancy if the potential benefits are considered to outweigh the risks to the fetus.

25.6.3.5.5 Hyperammonemia.

Combining valproic acid with topiramate poses a risk of hyperammonemia (excessive ammonia in the blood), which may occur with or without encephalopathy. Symptoms include vomiting, lethargy, altered level of consciousness, and altered cognitive function. If these symptoms develop, hyperammonemic encephalopathy should be suspected, and blood ammonia should be measured. As a rule, symptoms abate following removal of either drug.

25.6.3.5.6 Other Adverse Effects.

Valproic acid may cause *rash*, *weight gain*, *hair loss*, *tremor*, and *blood dyscrasias* (leukopenia, thrombocytopenia, red blood cell aplasia). Significant CNS effects are uncommon.

25.6.3.6 Drug Interactions

25.6.3.6.1 Phenobarbital.

Valproic acid decreases the rate at which phenobarbital is metabolized. Blood levels of phenobarbital may rise by 40%, resulting in significant CNS depression. When the combination is used, levels of phenobarbital should be monitored and, if they rise too high, phenobarbital dosage should be reduced.

25.6.3.6.2 Phenytoin.

Valproic acid can displace phenytoin from binding sites on plasma proteins. The resultant increase in free phenytoin may lead to toxicity. Phenytoin levels and clinical status should be monitored.

25.6.3.6.3 Topiramate.

See discussion of *Hyperammonemia* above.

25.6.3.7 Preparations, Dosage, and Administration

25.6.3.7.1 Preparations.

Valproic acid is available in several oral formulations (see [Table 24-4](#)) and in a 100-mg/mL solution [Depacon] for IV use.

25.6.3.7.2 Oral Dosage and Administration.

Daily doses are small initially and then gradually increased. For *adults and older children*, the initial dosage is 5 to 15 mg/kg/day, usually administered in two divided doses. The usual maintenance dosage is 0.75 to 3 gm/day. For *children ages 1 to 12 years*, the initial dosage is 10 to 30 mg/kg/day, usually administered in divided doses. The usual maintenance dosage is 15 to 45 mg/kg/day. For both adults and children, the dosage should be increased if phenobarbital or another inducer of hepatic drug metabolism is taken concurrently.

Patients should be instructed to swallow the tablets and capsules intact, without chewing or crushing. Gastric discomfort can be decreased by administering valproic acid with meals and by using an enteric-coated formulation.

25.6.4 Ethosuximide

25.6.4.1 Therapeutic Use.

Ethosuximide [Zarontin] is a drug of choice for absence seizures, the only indication the drug has. Absence seizures are abolished in 60% of patients, and, in newly diagnosed patients, practical control is achieved in 80% to 90%. Ethosuximide is inactive against tonic-clonic, simple partial, and complex partial seizures.

25.6.4.2 Mechanism of Action.

Ethosuximide suppresses neurons in the thalamus that are responsible for generating absence seizures. The specific mechanism is inhibition of low-threshold calcium currents, known as T currents. Ethosuximide does not block sodium channels and does not enhance GABA-mediated neuronal inhibition.

25.6.4.3 Pharmacokinetics.

Ethosuximide is well absorbed following oral administration. Therapeutic plasma levels range between 40 and 100 mcg/mL. The drug is eliminated by a combination of hepatic metabolism and renal excretion. Its half-life is 60 hours in adults and 30 hours in children. Ethosuximide does not induce drug-metabolizing enzymes.

228

25.6.4.4 Adverse Effects and Drug Interactions.

229

Ethosuximide is generally devoid of significant adverse effects and interactions. During initial treatment, it may cause *drowsiness*, *dizziness*, and *lethargy*. These diminish with continued use. *Nausea* and *vomiting* may occur and can be reduced by administering the drug with food. Rare but serious reactions include *systemic lupus erythematosus*, *leukopenia*, *aplastic anemia*, and *Stevens-Johnson syndrome*.

25.6.4.5 Preparations, Dosage, and Administration.

Ethosuximide [Zarontin] is available in capsules (250 mg) and in a syrup (250 mg/5 mL). For *children ages 3 to 6 years*, the initial dosage is 250 mg/day. For *older children and adults*, the initial dosage is 500 mg/day. Dosage should be gradually increased until control of seizures is

obtained. The usual maintenance dosage is 750 mg/day for adults, and between 15 and 40 mg/kg/day for children. Because ethosuximide has a long half-life, dosing can be done just once a day. However, dosing twice a day is better tolerated.

Since absence seizures occur many times each day, monitoring the clinical response rather than plasma drug levels is the preferred method for dosage determination. Dosage should be increased until seizures have been controlled or until adverse effects become too great.

When withdrawing ethosuximide, dosage should be reduced gradually.

25.6.5 Phenobarbital

Phenobarbital is one of our oldest AEDs. The drug is effective, is inexpensive, and can be administered just once a day. Unfortunately, certain side effects—lethargy, depression, learning impairment—can be significant. Hence, although phenobarbital was used widely in the past, it has largely been replaced by newer drugs that are equally effective but better tolerated.

Phenobarbital belongs to the barbiturate family. However, in contrast to most barbiturates, which produce generalized depression of the CNS, phenobarbital is able to suppress seizures at doses that produce only moderate disruption of CNS function. Because it can reduce seizures without causing sedation, phenobarbital is classified as an *anticonvulsant barbiturate* (to distinguish it from most other barbiturates, which are employed as daytime sedatives or “sleeping pills”).

The basic pharmacology of the barbiturates is discussed in [Chapter 34](#). Discussion here is limited to the use of phenobarbital for seizures.

25.6.5.1 Mechanism of Antiseizure Action

Phenobarbital suppresses seizures by potentiating the effects of GABA. Specifically, the drug binds to GABA receptors, causing the receptor to respond more intensely to GABA itself.

25.6.5.2 Pharmacokinetics

Phenobarbital is administered orally, and absorption is complete. Elimination occurs through hepatic metabolism and renal excretion. Phenobarbital has a *long half-life*—about 4 days. As a result, once-daily dosing is adequate for most patients. In addition to permitting once-daily dosing, the long half-life has another consequence: 2 to 3 weeks are required for plasma levels to reach plateau. (Recall that, in the absence of a loading dose, an interval equivalent to four half-lives is required to reach plateau.)

25.6.5.3 Therapeutic Uses

25.6.5.3.1 Epilepsy.

Phenobarbital is effective against partial seizures and generalized tonic-clonic seizures but not absence seizures. In the past, phenobarbital was a drug of choice for tonic-clonic seizures and partial seizures in older children and adults. However, most clinicians now prefer to treat these epilepsies with carbamazepine, phenytoin, or valproic acid—drugs that cause fewer neuropsychologic effects than phenobarbital. Intravenous phenobarbital can be used for generalized convulsive SE, but lorazepam and phenytoin are preferred.

25.6.5.3.2 Sedation and Induction of Sleep.

Like other barbiturates, phenobarbital can be used for daytime sedation and to promote sleep at night. These applications are discussed in [Chapter 34](#).

25.6.5.4 Adverse Effects

25.6.5.4.1 Neuropsychologic Effects.

Drowsiness is the most common CNS effect. During the initial phase of therapy, sedation develops in practically all patients. With continued treatment, tolerance to sedation develops. Some children experience paradoxical responses: Instead of becoming sedated, they may become irritable and hyperactive. Depression may occur in adults. Elderly patients may experience agitation and confusion.

25.6.5.4.2 Physical Dependence.

Like all other barbiturates, phenobarbital can cause physical dependence. However, at the doses employed to treat epilepsy, significant dependence is unlikely.

25.6.5.4.3 Exacerbation of Intermittent Porphyria.

Phenobarbital and other barbiturates can increase the risk of acute intermittent porphyria. Accordingly, barbiturates are absolutely contraindicated for patients with a history of this disorder. The relationship of barbiturates to intermittent porphyria is discussed further in [Chapter 34](#).

25.6.5.4.4 Use in Pregnancy.

Use of phenobarbital during pregnancy poses a significant risk of major fetal malformations. Women who take phenobarbital during pregnancy or become pregnant while taking the drug should be informed of the potential risk to the fetus.

Like phenytoin, phenobarbital can decrease synthesis of vitamin K–dependent clotting factors, and can thereby cause *bleeding tendencies in newborns*. The risk of neonatal bleeding can be decreased by administering vitamin K to the mother for 1 month prior to delivery and during delivery, and to the infant immediately after delivery.

25.6.5.4.5 Other Adverse Effects.

Like phenytoin, phenobarbital can interfere with the metabolism of vitamins D and K. Disruption of vitamin D metabolism can cause *rickets* and *osteomalacia*.

25.6.5.5 Toxicity

When taken in moderately excessive doses, phenobarbital causes nystagmus and ataxia. Severe overdose produces generalized CNS depression; death results from depression of respiration. Barbiturate toxicity and its treatment are discussed at length in [Chapter 34](#).

25.6.5.6 Drug Interactions

25.6.5.6.1 Induction of Drug-Metabolizing Enzymes.

Phenobarbital induces hepatic drug-metabolizing enzymes, and can thereby accelerate the metabolism of other drugs, causing a loss of therapeutic effects. This is of particular concern with oral contraceptives and warfarin.

25.6.5.6.2 CNS Depressants.

Being a CNS depressant itself, phenobarbital can intensify CNS depression caused by other drugs (eg, alcohol, benzodiazepines, opioids). Severe respiratory depression and coma could result. Patients should be warned against combining phenobarbital with other drugs that have CNS-depressant actions.

25.6.5.6.3 Valproic Acid.

Valproic acid is an AED that has been used in combination with phenobarbital. By competing with phenobarbital for drug-metabolizing enzymes, valproic acid can increase plasma levels

of phenobarbital by approximately 40%. Hence, when this combination is used, the dosage of phenobarbital must be reduced.

25.6.5.7 Drug Withdrawal

When phenobarbital is withdrawn, *dosage should be reduced gradually*, since abrupt withdrawal can precipitate SE. Patients should be warned of this danger and instructed not to discontinue phenobarbital too quickly.

25.6.5.8 Preparations, Dosage, and Administration

25.6.5.8.1 Preparations.

Phenobarbital is available in three oral formulations—tablets, capsules, and elixir—and in solution (as Luminal) for IM and IV administration.

25.6.5.8.2 Dosage.

Adult maintenance dosages range from 60 to 120 mg/day administered as a single dose or two divided doses. *Pediatric* maintenance dosages range from 3 to 6 mg/kg/day. When dosage is being established, plasma drug levels may be used as a guide; target levels are 15 to 45 mcg/mL.

Loading doses may be needed. Because phenobarbital has a long half-life, several weeks are required for drug levels to reach plateau. If plateau must be reached sooner, a loading schedule can be employed. For example, doses that are twice normal can be given for 4 days. Unfortunately, these large doses are likely to produce substantial CNS depression.

25.6.5.8.3 Administration.

Phenobarbital may be administered orally, IV, or IM. Oral administration is employed for routine therapy. Intravenous administration is needed for SE. Intramuscular administration is used only when oral dosing is not feasible.

Intravenous injection must be done slowly. If done too fast, excessive CNS depression may result. Phenobarbital is highly alkaline and may cause local tissue injury if extravasation occurs.

25.6.6 Primidone

Primidone [Mysoline] is active against all major seizure disorders except absence seizures. The drug is nearly identical in structure to phenobarbital. As a result, the pharmacology of both agents is very similar.

229

25.6.6.1 Pharmacokinetics.

230

Primidone is readily absorbed following oral administration. In the liver, much of the drug undergoes conversion to two active metabolites: phenobarbital and phenylethylmalonamide. Seizure control is produced by primidone itself and by its metabolites. Therapeutic plasma levels range from 5 to 15 mcg/mL.

25.6.6.2 Therapeutic Uses.

Primidone is effective against tonic-clonic, simple partial, and complex partial seizures. The drug is not active against absence seizures.

As a rule, primidone is employed in combination with another AED, usually phenytoin or carbamazepine. Primidone is never taken together with phenobarbital. Why? Because phenobarbital is an active metabolite of primidone, and hence concurrent use would be irrational.

25.6.6.3 Adverse Effects.

Sedation, ataxia, and dizziness are common during initial treatment but diminish with continued drug use. Like phenobarbital, primidone can cause confusion in the elderly and paradoxical hyperexcitability in children. A sense of acute intoxication can occur shortly after administration. As with phenobarbital, primidone is absolutely contraindicated for patients with acute intermittent porphyria. Serious adverse reactions (acute psychosis, leukopenia, thrombocytopenia, systemic lupus erythematosus) can occur but are rare.

25.6.6.4 Drug Interactions.

Drug interactions for primidone are similar to those for phenobarbital. Primidone can induce hepatic drug-metabolizing enzymes and can thereby reduce the effects of oral contraceptives, warfarin, and other drugs. In addition, primidone can intensify responses to other CNS depressants.

25.6.6.5 Preparations, Dosage, and Administration.

Primidone [Mysoline] is available in 50- and 250-mg tablets. Therapy in *adults* is initiated with 100 to 125 mg at bedtime. Dosage is gradually increased over the next 10 days to a maintenance level of 250 mg 2 or 3 times a day. The maximum dosage is 500 mg 4 times a day.

25.7 NEWER ANTIEPILEPTIC DRUGS

The group of newer AEDs has seven principal members: gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, and zonisamide. The oldest of these—gabapentin—was introduced in 1993, and the most recent—zonisamide—was introduced in 2000. Although most newer AEDs have not been compared directly with the traditional AEDs (or with each other, for that matter), all of these drugs appear equally effective. However, because clinical experience with the newer drugs is still limited, they are prescribed less often than the traditional AEDs. Oxcarbazepine and lamotrigine are the primary exceptions to this rule.

Do the newer AEDs have properties that make them appealing? Certainly. As a group, they are better tolerated than the traditional AEDs, and may pose a smaller risk to the developing fetus. Furthermore, only one—oxcarbazepine—induces drug-metabolizing enzymes, and hence interactions with other drugs, including other AEDs, are relatively minor.

The subject of approved indications for the newer AEDs requires comment. When these drugs were introduced, FDA-approved indications were limited to *adjunctive* therapy of certain seizure disorders. None of these drugs was approved for *monotherapy*. Why? Because clinical trials were limited to patients who were refractory to traditional AEDs. When the trials were conducted, rather than switching patients from a traditional AED to the experimental AED, the experimental AED was *added* to the existing regimen. Hence, when the trials were completed, all we knew for sure was that the new AED was effective when used together with an older AED. We had no data on use of the newer AED alone. As a result, the FDA had no option but to approve the new drug for adjunctive therapy. Since being released, several of the newer AEDs have received FDA approval for monotherapy.

To help prescribers be more comfortable with the newer AEDs, two organizations—the American Academy of Neurology (AAN) and American Epilepsy Society (AES)—convened a panel to evaluate the efficacy and tolerability of these drugs. For some of the newer AEDs, the AAN/AES panel recommended uses not yet approved by the FDA. These recommendations, along with FDA-approved indications, are discussed below.

25.7.1 Oxcarbazepine

25.7.1.1 Actions and Uses.

Oxcarbazepine [Trileptal], a derivative of carbamazepine, is indicated for monotherapy and adjunctive therapy of partial seizures in adults and children. The drug is as effective as carbamazepine and better tolerated. However, it's also more expensive. Antiseizure effects result from blockade of voltage-sensitive sodium channels in neuronal membranes, an action that stabilizes hyperexcitable neurons and thereby suppresses seizure spread. The drug does not affect neuronal GABA receptors.

25.7.1.2 Pharmacokinetics.

Oxcarbazepine is well absorbed both in the presence and absence of food. In the liver, the drug undergoes rapid conversion to a 10-monohydroxy metabolite (MHD), its active form. MHD has a half-life of 9 hours and undergoes excretion in the urine.

25.7.1.3 Adverse Effects.

The most common adverse effects are dizziness (22% to 49%), drowsiness (19% to 36%), double vision (14% to 40%), nystagmus (7% to 26%), headache (13% to 32%), nausea (15% to 29%), vomiting (7% to 36%), and ataxia (5% to 31%). Patients should avoid driving and other hazardous activities, unless the degree of drowsiness is low.

Clinically significant *hyponatremia* (sodium concentration less than 125 mmol/L) develops in 2.5% of patients. Signs include nausea, drowsiness, headache, and confusion. If oxcarbazepine is combined with other drugs that can decrease sodium levels (especially diuretics), monitoring of sodium levels may be needed.

Like carbamazepine, oxcarbazepine can cause *serious skin reactions*, including Stevens-Johnson syndrome and toxic epidermal necrolysis. There is 30% cross sensitivity among patients with hypersensitivity to carbamazepine. Accordingly, patients with a history of severe reactions to either drug should probably not use the other.

Oxcarbazepine has not caused the severe hematologic abnormalities seen with carbamazepine. Accordingly, routine monitoring of blood counts is not required.

Oxcarbazepine has been associated with serious *multiorgan hypersensitivity reactions*. Although manifestations are varied, patients typically present with fever and rash, associated with one or more of the following: lymphadenopathy, hematologic abnormalities, pruritus, hepatitis,

nephritis, hepatorenal syndrome, oliguria, arthralgia, or asthenia. If this reaction is suspected, oxcarbazepine should be discontinued.

25.7.1.4 Use in Pregnancy and Breast-Feeding.

Like carbamazepine (FDA Pregnancy Risk Category D), oxcarbazepine (FDA Pregnancy Risk Category C) may pose a risk of birth defects. Accordingly, women of child-bearing age should use effective contraception. Clearly, the drug should be avoided by women who are already pregnant. In addition, since both oxcarbazepine and its metabolite are excreted in breast milk, the drug should be avoided by women who are breast-feeding.

25.7.1.5 Drug Interactions.

Oxcarbazepine induces some drug-metabolizing enzymes and inhibits others. It does not induce enzymes that metabolize other AEDs. However, it does induce enzymes that metabolize *oral contraceptives*, and can thereby render them less effective. Accordingly, women should employ an alternative birth control method.

Oxcarbazepine inhibits the enzymes that metabolize phenytoin, and can thereby raise phenytoin levels. Toxicity can result. Phenytoin levels should be monitored and dosage adjusted accordingly.

Drugs that induce drug-metabolizing enzymes (eg, phenytoin, phenobarbital, carbamazepine) can reduce levels of MHD, the active form of oxcarbazepine. Accordingly, dosage of oxcarbazepine may need to be increased.

Alcohol can intensify CNS depression caused by oxcarbazepine, and hence should be avoided.

As noted, oxcarbazepine should be used with caution in patients taking *diuretics* and other drugs that can lower sodium levels.

25.7.1.6 Preparations, Dosage, and Administration.

Oxcarbazepine [Trileptal] is available in film-coated tablets (150, 300, and 600 mg) and an oral suspension (60 mg/mL).

For *monotherapy in adults*, the initial dosage is 300 mg twice daily. The maximum dosage is 1200 mg twice daily.

For *adjunctive therapy in adults*, the initial dosage is 300 mg twice daily. The maximum dosage is 600 mg twice daily.

230

231

For *monotherapy in children* (ages 4 to 16), the initial dosage is 8 to 10 mg/kg/day in two divided doses. Maintenance dosages are related to body weight (see manufacturer's recommendations).

For *adjunctive therapy in children* (ages 2 to 16), the initial dosage is 8 to 10 mg/kg/day in two divided doses. Maintenance dosages are related to body weight: For children weighing 20 to 29 kg, the dosage is 900 mg/day; for children weighing 29.1 to 30 kg, the dosage is 1200 mg/day; and for children weighing above 39 kg, the dosage is 1800 mg/day.

25.7.2 Lamotrigine

25.7.2.1 Therapeutic Uses.

Lamotrigine [Lamictal], introduced in 1994, has a broad spectrum of antiseizure activity. The drug is FDA approved for (1) adjunctive therapy of partial seizures in adults and children over 2 years old, (2) adjunctive therapy of generalized seizures associated with Lennox-Gastaut syndrome in adults and children over 2 years old, (3) adjunctive therapy of primary generalized tonic-clonic seizures in adults and children over 2 years old, and (4) monotherapy of partial seizures in patients at least 16 years old who are converting from another AED. In addition, the AAN/AES guidelines recommend using lamotrigine for absence seizures. Lamotrigine is also FDA approved for long-term maintenance therapy of bipolar disorder (see [Chapter 33](#)). Investigational uses include myoclonic, absence, and temporal lobe seizures.

25.7.2.2 Mechanism of Action.

Benefits derive mainly from blockade of sodium channels and partly from blockade of calcium channels. Both actions decrease release of glutamate, an excitatory neurotransmitter.

25.7.2.3 Pharmacokinetics.

Administration is oral, and absorption is nearly complete both in the presence and absence of food. Blood levels peak in 1.5 to 5 hours and decline with a half-life of 24 hours. The drug undergoes hepatic metabolism followed by renal excretion.

25.7.2.4 Drug Interactions.

The half-life is dramatically affected by drugs that induce or inhibit hepatic drug-metabolizing enzymes. Enzyme inducers (eg, carbamazepine, phenytoin, phenobarbital) decrease the half-life of lamotrigine to 10 hours, whereas valproate (an enzyme inhibitor) increases the half-life to about 60 hours. Lamotrigine itself is not an inducer or inhibitor of drug-metabolizing enzymes.

25.7.2.5 Adverse Effects.

Lamotrigine can cause *life-threatening rashes*, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Deaths have occurred. The incidence of severe rash is about 0.8% in patients under 16 years old and 0.3% in adults. Concurrent use of valproic acid increases risk. If a rash develops, lamotrigine should be withdrawn immediately.

In addition to severe rash, lamotrigine commonly causes dizziness, diplopia (double vision), blurred vision, nausea, vomiting, and headache. When used during pregnancy, lamotrigine may pose a small risk of cleft lip and cleft palate. Whether the drug poses other risks in pregnancy or in breast-feeding has not been determined.

25.7.2.6 Preparations, Dosage, and Administration.

Lamotrigine [Lamictal] is available in standard tablets (25, 100, 150, and 200 mg) and chewable dispersible tablets (2, 5, and 25 mg). The dosage depends on which other AEDs are being taken. For patients taking an *inducer* of drug metabolism (eg, carbamazepine, phenytoin, phenobarbital), dosing is begun at 50 mg/day, and then gradually increased to between 150 and 500 mg twice a day for maintenance. For patients taking *valproate* (an enzyme inhibitor), dosing is begun at 25 mg every other day, and then gradually increased to between 50 and 75 mg twice daily for maintenance.

25.7.3 Gabapentin

25.7.3.1 Therapeutic Uses.

Gabapentin [Neurontin], introduced in 1993, has a broad spectrum of antiseizure activity. However, its only FDA-approved use in epilepsy is adjunctive therapy of partial seizures (with or without secondary generalization). The AAN/AES guidelines also recommend the drug for monotherapy of partial seizures. In 2002, gabapentin was approved for treating postherpetic neuralgia. Interestingly, more than 80% of prescriptions are written for off-label uses, including relief of neuropathic pain (other than postherpetic neuralgia), prophylaxis of migraine, and relief of postmenopausal hot flashes. The drug does not appear effective in bipolar disorder.

25.7.3.2 Mechanism of Action.

Gabapentin's precise mechanism of action is unknown. The drug is an analog of GABA, but does not directly affect GABA receptors. Rather, it may enhance GABA release, thereby increasing GABA-mediated inhibition of neuronal firing.

25.7.3.3 Pharmacokinetics.

Gabapentin is rapidly absorbed following oral administration and reaches peak plasma levels in 2 to 3 hours. Absorption is not affected by food. However, as the dosage gets larger, the percentage absorbed gets smaller. Why? Because at high doses, the intestinal transport system for uptake of the drug becomes saturated. Gabapentin is not metabolized and is excreted intact in the urine. Its half-life is 5 to 7 hours.

25.7.3.4 Drug Interactions.

Unlike most AEDs, gabapentin is devoid of significant interactions. It doesn't induce or inhibit drug-metabolizing enzymes, and doesn't affect the metabolism of other drugs. As a result, gabapentin is well suited for combined use with other AEDs.

25.7.3.5 Adverse Reactions.

Gabapentin is very well tolerated. The most common side effects are somnolence, dizziness, ataxia, fatigue, nystagmus, and peripheral edema. These are usually mild to moderate and often diminish with continued drug use. Patients should avoid driving and other hazardous activities until they are confident they are not impaired. Safety in pregnancy and breast-feeding has not been established.

25.7.3.6 Preparations, Dosage, and Administration.

Gabapentin [Neurontin] is available in capsules (100, 300, and 400 mg), tablets (600 and 800 mg), and an oral solution (50 mg/mL). Dosing for adults begins with a 300-mg dose at bedtime, followed the next day by 600 mg (in two divided doses), and the next day by 900 mg (in three divided doses). Thereafter, the dosage can be raised rapidly to maintenance levels, typically 1200 to 3600 mg/day in three divided doses. Dosage should be reduced in patients with renal impairment.

25.7.4 Pregabalin

Pregabalin [Lyrica], an analog of GABA, is much like gabapentin. Like gabapentin, pregabalin is used for seizures and neuropathic pain. In addition, pregabalin is approved for fibromyalgia. Pregabalin has very few interactions with other drugs, but adverse effects are common, especially dizziness and sleepiness. Unlike most other antiseizure agents, pregabalin is regulated under the Controlled Substances Act. The drug was introduced in 2005.

25.7.4.1 Therapeutic Uses.

Pregabalin has four approved indications: neuropathic pain associated with diabetic neuropathy, postherpetic neuralgia, adjunctive therapy of partial seizures, and fibromyalgia. Of the four indications, fibromyalgia deserves special comment. The disorder is a chronic condition characterized by generalized muscle pain, fatigue, and disturbed sleep. In 2007, pregabalin became the first drug approved for treatment. Unfortunately, benefits are modest. In clinical trials, pregabalin produced a 50% reduction in pain in 28% of patients, compared with 13% of patients taking placebo. Also, for many patients with fibromyalgia, benefits fade within weeks or months.

25.7.4.2 Mechanism of Action.

Although the precise mechanism of action has not been established, we do know that pregabalin can bind with calcium channels on nerve terminals, and can thereby inhibit calcium influx, which in turn can inhibit release of several neurotransmitters, including glutamate, norepinephrine, and substance P. Reduced transmitter release may underlie seizure control and relief of neuropathic pain. Although pregabalin is an analog of GABA, the drug does not bind with GABA receptors or benzodiazepine receptors, and hence does not work by mimicking or enhancing the inhibitory actions of GABA.

25.7.4.3 Pharmacokinetics.

Pregabalin is well absorbed after oral administration. Plasma levels peak 1.5 hours after dosing. 231

Food reduces the rate of absorption but not the extent. Oral bioavailability is 90% or greater. 232

Pregabalin does not bind with plasma proteins, but does cross the blood-brain and placental barriers. Elimination is renal, 98% as unchanged drug. Metabolism is negligible. The half-life is 6.3 hours.

25.7.4.4 Adverse Effects.

Pregabalin can cause a variety of adverse effects. The most common are dizziness (29%) and somnolence (22%), which often persist as long as the drug is being taken. Blurred vision (6%) develops early, but resolves with continued drug use. About 8% of patients experience significant weight gain (7% or more of body weight in just a few months). Other adverse effects include difficulty thinking (6%), headache (5%), peripheral edema (6%), and dry mouth (4%).

In clinical trials, three patients developed rhabdomyolysis (muscle breakdown). However, it is not clear that pregabalin was the cause. Nonetheless, patients should be instructed to report

signs of muscle injury (pain, tenderness, weakness). If rhabdomyolysis is diagnosed, or even suspected, pregabalin should be withdrawn.

25.7.4.5 Abuse Potential and Physical Dependence.

In clinical trials, 4% to 12% of patients reported euphoria as an adverse effect. When given to recreational users of sedative-hypnotic drugs, pregabalin produced subjective effects perceived as similar to those of diazepam [Valium]. On the basis of these data, the Drug Enforcement Agency has classified pregabalin under Schedule V of the Controlled Substances Act.

Abrupt discontinuation can cause insomnia, nausea, headache, diarrhea, and other symptoms that suggest physical dependence. To avoid withdrawal symptoms, pregabalin should be discontinued slowly, over 1 week or more.

25.7.4.6 Reproductive Toxicity.

Pregabalin has adverse effects on reproduction and development when taken by females or males.

When given to pregnant female rats and rabbits, pregabalin caused fetal growth retardation, fetal death, structural abnormalities (eg, skeletal and visceral malformation), and impaired function of the nervous and reproductive systems. Data on human reproduction are lacking. At this time, pregabalin is classified in FDA Pregnancy Risk Category C: Animal studies show a risk of fetal harm, but no controlled studies in women have been done.

When given to male rats prior to and during mating with untreated females, pregabalin decreased sperm counts and motility, decreased fertility, reduced fetal weight, and caused fetal abnormalities. Men using the drug should be informed about the possibility of decreased fertility and male-mediated teratogenicity.

25.7.4.7 Drug Interactions.

Alcohol, opioids, benzodiazepines, and other CNS depressants may intensify the depressant effects of pregabalin. Accordingly, such combinations should be avoided.

Extensive studies have failed to show pharmacokinetic interactions with any other drugs. Pregabalin does not inhibit cytochrome P450 isozymes; whether it can induce these isozymes is unknown. Pregabalin does not interact with oral contraceptives, and does not alter the kinetics of any antiseizure drugs studied (carbamazepine, lamotrigine, phenobarbital, phenytoin, topiramate, valproic acid, and tiagabine).

25.7.4.8 Preparations, Dosage, and Administration.

Pregabalin [Lyrica] is available in capsules (25, 50, 75, 100, 150, 200, 225, and 300 mg) for administration with or without food. Dosage depends on the indication. For patients with renal impairment, dosage should be reduced. When pregabalin is discontinued, dosage should be gradually tapered, over 1 week or longer.

25.7.4.8.1 Neuropathic Pain Associated with Diabetic Peripheral Neuropathy.

Dosing is begun at 150 mg/day (50 mg 3 times a day) and may be increased in a week as needed and tolerated to a maintenance level of 300 mg/day (100 mg 3 times a day). Dosages above 300 mg/day are unlikely to increase benefits but will increase the risk of adverse effects.

25.7.4.8.2 Postherpetic Neuralgia.

Dosing should begin at 150 mg/day (75 mg twice daily or 50 mg 3 times a day) and may be increased as needed and tolerated to the usual maintenance level of 300 mg/day (150 mg twice daily or 100 mg 3 times a day). For patients with significant pain after 2 to 4 weeks at 300 mg/day, dosage may be increased to a maximum of 600 mg/day (300 mg twice daily or 200 mg 3 times a day).

25.7.4.8.3 Epilepsy.

Dosing is the same as for postherpetic neuralgia, with a maximum dosage of 600 mg/day.

25.7.4.8.4 Fibromyalgia.

Dosing begins at 75 mg twice daily, and may increase to 225 mg twice daily, if tolerated. Doses above this level increase the risk of side effects, but offer no increase in benefits.

25.7.5 Levetiracetam

Levetiracetam [Keppra], introduced in 1999, is a unique agent that is chemically and pharmacologically different from all other AEDs. How levetiracetam acts is unknown. All we do know is that it does not bind to receptors for GABA or any other known neurotransmitter. The drug is approved for adjunctive therapy of (1) myoclonic seizures in adults and adolescents age 12 and older, (2) partial-onset seizures in adults and children age 4 and older, and (3) primary generalized tonic-clonic seizures in adults and children age 6 years and older. Unlabeled uses include migraine, bipolar disorder, and new-onset pediatric epilepsy.

Following oral administration, levetiracetam undergoes rapid and complete absorption both in the presence and absence of food. Metabolism is minimal and not mediated by hepatic P450 enzymes. Levetiracetam is excreted in the urine, largely (66%) unchanged.

Adverse effects are generally mild to moderate. The most common are drowsiness (14.8%) and asthenia (14.7%). Neuropsychiatric symptoms (agitation, anxiety, depression, psychosis, hallucinations, depersonalization) occur in less than 1% of patients. In contrast to other AEDs, levetiracetam does not impair speech, concentration, or other cognitive functions. Safety for use during pregnancy or breast-feeding has not been determined.

Unlike most other AEDs, levetiracetam does not interact with other drugs. It does not alter plasma concentrations of oral contraceptives, warfarin, digoxin, or other AEDs. Given that levetiracetam is not metabolized by P450 enzymes, its lack of interactions is no surprise.

Levetiracetam is available in tablets (250, 500, 750, and 1000 mg), an oral solution (100 mg/mL), and a solution for IV injection (100 mg/mL). The initial adult dosage is 500 mg twice daily. The maximum dosage is 3000 mg/day. Because levetiracetam is eliminated by the kidneys, dosage should be reduced in patients with significant renal impairment.

25.7.6 Topiramate

25.7.6.1 Actions and Uses.

Topiramate [Topamax], introduced in 1996, is another broad-spectrum antiseizure agent. The drug is FDA-approved for (1) *adjunctive* treatment of adults and children 2 years and older with partial seizures, primary generalized tonic-clonic seizures, and seizures associated with Lennox-Gastaut syndrome; (2) *monotherapy* of adults and children 10 years and older with partial seizures or primary generalized tonic-clonic seizures; and (3) prophylaxis of migraine in adults (see [Chapter 30](#)). Seizure reduction occurs by four mechanisms: (1) potentiation of GABA-mediated inhibition, (2) blockade of voltage-dependent sodium channels, (3) blockade of calcium channels, and (4) blockade of receptors for glutamate, an excitatory neurotransmitter. Unlabeled uses include bipolar disorder, cluster headaches, neuropathic pain, infantile spasms, alcohol and cocaine dependence, binge-eating disorder, bulimia nervosa, and weight loss.

25.7.6.2 Pharmacokinetics.

Topiramate is rapidly absorbed following oral administration. Bioavailability is not affected by food. Plasma levels peak 2 hours after dosing. Most of the drug is eliminated unchanged in the urine.

25.7.6.3 Adverse Effects.

Although topiramate is generally well tolerated, it can cause multiple adverse effects. Common effects include somnolence (30%), dizziness (28%), ataxia (21%), nervousness (20%), diplopia (15%), nausea (13%), anorexia (12%), and weight loss (12%). Cognitive effects (confusion, memory difficulties, altered thinking, reduced concentration, difficulty finding words) can occur, but the incidence is low at recommended dosages. Kidney stones and paresthesias occur rarely.

Topiramate can cause *metabolic acidosis*. The drug inhibits carbonic anhydrase, and thereby increases renal excretion of bicarbonate, which causes plasma pH to fall. Mild to moderate metabolic acidosis develops in 30% of adult patients, but severe acidosis is rare. Serum bicarbonate should be measured at baseline and periodically thereafter. If metabolic acidosis develops, topiramate should be given in reduced dosage or discontinued.

Topiramate can cause *hypohidrosis* (reduced sweating), thereby posing a risk of hyperthermia. Significant hyperthermia is usually associated with vigorous activity and an elevated environmental temperature.

There have been case reports of *angle-closure glaucoma*. Left untreated, this rapidly leads to blindness. Patients should be informed about symptoms of glaucoma (ocular pain, unusual redness, sudden worsening or blurring of vision) and instructed to seek immediate attention if these develop. Fortunately, topiramate-induced glaucoma is rare.

25.7.6.4 Drug Interactions.

Phenytoin and carbamazepine can decrease levels of topiramate by about 45%. Topiramate may increase levels of phenytoin.

25.7.6.5 Preparations, Dosage, and Administration.

Topiramate [Topamax] is available in tablets (25, 50, 100, and 200 mg) and “sprinkle” capsules (15 and 25 mg). *Adult* dosing is begun at 50 mg/day and then gradually increased to 200 mg twice daily for maintenance. *Pediatric* dosing is begun at 25 mg (or less) per day and gradually increased to 3 to 9 mg/kg/day administered in two divided doses. Advise patients not to break the tablets because of bitter taste. The capsules can be swallowed whole or opened and sprinkled onto a small amount (1 tsp) of soft food.

232

25.7.7 Tiagabine**25.7.7.1 Actions and Uses.**

Tiagabine [Gabitril Filmtabs], introduced in 1997, is FDA-approved only for adjunctive therapy of partial seizures in patients at least 12 years old. The drug blocks reuptake of GABA by neurons and glia. As a result, the inhibitory influence of GABA is intensified, and seizures are suppressed. Off-label uses include migraine prophylaxis, bipolar disorder, and insomnia. However, owing to a risk of seizures (see below), such offlabel use is discouraged.

25.7.7.2 Pharmacokinetics.

Tiagabine has uncomplicated kinetics. Administration is oral. Absorption is rapid and nearly complete. Food reduces the rate of absorption but not the extent. Plasma levels peak about 45 minutes after dosing. In the blood, tiagabine is highly (96%) bound to plasma proteins. Elimination is by hepatic metabolism followed by excretion in the bile and, to a lesser extent, the urine. The serum half-life is 7 to 9 hours.

25.7.7.3 Adverse Effects.

Tiagabine is generally well tolerated. Common adverse effects are dizziness (27%), somnolence (18%), asthenia (20%), nausea (11%), nervousness (10%), and tremor (9%). Like most other AEDs, tiagabine can cause dose-related cognitive effects (eg, confusion, abnormal thinking, trouble concentrating).

Tiagabine has *caused* seizures in some patients—but only in those using the drug off-label (ie, those using the drug for a condition other than epilepsy). A few patients have developed SE, which can be life threatening. In most cases, seizures occurred soon after starting tiagabine or increasing the dosage. Because of seizure risk, off-label use of tiagabine should be avoided.

Why are people without epilepsy at risk? Possibly because they are not taking AEDs. Remember, tiagabine is approved only for adjunctive use with other AEDs. It may be that these drugs protect against tiagabine-induced seizures. Since people without epilepsy take tiagabine by itself, they are not protected from seizure development.

25.7.7.4 Drug Interactions.

Tiagabine does not alter the metabolism or serum concentrations of other AEDs. However, levels of tiagabine can be decreased by phenytoin, phenobarbital, and carbamazepine—all of which induce drug-metabolizing enzymes.

25.7.7.5 Preparations, Dosage, and Administration.

Tiagabine [Gabitril Filmtabs] is available in tablets (2, 4, 12, 16, and 20 mg) for oral administration. Dosing should be done with food. The initial dosage for adults and children is 4 mg once a day. Dosage can be increased by 4 to 8 mg/day at weekly intervals. The maximum daily dose, administered in two to four divided doses, is 56 mg for adults and 32 mg for children under age 18 years. Dosage should be increased in patients taking drugs that can accelerate tiagabine metabolism.

25.7.8 Zonisamide

25.7.8.1 Actions and Uses.

Zonisamide [Zonegran], introduced in 2000, is approved only for adjunctive therapy of partial seizures in adults. The drug belongs to the same chemical family as the sulfonamide antibiotics, but lacks antimicrobial activity. In animal models, zonisamide suppresses focal seizure activity and spread. The underlying mechanism appears to be blockade of neuronal sodium channels and calcium channels.

25.7.8.2 Pharmacokinetics.

Zonisamide undergoes rapid absorption from the GI tract. Bioavailability is nearly 100%, both in the presence and absence of food. In the blood, zonisamide is extensively bound to erythrocytes. As a result, its concentration in erythrocytes is 8 times higher than in plasma. Zonisamide is metabolized in the liver by the 3A4 isozyme of cytochrome P450 (CYP3A4). Excretion occurs in the urine, in the form of zonisamide itself (30%) and metabolites. The plasma half-life is 63 hours.

25.7.8.3 Adverse Effects.

The most common adverse effects are drowsiness (17%), dizziness (13%), anorexia (13%), headache (10%), and nausea (9%). Like most other AEDs, zonisamide can impair speech, concentration, and other cognitive processes. Because the drug can reduce alertness and impair cognition, patients should avoid driving and other hazardous activities until they know how the drug affects them.

Zonisamide can have severe *psychiatric effects*. During clinical trials, 2.2% of patients either discontinued treatment or were hospitalized because of severe depression; 1.1% attempted suicide. Psychosis caused another 2.2% to discontinue treatment.

Like all other sulfonamides, zonisamide can trigger *hypersensitivity reactions*, including some that are potentially fatal (eg, Stevens-Johnson syndrome, toxic epidermal necrolysis, fulminant hepatic necrosis). Accordingly, zonisamide is contraindicated for patients with a history of sulfonamide hypersensitivity. Patients who develop a rash should be followed closely, because rash can evolve into a more serious event. If severe hypersensitivity develops, zonisamide should be withdrawn immediately. Fortunately, serious reactions and fatalities are rare.

Zonisamide has adverse effects on the kidneys. In clinical trials, about 4% of patients developed *nephrolithiasis* (kidney stones). The risk can be reduced by drinking 6 to 8 glasses of water a day (to maintain hydration and urine flow). Patients should be informed about signs of kidney stones (sudden back pain, abdominal pain, painful urination, bloody or dark urine) and instructed to report them immediately. In addition to nephrolithiasis, zonisamide can *impair glomerular filtration*. Because of its effects on the kidney, zonisamide should be used with caution in patients with kidney disease.

Rarely, zonisamide causes *hypohidrosis* (decreased sweating) and *hyperthermia* (elevation of body temperature). Pediatric patients may be at special risk. In warm weather, hypohidrosis may lead to heat stroke and subsequent hospitalization. Patients should be monitored closely for reduced sweating and increased body temperature.

25.7.8.4 Use in Pregnancy and Breast-Feeding.

Zonisamide is teratogenic and embryolethal in laboratory animals. Cardiovascular abnormalities are common. Women of child-bearing age should use effective contraception. Zonisamide is classified in FDA Pregnancy Risk Category C, and hence should be avoided during pregnancy unless the benefits to the mother are deemed to outweigh the potential risks to the fetus. We do not know if zonisamide enters breast milk. Until more is known, prudence dictates that women who are breast-feeding should not take the drug.

25.7.8.5 Drug and Food Interactions.

Levels of zonisamide can be affected by agents that induce or inhibit CYP3A4. Inducers of CYP3A4—including St. John's wort (an herbal supplement used for depression) and several AEDs (eg, phenytoin, phenobarbital, carbamazepine)—can accelerate the metabolism of zonisamide, and thereby reduce the drug's half-life to as little as 27 hours. Conversely, inhibitors of CYP3A4—including grapefruit juice, azole antifungal agents (eg, ketoconazole), and several protease inhibitors (eg, ritonavir)—can slow the metabolism of zonisamide, and thereby prolong and intensify its effects.

25.7.8.6 Preparations, Dosage, and Administration.

Zonisamide is available in capsules (25, 50, and 100 mg). The initial dosage is 100 mg once daily. The maximum dosage is 600 mg/day in one or two divided doses.

25.7.9 Felbamate

Felbamate [Felbatol], introduced in 1993, is an effective AED with a broad spectrum of antiseizure activity. Unfortunately, the drug has potentially fatal adverse effects: aplastic anemia and liver failure. Accordingly, use is restricted to patients with severe epilepsy refractory to all other therapy.

25.7.9.1 Mechanism of Action.

Felbamate increases seizure threshold and suppresses seizure spread. The underlying mechanism is unknown. Unlike some AEDs (eg, phenobarbital, benzodiazepines), felbamate does not interact with GABA receptors and does not enhance the inhibitory actions of GABA.

25.7.9.2 Pharmacokinetics.

Felbamate is well absorbed following oral administration, in the presence or absence of food. Plasma levels peak in 1 to 4 hours. The drug readily penetrates to the CNS. Although therapeutic plasma levels have not been established, levels of 20 to 120 mcg/mL have been measured during clinical trials. Felbamate is eliminated in the urine, primarily unchanged. Its half-life is 14 to 23 hours.

25.7.9.3 Therapeutic Uses.

Felbamate is approved for (1) adjunctive or monotherapy in adults with partial seizures (with or without generalization), and (2) adjunctive therapy in children with Lennox-Gastaut syndrome. However, because of toxicity, use of the drug is very limited.

25.7.9.4 Adverse Effects.

Felbamate can cause *aplastic anemia* and *liver damage*. Aplastic anemia has occurred in at least 21 patients, 3 of whom died. Acute liver failure occurred in eight patients, four of whom died. Because of the risk of liver failure, felbamate should not be used by patients with pre-existing liver dysfunction. In addition, patients taking the drug should be monitored for indications of liver injury.

The most common adverse effects are GI disturbances (anorexia, nausea, vomiting) and CNS effects (insomnia, somnolence, dizziness, headache, diplopia). These occur more frequently when felbamate is combined with other drugs.

25.7.9.5 Drug Interactions.

Felbamate can alter plasma levels of other AEDs and vice versa. Felbamate increases levels of phenytoin and valproic acid. Levels of felbamate are increased by valproic acid and reduced by phenytoin and carbamazepine. Increased levels of phenytoin and valproic acid (and possibly felbamate) could lead to toxicity; reduced levels of felbamate could lead to therapeutic failure. Therefore, to keep levels of these drugs within the therapeutic range, their levels should be monitored and dosages adjusted accordingly.

25.7.9.6 Preparations, Dosage, and Administration.

Felbamate [Felbatol] is available in tablets (400 and 600 mg) and an oral suspension (120 mg/mL). For *older children* (over 14 years old) and *adults*, the initial dosage is 1200 mg/day in three divided doses; the maximum dosage is 3600 mg/day in three divided doses. For *younger children* (2 to 14 years old), the initial dosage is 15 mg/kg/day in three divided doses; the maximum dosage is 45 mg/kg/day or 3600 mg/day, whichever is less, administered in three divided doses.

233

25.7.10 Vigabatrin

234

Vigabatrin [Sabril] can suppress partial and secondarily generalized seizures, but may exacerbate absence and myoclonic seizures. The drug acts by inhibiting GABA transaminase, the enzyme that degrades GABA. By preventing GABA degradation, vigabatrin increases GABA availability in the CNS, and thereby enhances GABA-mediated inhibition of neuronal activity. Adverse effects include nausea, sedation, depression, psychosis, weight gain, and visual field constriction. The maintenance dosage is 2 to 4 gm once a day. Vigabatrin is available in Europe but not the United States.

25.8 MANAGEMENT OF EPILEPSY DURING PREGNANCY

Managing epilepsy during pregnancy is a challenge. Why? Because AEDs can harm the fetus, but so can uncontrolled seizures. There is solid evidence that all of the conventional AEDs increase the risk of minor malformations, major malformations, and growth retardation. At this time, the teratogenic potential of the newer AEDs is less clear. The most common malformations associated with AEDs are oral-facial clefts and midline heart defects. Valproic acid poses an especially high risk of spina bifida and other neural tube defects. The risk of malformation is proportional to AED dosage and to

the number of AEDs used. As with other teratogens, the risk of birth defects is greatest from exposure during the first trimester. How do AEDs cause birth defects? One likely mechanism is conversion to reactive epoxide metabolites. In addition to causing birth defects, certain AEDs can cause neonatal hemorrhage.

Uncontrolled seizures carry their own risks—although they don't cause fetal malformation. Generalized tonic-clonic seizures can induce labor and, very rarely, miscarriage. Major seizures during the last month of pregnancy can injure the baby. Seizures of all types can delay development and promote epilepsy in the child. Of course, seizures also pose a risk of falls and injury to the mother.

Given that seizures and AEDs both carry risks, what should we do? Should the drugs be withdrawn, thereby increasing the risk of injury from seizures? Or should the drugs be continued, thereby posing a risk of drug-induced injury? Most authorities agree that the risk to the fetus from uncontrolled seizures is greater than the risk from AEDs. Hence, as a general rule, women with major seizure disorders should continue to take AEDs throughout pregnancy. To minimize fetal risk, the lowest effective dosage should be determined and maintained. In addition, since the risk of malformation is proportional to the number of drugs taken, just one drug should be used whenever possible.

As discussed in [Chapter 9](#), drug disposition changes during pregnancy. In particular, renal excretion of drugs increases, as do hepatic metabolism and protein binding. As a result, the level of free (active) drug falls, posing a risk of breakthrough seizures. Accordingly, dosage should be increased. To determine dosing requirements, drug levels should be measured at least once a month.

To reduce the risk of neural tube defects, women should take supplemental folic acid prior to conception and throughout pregnancy. A dose of 2 mg/day has been recommended. (This is 5 times the dosage recommended for women not taking AEDs.) Although supplemental folic acid can prevent neural tube defects in the absence of AEDs, it may not prevent AED-induced defects.

Four drugs—*phenobarbital*, *phenytoin*, *carbamazepine*, and *primidone*—reduce levels of vitamin K–dependent clotting factors (by inducing hepatic enzymes). As a result, these drugs increase the risk of bleeding. To reduce this risk, women should be given 10 mg of vitamin K daily during the last few weeks of pregnancy, and the baby should be given a 1-mg IM injection of vitamin K at birth.

In addition to their influence on clotting, inducers of hepatic metabolism can decrease blood levels of oral contraceptives, thereby rendering them ineffective. All women of child-bearing age should be informed of this drug interaction, and dosages of oral contraceptives should be increased as required.

25.9 MANAGEMENT OF GENERALIZED CONVULSIVE STATUS EPILEPTICUS

Convulsive SE is defined as a continuous series of tonic-clonic seizures that lasts for at least 20 to 30 minutes. Consciousness is lost during the entire attack. Tachycardia, elevation of blood pressure, and hyperthermia are typical. Metabolic sequelae include hypoglycemia and acidosis. If SE persists for more than 20 minutes, it can cause permanent neurologic injury (cognitive impairment, memory loss, worsening of the underlying seizure disorder) and even death. About 125,000 Americans suffer SE each year. About 20% of them die.

Generalized convulsive SE is a medical emergency that requires immediate treatment. Ideally, treatment should commence within 5 minutes of seizure onset. Experience has shown that, as time passes, SE becomes more and more resistant to therapy.

The goal of treatment is to maintain ventilation, correct hypoglycemia, and terminate the seizure. An IV line is established to draw blood for analysis of glucose levels, electrolyte levels, and drug levels. The line is also used to administer glucose and AEDs.

An IV benzodiazepine—either *lorazepam* [Ativan] or *diazepam* [Valium]—is used initially. Both drugs can terminate seizures quickly. Diazepam has a short duration of action, and hence must be administered repeatedly. In contrast, effects of lorazepam last up to 72 hours. Because of its prolonged effects, lorazepam is generally preferred. The dosage for lorazepam is 0.1 mg/kg administered at a rate of 2 mg/min. The initial dose for diazepam is 0.2 mg/kg administered at a rate of 5 mg/min.

Once seizures have been stopped with a benzodiazepine, either *phenytoin* [Dilantin] or *fosphenytoin* [Cerebyx]^{*} may be given for long-term suppression. Because the effects of diazepam are short lived, follow-up treatment with a longacting drug is essential when diazepam is used for initial control. However, when lorazepam is used for initial control, follow-up therapy may be unnecessary.

234

25.9.1 KEY POINTS

- Seizures are initiated by discharge from a group of hyperexcitable neurons, called a focus.
- In partial seizures, excitation undergoes limited spread from the focus to adjacent cortical areas.
- In generalized seizures, excitation spreads widely throughout both hemispheres of the brain.

235

- AEDs act through four basic mechanisms: blockade of sodium channels, blockade of calcium channels, blockade of receptors for glutamate (an excitatory neurotransmitter), and potentiation of GABA (an inhibitory neurotransmitter).
- The goal in treating epilepsy is to reduce seizures to an extent that enables the patient to live a normal or near-normal life. Complete elimination of seizures may not be possible without causing intolerable side effects.
- AEDs can be divided into two main groups: traditional AEDs and newer AEDs, which were introduced in 1993 or later.
- Many AEDs are selective for particular seizures, and hence successful treatment depends on choosing the correct drug.
- Monitoring plasma drug levels can be valuable for adjusting dosage, monitoring adherence, determining the cause of lost seizure control, and identifying the cause of toxicity, especially in patients taking more than one drug.
- Nonadherence accounts for nearly half of all treatment failures. Hence, promoting adherence is a priority.
- Withdrawal of AEDs must be done very gradually, because abrupt withdrawal can trigger SE.
- All AEDs may pose a risk of suicidal thoughts and behavior.
- Most AEDs cause CNS depression, which can be deepened by concurrent use of other CNS depressants (eg, alcohol, antihistamines, opioids, other AEDs).
- Phenytoin is active against partial seizures and tonic-clonic seizures but not absence seizures.
- The capacity of the liver to metabolize phenytoin is limited. As a result, doses only slightly greater than those needed for therapeutic effects can push phenytoin levels into the toxic range.
- The therapeutic range for phenytoin is 10 to 20 mcg/mL.
- When phenytoin levels rise above 20 mcg/mL, CNS toxicity develops. Signs include nystagmus, sedation, ataxia, diplopia, and cognitive impairment.
- Phenytoin causes gingival hyperplasia in 20% of patients.

- Like phenytoin, carbamazepine is active against partial seizures and tonic-clonic seizures.
- Because carbamazepine is better tolerated than phenytoin, it is often preferred.
- Carbamazepine can cause leukopenia, anemia, and thrombocytopenia—and, very rarely, fatal aplastic anemia. To reduce the risk of serious hematologic toxicity, complete blood counts should be obtained at baseline and periodically thereafter.
- Valproic acid is a very-broad-spectrum AED, having activity against partial seizures and most generalized seizures, including tonic-clonic, absence, atonic, and myoclonic seizures.
- Valproic acid can cause potentially fatal liver injury, especially in children under 2 years old who are taking other AEDs.
- Valproic acid can cause potentially fatal pancreatitis.
- In contrast to other barbiturates, phenobarbital is able to suppress seizures without causing generalized CNS depression.
- Phenytoin, carbamazepine, and phenobarbital induce the synthesis of hepatic drug-metabolizing enzymes, and can thereby accelerate inactivation of other drugs. Inactivation of oral contraceptives and warfarin is of particular concern.
- AEDs can interact with one another in complex ways, causing their blood levels to change. Dosages must be adjusted to compensate for these interactions.
- All traditional AEDs (and some newer AEDs) can harm the developing fetus, especially during the first trimester. However, the fetus and mother are at greater risk from uncontrolled seizures than from AEDs. Accordingly, women with major seizure disorders should continue taking AEDs throughout pregnancy.
- Fetal risk can be minimized by using just one AED (if possible) and in the lowest effective dosage.
- Initial control of generalized convulsive SE is accomplished with an IV benzodiazepine—either diazepam or lorazepam. When diazepam is used, follow-up treatment with phenytoin or fosphenytoin is essential for prolonged seizure suppression.

Summary of Major Nursing Implications*

NURSING IMPLICATIONS THAT APPLY TO ALL ANTIEPILEPTIC DRUGS

Preadministration Assessment

Therapeutic Goal

The goal of treatment is to minimize or eliminate seizure events, thereby allowing the patient to live a normal or near-normal life.

* Fosphenytoin is a prodrug form of phenytoin indicated only for convulsive SE. The drug is given IV and undergoes immediate conversion to phenytoin. Compared with solutions of phenytoin, solutions of fosphenytoin are less irritating to veins and can be infused faster without risk of cardiovascular collapse.

Baseline Data

Before initiating treatment, it is essential to know the type of seizure involved (eg, absence, generalized tonic-clonic) and how often seizure events occur.

Implementation: Administration

Dosage Determination

Dosages are often highly individualized and difficult to establish. Clinical evaluation of therapeutic and adverse effects is essential to establish a dosage that is both safe and effective. For several AEDs (especially those used to treat tonic-clonic seizures), knowledge of plasma AED levels can facilitate dosage adjustment.

Promoting Adherence

Seizure control requires rigid adherence to the prescribed regimen; nonadherence is a major cause of therapeutic failure. **To promote adherence, educate patients about the importance of taking AEDs exactly as prescribed.** Monitoring plasma AED levels can motivate adherence and facilitate assessment of nonadherence.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Teach the patient (or a family member) to maintain a seizure frequency chart, indicating the date, time, and nature of all seizure events. The prescriber can use this record to evaluate treatment, make dosage adjustments, and alter drug selections.

Minimizing Danger from Uncontrolled Seizures

Advise patients to avoid potentially hazardous activities (eg, driving, operating dangerous machinery) until seizure control has been achieved. Also, because seizures may recur after they are largely under control, advise patients to carry some form of identification (eg, Medic Alert bracelet) to aid in diagnosis and treatment if a seizure occurs.

Minimizing Adverse Effects

CNS Depression.

Most AEDs depress the CNS. Signs of CNS depression (sedation, drowsiness, lethargy) are most prominent during the initial phase of treatment and decline with continued drug use. **Forewarn patients about CNS depression, and advise them to avoid driving and other hazardous activities if CNS depression is significant.**

Withdrawal Seizures.

Abrupt discontinuation of AEDs can lead to status epilepticus (SE). Consequently, medication withdrawal should be done slowly (over 6 weeks to several months). **Inform patients about the dangers of abrupt drug withdrawal, and instruct them never to discontinue drug use without consulting the prescriber. Advise patients who are planning a trip to carry extra medication to ensure an uninterrupted supply in the event they become stranded where medication is unavailable.**

Usage in Pregnancy.

In most cases, the risk from uncontrolled seizures exceeds the risk from medication, hence women with major seizure disorders should continue to take AEDs during pregnancy. However, the lowest effective dosage should be employed and, if possible,

only one drug should be used. To reduce the risk of neural tube defects, **advise women to take folic acid supplements prior to and throughout pregnancy.**

Suicidal Thoughts and Behavior.

The AEDs pose small risk of suicidal thoughts and behavior, beginning as soon as 1 week after starting treatment. **Patients, families, and caregivers should be informed about signs that may precede suicidal behavior (eg, increased anxiety, agitation, mania, or hostility) and advised to report these immediately.**

Minimizing Adverse Interactions

CNS Depressants.

Drugs with CNS-depressant actions (eg, alcohol, antihistamines, barbiturates, opioids) will intensify the depressant effects of AEDs, thereby posing a serious risk. **Warn patients against using alcohol and other CNS depressants.**

PHENYTOIN

Nursing implications for phenytoin include those presented below as well as those presented above under *Nursing Implications That Apply to All Antiepileptic Drugs*.

Preadministration Assessment

Therapeutic Goal

Oral phenytoin is used to treat partial seizures (simple and complex) and tonic-clonic seizures. Intravenous phenytoin is used to treat convulsive SE.

Identifying High-Risk Patients

Intravenous phenytoin is *contraindicated* for patients with sinus bradycardia, sinoatrial block, second- or third-degree atrioventricular block, or Stokes-Adams syndrome.

Implementation: Administration

Routes

Oral, IV, and (rarely) IM.

25.9....	Administration	
25.9....	Oral. Instruct patients to take phenytoin exactly as prescribed. Inform them that, once a safe and effective dosage has been established, small deviations in dosage can lead to toxicity or to loss of seizure control. Advise patients to take phenytoin with meals to reduce gastric discomfort.	236
	Instruct patients to shake the phenytoin oral suspension before dispensing in order to provide consistent dosing.	237
25.9....	Intravenous. To minimize the risk of severe reactions (eg, cardiovascular collapse), infuse phenytoin slowly (no faster than 50 mg/min). Do not mix phenytoin solutions with other drugs. To minimize venous inflammation at the injection site, flush the needle or catheter with saline immediately after completing the phenytoin infusion.	
25.9....	Ongoing Evaluation and Interventions	
25.9....	Minimizing Adverse Effects	
25.9....	CNS Effects. Inform patients that excessive doses can produce sedation, ataxia, diplopia, and interference with cognitive function. Instruct them to notify the prescriber if these occur.	
25.9....	Gingival Hyperplasia. Inform patients that phenytoin often promotes overgrowth of gum tissue. To minimize harm and discomfort, teach them proper techniques of brushing, flossing, and gum massage.	

25.9....

Use in Pregnancy.

Phenytoin can cause fetal hydantoin syndrome and bleeding tendencies in the neonate. Decrease bleeding risk by giving the mother vitamin K for 1 month prior to delivery and during delivery and to the infant immediately after delivery. Decrease the risk of fetal hydantoin syndrome by using the lowest effective phenytoin dosage.

25.9....

Skin Rash.

Inform patients that phenytoin can cause a morbilliform (measles-like) rash that may progress to a more serious reaction. Instruct them to notify the prescriber immediately if a rash develops. Use of phenytoin should stop.

25.9....

Withdrawal Seizures.

Abrupt discontinuation of phenytoin can trigger convulsive SE. **Warn patients against abrupt cessation of treatment.**

25.9....

Minimizing Adverse Interactions

Phenytoin is subject to a large number of significant interactions with other drugs; a few are noted below. **Warn patients against use of any drugs not specifically approved by the prescriber.**

25.9....

CNS Depressants.

Warn patients against use of alcohol and all other drugs with CNS-depressant properties, including opioids, barbiturates, and antihistamines.

25.9....

Warfarin and Oral Contraceptives.

Phenytoin can decrease the effects of these agents (as well as other drugs) by inducing hepatic drug-metabolizing enzymes. Dosages of warfarin and oral contraceptives may need to be increased.

25.9....

CARBAMAZEPINE

Nursing implications for carbamazepine include those presented below as well as those presented above under *Nursing Implications That Apply to All Antiepileptic Drugs*.

Preadministration Assessment

Therapeutic Goal

Carbamazepine is used to treat partial seizures (simple and complex) and tonic-clonic seizures.

Baseline Data

Obtain complete blood counts prior to treatment.

Identifying High-Risk Patients

Carbamazepine is *contraindicated* for patients with a history of bone marrow depression or adverse hematologic reactions to other drugs.

Implementation: Administration

Route

Oral.

Administration

Advise patients to administer carbamazepine with meals to decrease gastric upset.

To minimize adverse CNS effects, use low initial doses and give the largest portion of the daily dose at bedtime.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

CNS Effects.

Carbamazepine can cause headache, visual disturbances (nystagmus, blurred vision, diplopia), ataxia, vertigo, and unsteadiness. To minimize these effects, initiate therapy with low doses and have the patient take the largest part of the daily dose at bedtime.

25.9....

Hematologic Effects.

Carbamazepine can cause leukopenia, anemia, thrombocytopenia, and, very rarely, fatal aplastic anemia. To reduce the risk of serious hematologic effects, (1) obtain complete blood counts at baseline and periodically thereafter, (2) avoid carbamazepine in patients with pre-existing hematologic abnormalities, and (3) **inform patients about manifestations of hematologic abnormalities (fever, sore throat, pallor, weakness, infection, easy bruising, petechiae), and instruct them to notify the prescriber if these occur.**

25.9....

Birth Defects.

Carbamazepine can cause neural tube defects. Use in pregnancy only if the benefits of seizure suppression outweigh the risks to the fetus.

25.9....

Severe Skin Reactions.

Carbamazepine can cause Stevens-Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN), especially among patients of Asian descent. To reduce risk, the FDA recommends that patients of Asian descent be tested for HLA-B*1502, a genetic variant that predisposes to these reactions. If SJS or TEN develops, carbamazepine should be discontinued.

25.9....

Minimizing Adverse Interactions

25.9....

Interactions Due to Induction of Drug Metabolism.

Carbamazepine can decrease responses to other drugs by inducing hepatic drug-metabolizing enzymes. Effects on oral contraceptives and warfarin are of particular concern. Patients using these drugs will require increased dosages to maintain therapeutic responses.

25.9....

Phenytoin and Phenobarbital.

These drugs can decrease responses to carbamazepine by inducing drugmetabolizing enzymes (beyond the degree of induction caused by carbamazepine itself). Dosage of carbamazepine may need to be increased.

237

238

25.9....

Grapefruit Juice.

Grapefruit juice can increase levels of carbamazepine. **Instruct patients not to drink grapefruit juice.**

25.9....

VALPROIC ACID

Nursing implications for valproic acid include those presented below as well as those presented above under *Nursing Implications That Apply to All Antiepileptic Drugs*.

25.9....

Preadministration Assessment

25.9....

Therapeutic Goal

Valproic acid is used to treat all major seizure disorders: tonic-clonic, absence, myoclonic, atonic, and partial (simple, complex, and secondarily generalized).

25.9....

Baseline Data

Obtain baseline tests of liver function.

25.9....

Identifying High-Risk Patients

Valproic acid is *contraindicated* for patients with significant hepatic dysfunction and for children under the age of 3 years who are taking other AEDs.

25.9....

Implementation: Administration

25.9....

Routes

Oral, IV.

25.9....

Administration

Advise patients to take valproic acid with meals, and instruct them to ingest tablets and capsules intact, without crushing or chewing.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Gastrointestinal Effects.

Nausea, vomiting, and indigestion are common. These can be reduced by using an enteric-coated formulation (see [Table 24-4](#)) and by taking valproic acid with meals.

Hepatotoxicity.

Rarely, valproic acid has caused fatal liver injury. To minimize risk, (1) don't use valproic acid in conjunction with other drugs in children under the age of 3 years; (2) don't use valproic acid in patients with preexisting liver dysfunction; (3) evaluate liver function at baseline and periodically thereafter; (4) **inform patients about signs and symptoms of liver injury (reduced appetite, malaise, nausea, abdominal pain, jaundice), and instruct them to notify the prescriber if these develop;** and (5) use valproic acid in the lowest effective dosage.

Pancreatitis.

Valproic acid can cause life-threatening pancreatitis. **Inform patients about signs of pancreatitis (abdominal pain, nausea, vomiting, anorexia) and instruct them to get immediate evaluation if these develop.** If pancreatitis is diagnosed, valproic acid should be withdrawn.

Teratogenesis.

Valproic acid may cause neural tube defects and other birth defects. **Advise women of childbearing age to use an effective form of birth control and to take 5 mg of folic acid daily (to reduce the risk of neural tube defects if pregnancy should occur.)**

Hyperammonemia.

Combining valproic acid with topiramate poses a risk of hyperammonemia. If symptoms develop (vomiting, lethargy, altered level of consciousness and/or cognitive function), blood ammonia should be measured. If the level is excessive, either valproic acid or topiramate should be withdrawn.

Minimizing Adverse Interactions

Antiepileptic Drugs.

Valproic acid can elevate plasma levels of phenytoin and phenobarbital. Levels of phenobarbital and phenytoin should be monitored and their dosages adjusted accordingly.

Topiramate.

See *Hyperammonemia* above.

PHENOBARBITAL

Nursing implications that apply to the antiseizure applications of phenobarbital include those presented below and those presented above under *Nursing Implications That Apply to All Antiepileptic Drugs*. Nursing implications that apply to the barbiturates as a group are summarized in [Chapter 34](#).

Preadministration Assessment

Therapeutic Goal

Oral phenobarbital is used for partial seizures (simple and complex) and tonic-clonic seizures. Intravenous therapy is used for convulsive SE.

Identifying High-Risk Patients

Phenobarbital is *contraindicated* for patients with a history of acute intermittent porphyria.

Use with *caution* during pregnancy.

Implementation: Administration

Routes

Oral and IV.

25.9.... Administration

25.9.... Oral.

A loading schedule may be employed to initiate treatment. Monitor for excessive CNS depression when these large doses are used.

25.9.... Intravenous.

Rapid IV infusion can cause severe adverse effects. Perform infusions slowly.

25.9.... Ongoing Evaluation and Interventions

25.9.... Minimizing Adverse Effects

25.9.... Neuropsychologic Effects.

Warn patients that sedation may occur during the initial phase of treatment. Advise them to avoid hazardous activities if sedation is significant.

Inform parents that children may become irritable and hyperactive, and instruct them to notify the prescriber if these behaviors occur.

25.9.... Exacerbation of Intermittent Porphyria.

Phenobarbital can exacerbate acute intermittent porphyria, and hence is absolutely contraindicated for patients with a history of this disorder.

238

239

25.9.... Use in Pregnancy.

Warn women of child-bearing age that barbiturates may cause birth defects.

25.9.... Withdrawal Seizures.

Abrupt withdrawal of phenobarbital can trigger seizures. **Warn patients against abrupt cessation of treatment.**

25.9....

Minimizing Adverse Interactions

25.9....

Interactions Caused by Induction of Drug Metabolism.

Phenobarbital induces hepatic drug-metabolizing enzymes, and can thereby decrease responses to other drugs. Effects on *oral contraceptives* and *warfarin* are a particular concern; their dosages should be increased.

25.9....

CNS Depressants.

Warn patients against use of alcohol and all other drugs with CNS-depressant properties (eg, opioids, benzodiazepines).

25.9....

Valproic Acid.

Valproic acid increases blood levels of phenobarbital. To avoid toxicity, reduce phenobarbital dosage.

* Patient education information is highlighted as **blue text**.

²⁶CHAPTER 25 Drugs for Muscle Spasm and Spasticity

In this chapter we consider two groups of drugs that cause skeletal muscle relaxation. One group is used for localized muscle spasm. The other is used for spasticity. With only one exception (dantrolene), these drugs produce their effects through actions in the central nervous system (CNS). As a rule, the drugs used to treat spasticity do not relieve acute muscle spasm and vice versa. Hence, the two groups are not interchangeable.

^{26.1} DRUG THERAPY OF MUSCLE SPASM: CENTRALLY ACTING MUSCLE RELAXANTS

Muscle spasm is defined as involuntary contraction of a muscle or muscle group. Muscle spasm is often painful and decreases the patient's level of functioning. Spasm can result from a variety of causes, including epilepsy, hypocalcemia, acute and chronic pain syndromes, and trauma (localized skeletal muscle injury). Discussion here is limited to spasm resulting from muscle injury.

Treatment of spasm involves physical measures as well as drug therapy. Physical measures include immobilization of the affected muscle, application of cold compresses, whirlpool baths, and physical therapy. For drug therapy, two groups of medicines are used: (1) analgesic anti-inflammatory agents (eg, aspirin), and (2) centrally acting muscle relaxants. The analgesic anti-inflammatory agents are discussed in [Chapter 70](#). The centrally acting muscle relaxants are discussed below.

The family of centrally acting muscle relaxants consists of 9 drugs ([Table 25-1](#)). All have similar pharmacologic properties. Hence, we will consider them as a group.

^{26.1.1} Mechanism of Action

For most centrally acting muscle relaxants, the mechanism of spasm relief is unclear. In laboratory animals, high doses can depress spinal motor reflexes. However, these doses are much higher than those used in humans. Hence, many investigators believe that relaxation of spasm results primarily from the *sedative properties* of these drugs, and not from specific actions exerted on CNS pathways that control muscle tone.

Two drugs—diazepam and tizanidine—are thought to relieve spasm by enhancing presynaptic inhibition of motor neurons in the CNS. Diazepam promotes presynaptic inhibition by enhancing the effects of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter. Tizanidine promotes inhibition by acting as an agonist at presynaptic α_2 receptors.

TABLE 25-1 Drugs for Muscle Spasm: Centrally Acting Muscle Relaxants

Generic Name	Trade Names	Usual Adult Oral Maintenance Dosage
Baclofen	Lioresal	15–20 mg 3 or 4 times/day
Carisoprodol	Soma	350 mg 3 or 4 times/day
Chlorzoxazone	Paraflex, Parafon Forte, Remular-S	250 mg 3 or 4 times/day
Cyclobenzaprine	Flexeril, Fexmid	5–10 mg 3 times/day
Cyclobenzaprine ER*	Amrix	15 or 30 mg once daily
Diazepam	Valium	2–10 mg 3 or 4 times/day
Metaxalone	Skelaxin	800 mg 3 or 4 times/day
Methocarbamol	Robaxin	1000 mg 4 times/day
Orphenadrine	Norflex	100 mg morning and evening
Tizanidine	Zanaflex	4–8 mg 3 or 4 times/day

* ER = extended release.

240

241

26.1.2 Therapeutic Use

The centrally acting muscle relaxants are used to relieve localized spasm resulting from muscle injury. These agents can decrease local pain and tenderness and can increase range of motion. Treatment is almost always associated with sedation. The ability of central muscle relaxants to relieve discomfort of muscle spasm appears about equal to that of aspirin and the other analgesic anti-inflammatory drugs. Since there are no studies to indicate the superiority of one centrally acting muscle relaxant over another, drug selection is based largely on prescriber preference and patient response. With the exception of diazepam, the central muscle relaxants are not useful for treating spasticity or other muscle disorders resulting from CNS pathology.

26.1.3 Adverse Effects

26.1.3.1 CNS Depression.

All of the centrally acting muscle relaxants can produce generalized depression of the CNS. *Drowsiness, dizziness, and lightheadedness* are common. Patients should be warned not to participate in hazardous activities (eg, driving) if CNS depression is significant. In addition, they should be advised to avoid alcohol and all other CNS depressants.

26.1.3.2 Hepatic Toxicity.

Tizanidine [Zanaflex] and *metaxalone* [Skelaxin] can cause liver damage. Liver function should be assessed before starting treatment and periodically thereafter. If liver injury develops, these drugs should be discontinued. If the patient has pre-existing liver disease, these drugs should be avoided.

Chlorzoxazone [Paraflex, others] can cause hepatitis and potentially fatal hepatic necrosis. Because of this potential for harm, and because the benefits of chlorzoxazone are questionable, the drug should not be used.

26.1.3.3 Physical Dependence.

Chronic, high-dose therapy can cause physical dependence, manifesting as a potentially life-threatening abstinence syndrome if these drugs are abruptly withdrawn. Accordingly, withdrawal should be done slowly.

26.1.3.4 Other Adverse Effects.

Cyclobenzaprine and *orphenadrine* have significant anticholinergic (atropine-like) properties, and hence may cause dry mouth, blurred vision, photophobia, urinary retention, and constipation. *Methocarbamol* may turn urine brown, black, or dark green; patients should be forewarned of this harmless effect. *Tizanidine* can cause dry mouth, hypotension, hallucinations, and psychotic symptoms. *Carisoprodol* can be hazardous to patients predisposed to intermittent porphyria, and hence is contraindicated for this group.

26.1.4 Dosage and Administration

All centrally acting skeletal muscle relaxants can be administered orally. In addition, two agents—methocarbamol and diazepam—can be administered by injection (IM and IV). Average oral maintenance dosages for adults are listed in [Table 25-1](#).

26.2 DRUGS FOR SPASTICITY

The term *spasticity* refers to a group of movement disorders of CNS origin. These disorders are characterized by heightened muscle tone, spasm, and loss of dexterity. The most common causes are multiple sclerosis and cerebral palsy. Other causes include traumatic spinal cord lesions and stroke. Spasticity is managed with a combination of drugs and physical therapy.

Figure 25-1 Structural similarity between baclofen and gamma-aminobutyric acid (GABA).

Three drugs—baclofen, diazepam, and dantrolene—can relieve spasticity. Two of these—baclofen and diazepam—act in the CNS. In contrast, dantrolene acts directly on skeletal muscle. With the exception of diazepam, the drugs employed to treat muscle spasm (ie, the centrally acting muscle relaxants) are not effective against spasticity.

26.2.1 Baclofen

26.2.1.1 Mechanism of Action

Baclofen [Lioresal] acts within the spinal cord to suppress hyperactive reflexes involved in regulation of muscle movement. The precise mechanism of reflex attenuation is unknown. Since baclofen is a structural analog of the inhibitory neurotransmitter GABA ([Fig. 25-1](#)), it may act by mimicking the actions of GABA on spinal neurons. Baclofen has no direct effects on skeletal muscle.

26.2.1.2 Therapeutic Use

Baclofen can reduce spasticity associated with multiple sclerosis, spinal cord injury, and cerebral palsy—but not with stroke. The drug decreases flexor and extensor spasms and

suppresses resistance to passive movement. These actions reduce the discomfort of spasticity and allow increased performance. Because baclofen has no direct musclerelaxant action, and hence does not decrease muscle strength, baclofen is preferred to dantrolene in patients whose spasticity is associated with significant muscle weakness. Baclofen does not relieve the spasticity of Parkinson's disease or Huntington's chorea.

26.2.1.3 Adverse Effects

The most common side effects involve the CNS and GI tract. Serious adverse effects are rare.

26.2.1.3.1 CNS Effects.

Baclofen is a CNS depressant and hence frequently causes *drowsiness*, *dizziness*, *weakness*, and *fatigue*. These responses are most intense during the early phase of therapy and diminish with continued drug use. CNS depression can be minimized with doses that are small initially and then gradually increased. Patients should be cautioned to avoid alcohol and other CNS depressants, because baclofen will potentiate the depressant actions of these drugs.

Overdose can produce *coma* and *respiratory depression*. Since there is no antidote to baclofen poisoning, treatment is supportive.

26.2.1.3.2 Withdrawal.

Although baclofen does not appear to cause physical dependence, abrupt discontinuation has been associated with adverse reactions. Abrupt stoppage of *oral* baclofen can cause visual hallucinations, paranoid ideation, and seizures. Accordingly, withdrawal should be done slowly (over 1 to 2 weeks). Abrupt stoppage of *intrathecal* baclofen can be more dangerous. Potential reactions include high fever, altered mental status, exaggerated rebound spasticity, and muscle rigidity that, in rare cases, has advanced to rhabdomyolysis (muscle breakdown), multiple organ system failure, and death. To avoid disaster, the infusion system must be programmed properly and carefully monitored.

241

242

26.2.1.3.3 Other Adverse Effects.

Baclofen frequently causes *nausea*, *constipation*, and *urinary retention*. Patients should be warned about these possible reactions.

26.2.1.4 Preparations, Dosage, and Administration

26.2.1.4.1 Oral.

Baclofen [Lioresal] is available in tablets (10 and 20 mg) for oral use. Dosages are low initially (eg, 5 mg 3 times a day) and then gradually increased. Maintenance dosages range from 15 to 20 mg administered 3 to 4 times a day.

26.2.1.4.2 Intrathecal.

Baclofen can be administered by intrathecal infusion using an implantable pump. The average maintenance dosage is 300 to 800 mcg/day. Intrathecal administration is reserved for patients who are unresponsive to or intolerant of oral baclofen.

26.2.2 Diazepam

Diazepam [Valium] is a member of the benzodiazepine family. Although diazepam is the only benzodiazepine labeled for treating spasticity, other benzodiazepines would probably be effective. The basic pharmacology of the benzodiazepines is discussed in [Chapter 34](#).

26.2.2.1 Actions.

Like baclofen, diazepam acts in the CNS to suppress spasticity. Beneficial effects appear to result from mimicking the actions of GABA at receptors in the spinal cord and brain. Diazepam does not affect skeletal muscle directly. Since diazepam has no direct effects on muscle strength, the drug is preferred to dantrolene in patients whose strength is marginal.

26.2.2.2 Adverse Effects.

Sedation is common when treating spasticity. To minimize sedation, initial doses should be low. Other adverse effects are discussed in [Chapter 34](#).

26.2.2.3 Preparations, Dosage, and Administration.

For oral use, diazepam [Valium] is available in tablets (2, 5, and 10 mg), sustained-release capsules (15 mg), and solution (1 and 5 mg/mL). The drug is also available in solution (5 mg/mL) for IM and IV administration. The usual oral dosage for adults is 2 to 10 mg 3 or 4 times a day.

26.2.3 Dantrolene

26.2.3.1 Mechanism of Action

Unlike baclofen and diazepam, which act within the CNS, dantrolene [Dantrium] acts directly on skeletal muscle. The drug relieves spasm by suppressing release of calcium from the sarcoplasmic reticulum (SR), and hence the muscle is less able to contract. Fortunately, therapeutic doses have only minimal effects on contraction of smooth muscle and cardiac muscle.

26.2.3.2 Therapeutic Uses

26.2.3.2.1 Spasticity.

Dantrolene can relieve spasticity associated with multiple sclerosis, cerebral palsy, and spinal cord injury. Unfortunately, since dantrolene suppresses spasticity by causing a generalized reduction in the ability of skeletal muscle to contract, treatment may be associated with a significant reduction in strength. As a result, for some patients, overall function may be reduced rather than improved. Accordingly, care must be taken to ensure that the benefits of therapy (reduced spasticity) outweigh the harm (reduced strength).

26.2.3.2.2 Malignant Hyperthermia.

Malignant hyperthermia is a rare, life-threatening syndrome that can be triggered by any general anesthetic (except nitrous oxide) and by succinylcholine, a neuromuscular blocking agent. Onset of symptoms is most abrupt with succinylcholine (when used alone or in combination with an anesthetic). Prominent symptoms are muscle rigidity and profound elevation of temperature. The heat of malignant hyperthermia is generated by muscle contraction occurring secondary to massive release of calcium from the SR. Dantrolene relieves symptoms by acting on the SR to block calcium release. Malignant hyperthermia is discussed further in [Chapter 16](#).

26.2.3.3 Adverse Effects

26.2.3.3.1 Hepatic Toxicity.

Dose-related liver damage is dantrolene's most serious adverse effect. The incidence is 1 in 1000. Death has occurred. Hepatotoxicity is most common in women over age 35 years. By contrast, liver injury is rare in children under 10 years. To reduce the risk of liver damage,

liver function tests (LFTs) should be performed at baseline and periodically thereafter. If LFTs indicate liver injury, dantrolene should be withdrawn. Because of the potential for liver damage, dantrolene should be administered in the lowest effective dosage and for the shortest time necessary.

26.2.3.3.2 Other Adverse Effects.

Muscle weakness, drowsiness, and diarrhea are the most common side effects. Muscle weakness is a direct extension of dantrolene's pharmacologic action. Other disturbing reactions include *anorexia, nausea, vomiting, and acne-like rash*.

26.2.3.4 Preparations, Dosage, and Administration

26.2.3.4.1 Preparations.

Dantrolene sodium [Dantrium] is available in capsules (25, 50, and 100 mg) for oral use and as a powder to be reconstituted for IV injection.

26.2.3.4.2 Use in Spasticity.

For treatment of spasticity, administration is oral. The initial adult dosage is 25 mg once daily. The usual maintenance dosage is 100 mg 2 to 4 times a day. If beneficial effects do not develop within 45 days, dantrolene should be stopped.

26.2.3.4.3 Use in Malignant Hyperthermia

26.2.3.4.3.1 Preoperative Prophylaxis.

Patients with a history of malignant hyperthermia can be given dantrolene for prophylaxis prior to elective surgery. The dosage is 4 to 8 mg/kg/day in four divided doses for 1 to 2 days preceding surgery.

26.2.3.4.3.2 Treatment of an Ongoing Crisis.

For treatment of malignant hyperthermia, dantrolene is administered by IV push. The initial dose is 2 mg/kg. Administration is repeated until symptoms are controlled or until a total dose of 10 mg/kg has been given. Other management measures are discussed in [Chapter 16](#).

242

26.2.3.4.3.2.1

KEY POINTS

- Localized muscle spasm is treated with centrally acting muscle relaxants and aspirin-like drugs.
- Spasticity is treated with three drugs: baclofen, diazepam, and dantrolene.
- All centrally acting muscle relaxants produce generalized CNS depression.
- Chlorzoxazone, a central muscle relaxant, is marginally effective and can cause fatal hepatic necrosis. Accordingly, the drug should be avoided.
- Baclofen and diazepam relieve spasticity by mimicking the inhibitory actions of GABA in the CNS.
- Like the centrally acting muscle relaxants, baclofen and diazepam cause generalized CNS depression.
- In contrast to all other drugs discussed in this chapter, dantrolene acts directly on muscle to promote relaxation.
- Abrupt discontinuation of *intrathecal* baclofen can lead to rhabdomyolysis, multiple organ system failure, and death.
- With prolonged use, dantrolene can cause potentially fatal liver damage. Monitor liver function and minimize dosage and duration of treatment.
- In addition to relief of spasticity, dantrolene is used to treat malignant hyperthermia, a potentially fatal condition caused by succinylcholine and general anesthetics.

26.2.3.4.3.2.2

Summary of Major Nursing Implications*

26.2.3.4.3.2.2.1

DRUGS USED TO TREAT MUSCLE SPASM: CENTRALLY ACTING SKELETAL MUSCLE RELAXANTS

Baclofen

Carisoprodol

Chlorzoxazone

Cyclobenzaprine

Diazepam

Metaxalone

Methocarbamol

Orphenadrine

Tizanidine

Except where noted, the nursing implications summarized below apply to all centrally acting muscle relaxants used to treat muscle spasm.

26.2.3.4.3.2.2.1.1

Preadministration Assessment

26.2.3.4.3.2.2.1....

Therapeutic Goal

Relief of signs and symptoms of muscle spasm.

26.2.3.4.3.2.2.1....

Baseline Data

For patients taking metaxalone and tizanidine, obtain baseline LFTs.

26.2.3.4.3.2.2.1....

Identifying High-Risk Patients

Avoid *chlorzoxazone*, *metaxalone*, and *tizanidine* in patients with liver disease.

26.2.3.4.3.2.2.1.2

Implementation: Administration

26.2.3.4.3.2.2.1....

Routes

26.2.3.4.3.2.2.1....

Oral.

All central skeletal muscle relaxants.

26.2.3.4.3.2.2.1....

Parenteral.

Methocarbamol and diazepam may be given IM and IV as well as PO.

26.2.3.4.3.2.2.1....

Dosage

See [Table 25-1](#).

26.2.3.4.3.2.2.1....

Implementation: Measures to Enhance Therapeutic Effects

The treatment plan should include appropriate physical measures (eg, immobilization of the affected muscle, application of cold compresses, whirlpool baths, and physical therapy).

26.2.3.4.3.2.2.1.3

Ongoing Evaluation and Interventions

26.2.3.4.3.2.2.1....

Minimizing Adverse Effects

26.2.3.4.3.2.2.1....

CNS Depression.

All central muscle relaxants cause CNS depression. **Inform patients about possible effects (drowsiness, dizziness, lightheadedness, fatigue) and advise them to avoid driving and other hazardous activities if significant impairment occurs.**

26.2.3.4.3.2.2.1....

Hepatic Toxicity.

Metaxalone and tizanidine can cause liver damage. Obtain LFTs before treatment and periodically thereafter. If liver damage develops, discontinue treatment. Avoid these drugs in patients with pre-existing liver disease.

Chlorzoxazone can cause hepatitis and potentially fatal hepatic necrosis. The drug should not be used.

26.2.3.4.3.2.2.1....	Minimizing Adverse Interactions	
26.2.3.4.3.2.2.1....	CNS Depressants.	
	Caution patients to avoid CNS depressants (eg, alcohol, benzodiazepines, opioids, antihistamines) because these drugs will intensify the depressant effects of muscle relaxants.	
26.2.3.4.3.2.2.1....	Avoiding Withdrawal Reactions	
	Central muscle relaxants can cause physical dependence. To avoid an abstinence syndrome, withdraw gradually. Warn the patient against abrupt discontinuation of treatment.	
26.2.3.4.3.2.2.2	BACLOFEN	
26.2.3.4.3.2.2.2.1	Preadministration Assessment	
26.2.3.4.3.2.2.2....	Therapeutic Goal	
	Relief of signs and symptoms of spasticity.	243
26.2.3.4.3.2.2.2....	Baseline Data	244
	Assess for spasm, rigidity, pain, range of motion, and dexterity. Obtain baseline LFTs.	
26.2.3.4.3.2.2.2.2	Implementation: Administration	
26.2.3.4.3.2.2.2....	Routes	
	Oral, intrathecal.	
26.2.3.4.3.2.2.2....	Administration	
	Patients with muscle spasm may be unable to self-medicate. Provide assistance if needed.	

26.2.3.4.3.2.2.2.3

Ongoing Evaluation and Interventions

26.2.3.4.3.2.2.2....

Evaluating Therapeutic Effects

Monitor for reductions in rigidity, muscle spasm, and pain and for improvements in dexterity and range of motion.

26.2.3.4.3.2.2.2....

Minimizing Adverse Effects

26.2.3.4.3.2.2.2....

CNS Depression.

Baclofen is a CNS depressant. **Inform patients about possible depressant effects (drowsiness, dizziness, lightheadedness, fatigue) and advise them to avoid driving and other hazardous activities if significant impairment occurs.**

26.2.3.4.3.2.2.2....

Minimizing Adverse Interactions

26.2.3.4.3.2.2.2....

CNS Depressants.

Caution patients to avoid CNS depressants (eg, alcohol, benzodiazepines, opioids, antihistamines) because these drugs will intensify the depressant effects of baclofen.

26.2.3.4.3.2.2.2....

Avoiding Withdrawal Reactions

26.2.3.4.3.2.2.2....

Oral Baclofen.

Abrupt withdrawal can cause visual hallucinations, paranoid ideation, and seizures. **Caution the patient against abrupt discontinuation of treatment.**

26.2.3.4.3.2.2.2....

Intrathecal Baclofen.

Abrupt discontinuation can cause multiple adverse effects, including rhabdomyolysis, multiple organ system failure, and death. Make sure the infusion system is programmed properly and monitored with care.

26.2.3.4.3.2.2.3

DANTROLENE

The nursing implications summarized here apply only to the use of dantrolene for spasticity.

26.2.3.4.3.2.2.3.1

Preadministration Assessment

26.2.3.4.3.2.2.3....

Therapeutic Goal

Relief of signs and symptoms of spasticity.

26.2.3.4.3.2.2.3....

Baseline Data

Assess for spasm, rigidity, pain, range of motion, and dexterity. Obtain baseline LFTs.

26.2.3.4.3.2.2.3....

Identifying High-Risk Patients

Dantrolene is *contraindicated* for patients with active liver disease (eg, cirrhosis, hepatitis).

26.2.3.4.3.2.2.3.2

Implementation: Administration

26.2.3.4.3.2.2.3....

Route

Oral.

26.2.3.4.3.2.2.3....

Administration

Patients with muscle spasm may be unable to self-medicate. Provide assistance if needed.

26.2.3.4.3.2.2.3.3

Ongoing Evaluation and Interventions

26.2.3.4.3.2.2.3....

Summary of Monitoring

26.2.3.4.3.2.2.3....

Therapeutic Effects.

Monitor for reductions in rigidity, spasm, and pain and for improvements in dexterity and range of motion.

26.2.3.4.3.2.2.3....

Adverse Effects.

Monitor LFTs and assess for reduced muscle strength.

26.2.3.4.3.2.2.3....

Minimizing Adverse Effects

26.2.3.4.3.2.2.3....

CNS Depression.

Dantrolene is a CNS depressant. **Inform patients about possible depressant effects (drowsiness, dizziness, lightheadedness, fatigue) and advise them to avoid driving and other hazardous activities if significant impairment occurs.**

26.2.3.4.3.2.2.3....

Hepatic Toxicity.

Dantrolene is hepatotoxic. Assess liver function at baseline and periodically thereafter. If signs of liver dysfunction develop, withdraw dantrolene. **Inform patients about signs of liver dysfunction (eg, jaundice, abdominal pain, malaise) and instruct them to seek medical attention if these develop.**

26.2.3.4.3.2.2.3....

Muscle Weakness.

Dantrolene can decrease muscle strength. Evaluate muscle function to ensure that benefits of therapy (decreased spasticity) are not outweighed by reductions in strength.

26.2.3.4.3.2.2.3....

Minimizing Adverse Interactions

26.2.3.4.3.2.2.3....

CNS Depressants.

Warn patients to avoid CNS depressants (eg, alcohol, benzodiazepines, opioids, antihistamines), because these drugs will intensify depressant effects of dantrolene.

26.2.3.4.3.2.2.4

DIAZEPAM

Nursing implications for diazepam and the other benzodiazepines are summarized in [Chapter 34](#) (Sedative-Hypnotic Drugs).

* Patient education information is highlighted as **blue text**.

²⁷CHAPTER 26 Local Anesthetics

Local anesthetics are drugs that suppress pain by blocking impulse conduction along axons. Conduction is blocked only in neurons located near the site of anesthetic administration. The great advantage of local anesthesia, compared with inhalation anesthesia, is that pain can be suppressed without causing generalized depression of the entire nervous system. Hence, local anesthetics carry much less risk than that associated with general anesthetics.

We begin the chapter by considering the pharmacology of the local anesthetics as a group. After that, we discuss three prototypic agents: procaine, lidocaine, and cocaine. We conclude by discussing specific routes of anesthetic administration.

^{27.1}BASIC PHARMACOLOGY OF THE LOCAL ANESTHETICS

^{27.1.1} Classification

There are two major groups of local anesthetics: *esters* and *amides*. As shown in [Figure 26-1](#), the ester-type anesthetics, represented by *procaine* [Novocain], contain an ester linkage in their structure. In contrast, the amide-type agents, represented by *lidocaine* [Xylocaine], contain an amide linkage. The ester-type agents and amide-type agents differ in two important ways: method of inactivation and promotion of allergic responses. Contrasts between the esters and amides are summarized in [Table 26-1](#).

^{27.1.2} Mechanism of Action

Local anesthetics stop axonal conduction by *blocking sodium channels* in the axonal membrane. Recall that propagation of an action potential requires movement of sodium ions from outside the axon to the inside. This influx takes place through specialized sodium channels. By blocking axonal sodium channels, local anesthetics prevent sodium entry, and thereby bring conduction to a halt.

^{27.1.3} Selectivity of Anesthetic Effects

Local anesthetics are nonselective modifiers of neuronal function. That is, they will block action potentials in all neurons to which they have access. The only way we can achieve selectivity is by delivering the anesthetic to a limited area.

Although local anesthetics can block traffic in all neurons, blockade develops more rapidly in some neurons than others. Specifically, small, nonmyelinated neurons are blocked more rapidly than large, myelinated neurons. Because of this differential sensitivity, some sensations are

blocked sooner than others. Specifically, perception of pain is lost first, followed in order by perception of cold, warmth, touch, and deep pressure.

It should be noted that the effects of local anesthetics are not limited to sensory neurons; these drugs also block conduction in motor neurons (which is why your face looks funny when you leave the dentist).

27.1.4 Time Course of Local Anesthesia

Ideally, local anesthesia would begin promptly and would persist no longer (or shorter) than needed. Unfortunately, although onset of anesthesia is usually rapid (see [Tables 26-2](#) and [26-3 below](#)), duration of anesthesia is often less than ideal. In some cases, anesthesia persists longer than needed. In others, repeated administration is required to maintain anesthesia of sufficient duration.

Onset of local anesthesia is determined largely by the molecular properties of the anesthetic. Before anesthesia can occur, the anesthetic must diffuse from its site of administration to its sites of action within the axon membrane. Anesthesia is delayed until this movement has occurred. The ability of an anesthetic to penetrate the axon membrane is determined by three properties: *molecular size*, *lipid solubility*, and *degree of ionization at tissue pH*. Anesthetics of small size, high lipid solubility, and low ionization cross the axon membrane rapidly. In contrast, anesthetics of large size, low lipid solubility, and high ionization cross slowly. Obviously, anesthetics that penetrate the axon most rapidly have the fastest onset.

245

246

Figure 26-1 Structural formulas of representative local anesthetics.

TABLE 26-1 Contrasts Between Ester and Amide Local Anesthetics

	Ester-type Anesthetics	Amide-type Anesthetics
Characteristic Chemistry	Ester bond	Amide bond
Representative Agents	Procaine	Lidocaine
Incidence of Allergic Reactions	Low	Very low
Method of Metabolism	Plasma esterases	Hepatic enzymes

Termination of local anesthesia occurs as molecules of anesthetic diffuse out of neurons and are carried away in the blood. The same factors that determine onset of anesthesia (molecular size, lipid solubility, degree of ionization) also help determine duration. In addition, *regional blood flow* is an important determinant of how long anesthesia will last. In areas where blood flow is high, anesthetic is carried away quickly, and hence effects terminate with relative haste. In regions where blood flow is low, anesthesia is more prolonged.

27.1.5 Use with Vasoconstrictors

Local anesthetics are frequently administered in combination with a vasoconstrictor—usually *epinephrine*. The vasoconstrictor decreases local blood flow and thereby delays systemic absorption of the anesthetic. Delaying absorption has two benefits: It *prolongs anesthesia* and *reduces the risk of toxicity*. Why is toxicity reduced? First, because absorption is slowed, we can use less anesthetic. Second, by slowing absorption, we can establish a more favorable balance between the rate of entry of anesthetic into circulation and the rate of its conversion into inactive metabolites.

It should be noted that absorption of the vasoconstrictor itself can result in systemic toxicity (eg, palpitations, tachycardia, nervousness, hypertension). If adrenergic stimulation from absorption of epinephrine is excessive, symptoms can be controlled with alpha- and beta-adrenergic antagonists.

27.1.6 Fate in the Body

27.1.6.1 Absorption and Distribution.

Although administered for local effects, local anesthetics do get absorbed into the blood and become distributed to all parts of the body. The rate of absorption is determined largely by blood flow to the site of administration.

27.1.6.2 Metabolism.

The process by which a local anesthetic is metabolized depends on the class—ester or amide—to which it belongs. *Ester-type* local anesthetics are metabolized in the blood by enzymes known as *esterases*. In contrast, *amide-type* anesthetics are metabolized by enzymes in the *liver*. For both types of anesthetic, metabolism results in inactivation.

The balance between rate of absorption and rate of metabolism is clinically significant. If a local anesthetic is absorbed more slowly than it is metabolized, its level in blood will remain low, and hence systemic reactions will be minimal. Conversely, if absorption outpaces metabolism, plasma drug levels will rise, and the risk of systemic toxicity will increase.

27.1.7 Adverse Effects

Adverse effects can occur locally or distant from the site of administration. Local effects are less common.

27.1.7.1 Central Nervous System.

When absorbed in sufficient amounts, local anesthetics cause central nervous system (CNS) excitation followed by depression. During the excitation phase, *convulsions* may occur. If needed, excessive excitation can be managed with an IV benzodiazepine (diazepam or midazolam) or with IV thiopental (a rapid-acting barbiturate). Depressant effects range from *drowsiness* to *unconsciousness*. Death can occur secondary to *depression of respiration*. If respiratory depression is prominent, mechanical ventilation with oxygen is indicated.

246

247

27.1.7.2 Cardiovascular System.

When absorbed in sufficient amounts, local anesthetics can affect the heart and blood vessels. In the heart, these drugs suppress excitability in the myocardium and conducting system, and thereby can cause *bradycardia*, *heart block*, *reduced contractile force*, and *even cardiac arrest*. In blood vessels, anesthetics relax vascular smooth muscle; the resultant vasodilation can cause *hypotension*. As discussed in [Chapter 48](#) (Antidysrhythmic Drugs), the cardiosuppressant actions of one local anesthetic—lidocaine—are exploited to treat dysrhythmias.

27.1.7.3 Allergic Reactions.

An array of hypersensitivity reactions, ranging from *allergic dermatitis* to *anaphylaxis*, can be triggered by local anesthetics. These reactions, which are relatively uncommon, are much more likely with the *ester-type* anesthetics (eg, procaine) than with the amides. Patients allergic to one

ester-type anesthetic are likely to be allergic to all other ester-type agents. Fortunately, cross-hypersensitivity between the esters and amides has not been observed. Hence, the amides can be used when allergies contraindicate use of ester-type anesthetics. Because they are unlikely to cause hypersensitivity reactions, the amide-type anesthetics have largely replaced the ester-type agents when administration by injection is required.

27.1.7.4 Use in Labor and Delivery.

Local anesthetics can depress uterine contractility and maternal expulsion effort. Both actions can *prolong labor*. Also, local anesthetics can cross the placenta, causing *bradycardia and CNS depression in the neonate*.

27.2 PROPERTIES OF INDIVIDUAL LOCAL ANESTHETICS

27.2.1 Procaine

Procaine [Novocain] was synthesized in 1905 and is the prototype of the ester-type local anesthetics. The drug is not effective topically, and hence must be given by injection. Administration in combination with epinephrine delays absorption. Although procaine is readily absorbed, systemic toxicity is rare. Why? Because plasma esterases rapidly convert the drug to inactive, nontoxic products. Being an ester-type anesthetic, procaine poses a greater risk of allergic reactions than the amide-type anesthetics. Individuals allergic to procaine should be considered allergic to all other ester-type anesthetics, but not to the amides.

For many years, procaine was the local anesthetic most preferred for use by injection. However, with the development of newer agents, use of procaine has sharply declined. Once popular in dentistry, procaine is rarely employed in that setting today.

27.2.1.1 Preparations.

Procaine hydrochloride [Novocain] is available in solution (1%, 2%, and 10%) for administration by injection. Dilution is required for use by some routes. Epinephrine (at a final concentration of 1:100,000 or 1:200,000) may be combined with procaine to delay absorption.

27.2.2 Lidocaine

Lidocaine, introduced in 1948, is the prototype of the amide-type agents. One of today's most widely used local anesthetics, lidocaine can be administered topically and by injection. Anesthesia from lidocaine is more rapid, more intense, and more prolonged than with an equal dose of procaine. Effects can be extended by coadministration of epinephrine. Allergic reactions are rare, and individuals allergic to ester-type anesthetics are not cross-allergic to lidocaine. If plasma

levels of lidocaine climb too high, CNS and cardiovascular toxicity can result. Inactivation is by hepatic metabolism.

In addition to its use in local anesthesia, lidocaine is employed to treat dysrhythmias (see [Chapter 48](#)). Control of dysrhythmias results from suppression of cardiac excitability secondary to blockade of cardiac sodium channels.

27.2.2.1 Preparations.

Lidocaine hydrochloride [Xylocaine, others] is available in several formulations (cream, ointment, jelly, solution, aerosol, patch) for topical administration. Lidocaine for injection is available in concentrations ranging from 0.5% to 2%. Some injectable preparations contain epinephrine (1:50,000, 1:100,000, or 1:200,000).

27.2.3 Cocaine

Cocaine was our first local anesthetic. Clinical use was initiated in 1884 by Sigmund Freud and Karl Koller. Freud described the physiologic effects of cocaine while Koller focused on the drug's anesthetic actions. As you can see from its structure (see [Fig. 26-1](#)), cocaine is an ester-type anesthetic. In addition to causing local anesthesia, cocaine has pronounced effects on the sympathetic and central nervous systems. Sympathetic and CNS effects are due in large part to the drug's ability to block uptake of norepinephrine by adrenergic neurons.

27.2.3.1 Anesthetic Use.

Cocaine is an excellent local anesthetic. Administration is topical. The drug is employed for anesthesia of the ear, nose, and throat. Anesthesia develops rapidly and persists for about an hour. Unlike other local anesthetics, cocaine causes intense vasoconstriction (by blocking norepinephrine uptake at sympathetic nerve terminals on blood vessels). Accordingly, the drug should not be given in combination with epinephrine or any other vasoconstrictor. Despite its ability to constrict blood vessels, cocaine is readily absorbed following application to mucous membranes. Significant effects on the brain and heart can result. The drug is inactivated by plasma esterases and liver enzymes.

27.2.3.2 CNS Effects.

Cocaine produces generalized CNS stimulation. Moderate doses cause euphoria, loquaciousness, reduced fatigue, and increased sociability and alertness. Excessive doses can cause seizures. Excitation is followed by CNS depression. Respiratory arrest and death can result.

Although cocaine does not seem to cause substantial physical dependence, psychologic dependence can be profound. The drug is subject to widespread abuse and is classified under Schedule II of the Controlled Substances Act. Cocaine abuse is discussed in [Chapter 39](#).

27.2.3.3 Cardiovascular Effects.

Cocaine stimulates the heart and causes vasoconstriction. These effects result from (1) central stimulation of the sympathetic nervous system and (2) blockade of norepinephrine uptake in the periphery. Stimulation of the heart can produce *tachycardia* and potentially fatal *dysrhythmias*. 247

Vasoconstriction can cause *hypertension*. Cocaine presents an especially serious risk to individuals with cardiovascular disease (eg, hypertension, dysrhythmias, angina pectoris). 248

When used for local anesthesia, cocaine should not be combined with epinephrine. Why? Because the combination would increase the risk of cardiovascular toxicity. Furthermore, since a vasoconstrictor would not significantly retard cocaine absorption, the combination would be irrational as well as dangerous.

27.2.3.4 Preparations and Administration.

Cocaine hydrochloride is available as a powder (5 and 25 gm) and in solution (4% and 10%). Administration is topical. For application to the ear, nose, or throat, a 4% solution is usually employed. The drug must be dispensed in accord with the Controlled Substances Act.

27.2.4 Other Local Anesthetics

In addition to the drugs discussed above, several other local anesthetics are available. These agents differ with respect to indications, route of administration, mode of elimination, duration of action, and toxicity.

The local anesthetics can be grouped according to route of administration: topical versus injection. (Very few agents are administered by both routes. Why? Primarily because the drugs that are suitable for topical application are usually too toxic for parenteral use.) [Table 26-2](#) lists the topically administered local anesthetics along with trade names and time course of action. [Table 26-3](#) presents equivalent information for the injectable agents.

27.3 CLINICAL USE OF LOCAL ANESTHETICS

Local anesthetics may be administered *topically* (for surface anesthesia) and *by injection* (for infiltration anesthesia, nerve block anesthesia, intravenous regional anesthesia, epidural anesthesia, and spinal anesthesia). The uses and hazards of these anesthesia techniques are discussed below.

27.3.1 Topical Administration

Surface anesthesia is accomplished by applying the anesthetic directly to the skin or a mucous membrane. The agents employed most commonly are *lidocaine*, *tetracaine*, and *cocaine*.

27.3.1.1 Therapeutic Uses.

Local anesthetics are applied to the *skin* to relieve pain, itching, and soreness of various causes, including infection, thermal burns, sunburn, diaper rash, wounds, bruises, abrasions, plant poisoning, and insect bites. Application may be made to *mucous membranes* of the nose, mouth, pharynx, larynx, trachea, bronchi, vagina, and urethra. In addition, local anesthetics may be used to relieve discomfort associated with hemorrhoids, anal fissures, and pruritus ani.

27.3.1.2 Systemic Toxicity.

Topical anesthetics can be absorbed in amounts sufficient to produce systemic toxicity. Cardiovascular reactions and CNS reactions are the principal concerns. Because the extent of absorption is proportional to the surface area covered, the risk of toxicity is greatest when the surface area is large. Also, because absorption occurs more readily through mucous membranes than through the skin, application to mucous membranes poses the greater risk. If the skin is abraded or otherwise injured, absorption will be increased, thereby increasing risk.

27.3.2 Administration by Injection

Injection of local anesthetics carries significant risk and requires special skills. Accordingly, injections are usually performed by an anesthesiologist. Because severe systemic reactions may occur, equipment for resuscitation should be immediately available. Also, an IV line should be in place to permit rapid treatment of toxicity. Inadvertent injection into an artery or vein can cause severe toxicity. To ensure the needle is not in a blood vessel, it should be aspirated prior to injection. Following administration, the patient should be monitored for cardiovascular status, respiratory function, and state of consciousness. To reduce the risk of toxicity, local anesthetics should be administered in the lowest effective dose.

27.3.2.1 Infiltration Anesthesia

Infiltration anesthesia is achieved by injecting a local anesthetic directly into the immediate area of surgery or manipulation. Anesthesia can be prolonged by combining the anesthetic with epinephrine. However, epinephrine should not be used in areas supplied by end arteries (toes, fingers, nose, ears, penis), because restriction of blood flow at these sites may result in

Pharmacology for Nursing Care, 7th Edition

gangrene. The agents employed most frequently for infiltration anesthesia are *lidocaine* and *bupivacaine*.

TABLE 26-2 Topical Local Anesthetics: Trade Names, Indications, and Time Course of Action

Chemical Class	Generic Name	Trade Name	Indications		Time Course of Action*	
			Skin	Mucous Membranes	Peak Effect (min)	Duration (min)
Amides	Dibucaine	Nupercainal	✓		Less than 5	15–45
	Lidocaine†	Xylocaine, Lidoderm, others	✓	✓	2–5	15–45
Esters	Benzocaine	Many names	✓	✓	Less than 5	15–45
	Cocaine	Generic only	✓	✓	1–5	30–60
	Tetracaine†	Generic only	✓	✓	3–8	30–60
Others	Dyclonine	Sucrets (spray)		✓	Less than 10	Less than 60
	Pramoxine	Tronothane, others	✓		3–5	—

* Based primarily on application to mucous membranes.

† Also administered by injection.

248

TABLE 26-3 Injectable Local Anesthetics: Trade Names and Time Course of Action

	Generic Name	Trade Name	Time Course of Action [*]	
			Onset (min)	Duration (hr)
Amides	Lidocaine [†]	Xylocaine, Octocaine	Less than 2	0.5–1
	Articaine	Septocaine	1–6 [‡]	1 [‡]
	Bupivacaine	Marcaine, Sensorcaine	5	2–4
	Levobupivacaine	Chirocaine	10 [§]	8 [§]
	Mepivacaine	Carbocaine, Polocaine	3–5	0.75–1.5
	Prilocaine	Citanest	Less than 2	1 or more
	Ropivacaine	Naropin	10–30 [§]	0.5–6 [§]
Esters[¶]	Procaine	Novocain	2–5	0.25–1
	Chlorprocaine	Nesacaine	6–12	0.5
	Tetracaine [†]	Pontocaine	15 or less	2–3

* Values are for *infiltration* anesthesia in the absence of epinephrine (epinephrine prolongs duration two- to threefold).

† Also administered topically.

‡ Values are for *infiltration* anesthesia *with* epinephrine.

§ Values are for *epidural* administration (without epinephrine).

¶ Because of the risk of allergic reactions, the ester anesthetics are rarely administered by injection.

27.3.2.2 Nerve Block Anesthesia

Nerve block anesthesia is achieved by injecting a local anesthetic into or near nerves that supply the surgical field, but at a site distant from the field itself. This technique has the advantage of producing anesthesia with doses that are smaller than those needed for infiltration anesthesia. Drug selection is based on required duration of anesthesia. For shorter procedures, *lidocaine* or *mepivacaine* might be used. For longer procedures, *bupivacaine* would be appropriate.

27.3.2.3 Intravenous Regional Anesthesia

Intravenous regional anesthesia is employed to anesthetize the extremities—hands, feet, arms, and lower legs, but not the entire leg (because too much anesthetic would be needed). Anesthesia is produced by injection into a distal vein of an arm or leg. Prior to giving the anesthetic, blood is removed from the limb (by gravity or by application of an Esmarch bandage), and a tourniquet is applied to the limb (proximal to the site of anesthetic injection) to prevent anesthetic from entering the systemic circulation. To ensure complete blockade of arterial flow throughout the procedure, a double tourniquet is used. Following injection, the anesthetic diffuses out of the vasculature and becomes evenly distributed to all areas of the occluded limb. When the tourniquet is loosened at the end of surgery, about 15% to 30% of administered anesthetic is released into the systemic circulation. *Lidocaine—without epinephrine*—is the preferred agent for this type of anesthesia.

27.3.2.4 Epidural Anesthesia

Epidural anesthesia is achieved by injecting a local anesthetic into the epidural space (ie, within the spinal column but outside the dura mater). A catheter placed in the epidural space allows administration by bolus or by continuous infusion. Following administration, diffusion of anesthetic across the dura into the subarachnoid space blocks conduction in nerve roots and in the spinal cord itself. Diffusion through intervertebral foramina blocks nerves located in the paravertebral region. With epidural administration, anesthetic can reach the systemic circulation in significant amounts. As a result, when the technique is used during delivery, neonatal depression may result. *Lidocaine* and *bupivacaine* are popular drugs for epidural anesthesia. Because of the risk of death from cardiac arrest, the concentrated (0.75%) solution of bupivacaine must not be used in obstetric patients.

27.3.2.5 Spinal (Subarachnoid) Anesthesia

27.3.2.5.1 Technique.

Spinal anesthesia is produced by injecting local anesthetic into the subarachnoid space. Injection is made in the lumbar region below the termination of the cord. Spread of anesthetic within the subarachnoid space determines the level of anesthesia achieved. Movement of anesthetic within the subarachnoid space is determined by two factors: (1) the density of the anesthetic solution and (2) the position of the patient. Anesthetics employed most commonly are *bupivacaine*, *lidocaine*, and *tetracaine*. All must be free of preservatives.

27.3.2.5.2 Adverse Effects.

The most significant adverse effect of spinal anesthesia is hypotension. Blood pressure is reduced by venous dilation secondary to blockade of sympathetic nerves. (Loss of venous tone decreases the return of blood to the heart, causing a reduction in cardiac output and a corresponding fall in blood pressure.) Loss of venous tone can be compensated for by placing the patient in a 10- to 15-degree head-down position, which promotes venous return to the heart. If blood pressure cannot be restored through head-down positioning, drugs may be indicated; ephedrine and phenylephrine have been employed to promote vasoconstriction and enhance cardiac performance.

Autonomic blockade may disrupt function of the intestinal and urinary tracts, causing fecal incontinence and either urinary incontinence or urinary retention. The prescriber should be notified if the patient fails to void within 8 hours of the end of surgery.

Spinal anesthesia frequently causes headache. These “spinal” headaches are posture dependent and can be relieved by having the patient assume a supine position.

27.3.2.5.2.1

KEY POINTS

- Local anesthetics stop nerve conduction by blocking sodium channels in the axon membrane.
- Small, nonmyelinated neurons are blocked more rapidly than large, myelinated neurons.
- There are two classes of local anesthetics: ester-type anesthetics and amide-type anesthetics.
- Ester-type anesthetics (eg, procaine) occasionally cause allergic reactions and are inactivated by esterases in the blood.
- Amide-type anesthetics (eg, lidocaine) rarely cause allergic reactions and are inactivated by enzymes in the liver.
- Onset of anesthesia occurs most rapidly with anesthetics that are small, lipid soluble, and nonionized at physiologic pH.

- Termination of local anesthesia is determined in large part by regional blood flow. Hence, coadministration of epinephrine, a vasoconstrictor, will prolong anesthesia.

249

250

- Local anesthetics can be absorbed in amounts sufficient to cause systemic toxicity. Principal concerns are cardiac depression, vasodilation, and CNS excitation followed by depression.
- Because of the risk of systemic toxicity, an IV line should be in place prior to anesthetic administration (to permit administration of required emergency drugs), and facilities for resuscitation should be immediately available.

Therapeutic Goal

Production of local anesthesia for surgical, dental, and obstetric procedures.

27.3.2.5.2.2.2.2

Identifying High-Risk Patients

Ester-type local anesthetics are *contraindicated* for patients with a history of serious allergic reactions to these drugs.

27.3.2.5.2.2.2.3

Implementation: Administration

27.3.2.5.2.2.2...

Preparation of the Patient

The nurse may be responsible for preparing the patient to receive an injectable local anesthetic. Preparation includes cleansing the injection site, shaving the site when indicated, and placing the patient in a position appropriate to receive the injection. Children, elderly patients, and uncooperative patients may require restraint prior to injection by some routes.

27.3.2.5.2.2.2...

Administration

Injection of local anesthetics is performed by clinicians with special training in their use (physicians, dentists, nurse anesthetists).

27.3.2.5.2.2.2.4

Ongoing Evaluation and Interventions

27.3.2.5.2.2.2...

Minimizing Adverse Effects

27.3.2.5.2.2.2...

Systemic Reactions.

Absorption into the general circulation can cause systemic toxicity. Effects on the CNS and heart are of greatest concern. CNS toxicity manifests as a brief period of excitement, possibly including convulsions, followed by CNS depression, which can result in respiratory depression. Cardiotoxicity can manifest as bradycardia, AV heart block, and cardiac arrest. Monitor blood pressure, pulse rate, respiratory rate, and state of consciousness. Have facilities for cardiopulmonary resuscitation available. Manage CNS excitation with IV diazepam or IV thiopental.

27.3.2.5.2.2.2...

Allergic Reactions.

Severe allergic reactions are rare but can occur. These are most likely with ester-type anesthetics. Avoid ester-type agents in patients with a history of allergy to these drugs.

27.3.2.5.2.2.2...

Labor and Delivery.

Use of local anesthetics during delivery can cause bradycardia and CNS depression in the newborn. Monitor cardiac status. Avoid concentrated (0.75%) bupivacaine.

27.3.2.5.2.2.2...

Self-Inflicted Injury.

Since anesthetics eliminate pain, and since pain warns us about injury, patients recovering from anesthesia must be protected from inadvertent harm until the anesthetic wears off. **Caution the patient against activities that might result in unintentional harm.**

27.3.2.5.2.2.2...

Spinal Headache and Urinary Retention.

Patients recovering from spinal anesthesia may experience headache and urinary retention. Headache is posture dependent and can be minimized by having the patient remain supine for about 12 hours. Notify the prescriber if the patient fails to void within 8 hours.

* Patient education information is highlighted as **blue text**.

²⁸CHAPTER 27 General Anesthetics

General anesthetics are drugs that produce unconsciousness and a lack of responsiveness to all painful stimuli. In contrast, *local anesthetics* do not reduce consciousness and they blunt sensation only in a limited area (see [Chapter 26](#)).

General anesthetics can be divided into two groups: (1) inhalation anesthetics and (2) intravenous anesthetics. The inhalation anesthetics are the main focus of this chapter.

When considering the anesthetics, we need to distinguish between the terms *analgesia* and *anesthesia*. Analgesia refers specifically to loss of sensibility to pain. In contrast, anesthesia refers not only to loss of pain but to loss of all other sensations as well (eg, touch, temperature, taste). Hence, while analgesics (eg, aspirin, morphine) can selectively reduce pain without affecting other sensory modalities and without reducing consciousness, the general anesthetics have no such selectivity: During general anesthesia, all sensation is lost, and consciousness is lost as well.

The development of general anesthetics has had an incalculable impact on the surgeon's art. The first general anesthetic—ether—was introduced by Dr. William T. Morton in 1846. Prior to this, surgery was a brutal and exquisitely painful ordeal, undertaken only in the most desperate circumstances. Immobilization of the surgical field was accomplished with the aid of strong men and straps. Survival of the patient was determined by the surgeon's speed—not his finesse. With the advent of general anesthesia, all of this changed. General anesthesia produced a patient who slept through surgery and experienced no pain. These changes allowed surgeons to develop the lengthy and intricate procedures that are routine today. Such procedures were unthinkable before general anesthetics became available.

In addition to their use in surgery, general anesthetics are used to facilitate many other procedures, including endoscopy, urologic procedures, radiation therapy, electroconvulsive therapy, transbronchial biopsy, and various cardiologic procedures.

^{28.1}BASIC PHARMACOLOGY OF THE INHALATION ANESTHETICS

In this section, we consider the inhalation anesthetics as a group. Our focus is on properties of an ideal anesthetic, pharmacokinetics of inhalation anesthetics, adverse effects of the inhalation anesthetics, and drugs employed as adjuncts to anesthesia.

^{28.1.1} Properties of an Ideal Inhalation Anesthetic

An ideal inhalation anesthetic would produce unconsciousness, analgesia, muscle relaxation, and amnesia. Furthermore, induction of anesthesia would be brief and pleasant, as would the process of emergence. Depth of anesthesia could be raised or lowered with ease. Adverse effects would be

minimal, and the margin of safety would be large. As you might guess, the ideal inhalation anesthetic does not exist: No single agent has all of these qualities.

28.1.2 Balanced Anesthesia

The term *balanced anesthesia* refers to the use of a combination of drugs to accomplish what we cannot achieve with an inhalation anesthetic alone. Put another way, balanced anesthesia is a technique employed to compensate for the lack of an ideal anesthetic. Drugs are combined in balanced anesthesia to ensure that induction is smooth and rapid, and that analgesia and muscle relaxation are adequate. The agents used most commonly to achieve these goals are (1) short-acting barbiturates (for induction of anesthesia), (2) neuromuscular blocking agents (for muscle relaxation), and (3) opioids and nitrous oxide (for analgesia). The primary benefit of combining drugs to achieve surgical anesthesia is that doing so permits full general anesthesia at doses of the inhalation anesthetic that are lower (safer) than those that would be required if surgical anesthesia were attempted using an inhalation anesthetic alone.

252

253

28.1.3 Molecular Mechanism of Action

Our understanding of how inhalation anesthetics act has changed dramatically in the past decade. Attention has shifted from nonspecific effects on neuronal membranes to selective alteration of synaptic transmission. However, despite recent advances, we still don't know with certainty just how these drugs work.

More than 100 years ago, scientists postulated that inhalation anesthetics produced their effects through nonspecific interactions with lipid components of the neuronal cell membrane. This long-standing theory was based on the observation that there was a direct correlation between the potency of an anesthetic and its lipid solubility. That is, the more readily an anesthetic could dissolve in the lipid matrix of the neuronal membrane, the more readily that agent could produce anesthesia. Hence the theory that anesthetics dissolve into neuronal membranes, disrupt their structure, and thereby suppress axonal conduction and possibly synaptic transmission. However, this theory was called into question by an important observation: enantiomers of the same anesthetic have different actions. Recall that enantiomers are simply mirror-image molecules that have identical atomic components, and hence have identical physical properties, including lipid solubility. Therefore, since enantiomers have the same ability to penetrate the axonal membrane, but do not have the same ability to produce anesthesia, a property other than lipid solubility must underlie anesthetic actions.

Current data indicate that inhalation anesthetics work by *enhancing transmission at inhibitory synapses* and by *depressing transmission at excitatory synapses*. Except for nitrous oxide, all of the agents used today enhance activation of receptors for gamma-aminobutyric acid (GABA), the

principal inhibitory transmitter in the central nervous system (CNS). As a result, these drugs promote generalized inhibition of CNS function. It should be noted that anesthetics do not activate GABA receptors directly. Rather, by binding with the GABA receptor, they increase receptor sensitivity to activation by GABA itself. How does nitrous oxide work? Probably by blocking the actions of *N*-methyl-D-aspartate (NMDA), an excitatory neurotransmitter. Nitrous oxide appears to bind with the NMDA receptor and thereby prevent receptor activation by NMDA itself.

28.1.4 Minimum Alveolar Concentration

The minimum alveolar concentration (MAC), also known as the median alveolar concentration, is an index of inhalation anesthetic potency. The MAC is defined as *the minimum concentration of drug in the alveolar air that will produce immobility in 50% of patients exposed to a painful stimulus*. Note that, by this definition, a *low* MAC indicates *high* anesthetic potency.

From a clinical perspective, knowledge of the MAC of an anesthetic is of great practical value: The MAC tells us approximately how much anesthetic the inspired air must contain to produce anesthesia. A low MAC indicates that the inspired air need contain only low concentrations of the anesthetic to produce surgical anesthesia. The opposite is true for drugs with a high MAC. Fortunately, most inhalation anesthetics have low MACs ([Table 27-1](#)). However, one important agent—nitrous oxide—has a very high MAC. The MAC is so high, in fact, that surgical anesthesia cannot be achieved using nitrous oxide alone.

Please note that, to produce general anesthesia in *all* patients, the inspired anesthetic concentration should be 1.2 to 1.5 times the MAC. Why? Because if the concentration were simply equal to the MAC, 50% of patients would be receiving less than they need.

28.1.5 Pharmacokinetics

28.1.5.1 Uptake and Distribution

To produce therapeutic effects, an inhalation anesthetic must reach a CNS concentration sufficient to suppress neuronal excitability. The principal determinants of anesthetic concentration are (1) uptake from the lungs and (2) distribution to the CNS and other tissues. The kinetics of anesthetic uptake and distribution are complex, and we will not try to cover them in depth.

28.1.5.1.1 Uptake.

A major determinant of anesthetic uptake is the concentration of anesthetic in the inspired air: 253

The greater the anesthetic concentration, the more rapid uptake will be. Other factors that 254

influence uptake are pulmonary ventilation, solubility of the anesthetic in blood, and blood flow through the lungs. An increase in any of these will increase uptake rate.

TABLE 27-1 Properties of the Major Inhalation Anesthetics

Drug	MAC* (%)	Analgesic Effect	Effect on Blood Pressure	Effect on Respiration	Muscle Relaxant Effect	Extent of Metabolism	Compatible with Epinephrine
Nitrous oxide	105	+ + + +	→	→	0	0	Yes
Halothane	0.75	+ +	↓	↓ ↓	+	20%	No
Desflurane	4.58	+ +	↓	↓ ↓	+ +	0.02%	Yes
Enflurane	1.68	+ +	↓	↓ ↓	+ +	2.4%	Yes†
Isoflurane	1.15	+ +	↓	↓ ↓	+ +	0.2%	Yes
Sevoflurane	1.71	+ +	↓	↓ ↓	+ +	3%	Yes

* Minimal alveolar concentration.

† Enflurane sensitizes the myocardium to catecholamines, but less so than halothane.

28.1.5.1.2 Distribution.

Distribution to specific tissues is determined largely by regional blood flow. Anesthetic levels rise rapidly in the brain, kidney, heart, and liver—tissues that receive the largest fraction of the cardiac output. Anesthetic levels in these tissues equilibrate with those in blood 5 to 15 minutes after the onset of administration. In skin and skeletal muscle—tissues with an intermediate blood flow—equilibration occurs more slowly. The most poorly perfused tissues—fat, bone, ligaments, and cartilage—are the last to equilibrate with anesthetic levels in the blood.

28.1.5.2 Elimination

28.1.5.2.1 Export in the Expired Breath.

Inhalation anesthetics are eliminated almost entirely via the lungs; hepatic metabolism is minimal. The same factors that determine anesthetic uptake (pulmonary ventilation, blood flow to the lungs, anesthetic solubility in blood and tissues) also determine the rate of elimination. Since blood flow to the brain is high, anesthetic levels in the brain drop rapidly when administration is stopped. Anesthetic levels in tissues that have a lower blood flow

decline more slowly. Because anesthetic levels in the CNS decline more rapidly than levels in other tissues, patients can awaken from anesthesia long before all anesthetic has left the body.

28.1.5.2.2 Metabolism.

Most inhalation anesthetics undergo very little metabolism. Hence, metabolism does not influence the time course of anesthesia. However, since some metabolites can be toxic, metabolism is nonetheless clinically significant.

28.1.6 Adverse Effects

The adverse effects discussed here apply to the inhalation anesthetics as a group. Not all of these effects are seen with every anesthetic.

28.1.6.1 Respiratory and Cardiac Depression.

Depression of respiratory and cardiac function is a concern with virtually all inhalation anesthetics. Doses only 2 to 4 times greater than needed for surgical anesthesia are sufficient to cause potentially lethal depression of pulmonary and cardiac function. To compensate for respiratory depression, and to maintain a steady rate of administration, almost all patients require mechanical support of ventilation.

28.1.6.2 Sensitization of the Heart to Catecholamines.

Some anesthetics—most notably *halothane*—can increase the sensitivity of the heart to stimulation by catecholamines (eg, norepinephrine, epinephrine). While in this sensitized state, the heart may develop dysrhythmias in response to catecholamines. Exposure to catecholamines may result from two causes: (1) release of endogenous catecholamines (in response to pain or other stimuli of the sympathetic nervous system), and (2) topical application of catecholamines to control bleeding in the surgical field.

28.1.6.3 Malignant Hyperthermia.

Malignant hyperthermia is a rare but potentially fatal reaction that can be triggered by all inhalation anesthetics (except nitrous oxide). Predisposition to the reaction is genetic. Malignant hyperthermia is characterized by muscle rigidity and a profound elevation of temperature—sometimes to as high as 43°C (109°F). Left untreated, the reaction can rapidly prove fatal. The risk of malignant hyperthermia is greatest when an inhalation anesthetic is combined with *succinylcholine*, a neuromuscular blocker that also can trigger the reaction. Diagnosis and management of malignant hyperthermia are discussed in [Chapter 16](#).

28.1.6.4 Aspiration of Gastric Contents.

During the state of anesthesia, reflexes that normally prevent aspiration of gastric contents into the lungs are abolished. Aspiration of gastric fluids can cause bronchospasm and pneumonia. Use of an endotracheal tube isolates the trachea and can thereby help prevent these complications.

28.1.6.5 Hepatotoxicity.

Rarely, patients receiving inhalation anesthesia develop serious liver dysfunction. The risk is about equal with all anesthetics.

28.1.6.6 Toxicity to Operating Room Personnel.

Chronic exposure to low levels of anesthetics may harm operating room personnel. Suspected reactions include headache, reduced alertness, and spontaneous abortion. Risk can be reduced by venting anesthetic gases from the operating room.

28.1.7 Drug Interactions

Several classes of drugs—analgesics, CNS depressants, CNS stimulants—can influence the amount of anesthetic required to produce anesthesia. Opioid analgesics allow a reduction in anesthetic dosage. Why? Because, when opioids are present, analgesia needn't be produced by the anesthetic alone. Similarly, because CNS depressants (barbiturates, benzodiazepines, alcohol) add to the depressant effects of anesthetics, concurrent use of CNS depressants lowers the required dose of anesthetic. Conversely, concurrent use of CNS stimulants (amphetamines, cocaine) increases the required dose of anesthetic.

28.1.8 Adjuncts to Inhalation Anesthesia

Adjunctive drugs are employed to complement the beneficial effects of inhalation anesthetics and to counteract their adverse effects. Some adjunctive agents are administered before surgery, some during, and some after.

28.1.8.1 Preanesthetic Medications

Preanesthetic medications are administered for three main purposes: (1) reducing anxiety, (2) producing perioperative amnesia, and (3) relieving preoperative and postoperative pain. In addition, preanesthetic medications may be used to suppress certain adverse responses: excessive salivation, excessive bronchial secretion, coughing, bradycardia, and vomiting.

28.1.8.1.1 Benzodiazepines.

Benzodiazepines are given preoperatively to reduce anxiety and promote amnesia. When administered properly, these drugs produce sedation with little or no respiratory depression. Intravenous midazolam [Versed] is used most often.

28.1.8.1.2 Opioids.

Opioids (eg, morphine, fentanyl) are administered to relieve preoperative and postoperative pain. These drugs may also help by suppressing cough.

Opioids can have adverse effects. Because they depress the CNS, opioids can delay awakening after surgery. Effects on the bowel and urinary tract may result in postoperative constipation and urinary retention. Stimulation of the chemoreceptor trigger zone promotes vomiting. Opioid-induced respiratory depression adds with anesthetic-induced respiratory depression, thereby increasing the risk of postoperative respiratory distress.

254

28.1.8.1.3 Alpha₂-Adrenergic Agonists.

255

Two alpha₂ agonists—clonidine and dexmedetomidine—are employed as adjuncts to anesthesia. Both produce their effects through actions in the CNS.

Clonidine is used for hypertension and pain reduction. When administered prior to surgery, the drug reduces anxiety and causes sedation. In addition, it permits a reduction in anesthetic and analgesic dosages. Analgesic properties of clonidine are discussed further in [Chapter 28](#); antihypertensive properties are discussed in [Chapters 19](#) and [46](#). The formulation used for analgesia is marketed under the trade name *Duraclon*; the formulation for hypertension is marketed as *Catapres*.

Dexmedetomidine [Precedex] is a highly selective alpha₂-adrenergic agonist currently approved only for short-term sedation in critically ill patients. However, the drug is also used for other purposes, including enhancement of sedation and analgesia in patients undergoing anesthesia. The pharmacology of dexmedetomidine is discussed further in [Chapter 28](#).

28.1.8.1.4 Anticholinergic Drugs.

Anticholinergic drugs (eg, atropine) may be given to decrease the risk of bradycardia during surgery. Surgical manipulations can trigger parasympathetic reflexes, which in turn can produce profound vagal slowing of the heart. Pretreatment with a cholinergic antagonist prevents bradycardia from this cause.

At one time, anticholinergic drugs were needed to prevent excessive bronchial secretions associated with anesthesia. Older anesthetic agents (eg, ether) irritate the respiratory tract, and thereby cause profuse bronchial secretions. Cholinergic blockers were given to suppress this response. Since the inhalation anesthetics used today are much less irritating, bronchial secretions are minimal. Consequently, although anticholinergic agents are still employed as adjuncts to anesthesia, their purpose is no longer to suppress bronchial secretions (although they may still help by suppressing salivation).

28.1.8.2 Neuromuscular Blocking Agents

Most surgical procedures require skeletal muscle relaxation, a state achieved with neuromuscular blockers (eg, succinylcholine, pancuronium). By using these drugs, we can reduce the dose of general anesthetic. Why? Because we don't need the very high doses of anesthetic that would be required if we tried to produce muscle relaxation with the anesthetic by itself.

Muscle relaxants can have adverse effects. Neuromuscular blocking agents prevent contraction of all skeletal muscles, including the diaphragm and other muscles of respiration. Accordingly, patients require mechanical support of ventilation during surgery. Patients recovering from anesthesia may have reduced respiratory capacity owing to residual neuromuscular blockade. Accordingly, respiration must be monitored until recovery is complete.

TABLE 27-2 Classification of the Inhalation Anesthetics

Class	Anesthetic	
	Generic Name	Trade Name
Volatile Liquids	Halothane	Fluothane
	Enflurane	Ethrane
	Isoflurane	Forane
	Desflurane	Suprane
	Sevoflurane	Ultane
Gases	Nitrous oxide	

It is important to appreciate that neuromuscular blockers produce a state of total flaccid paralysis. In this condition, a patient could be fully awake while seeming asleep. Incidents in which paralyzed patients have been awake during surgery, but unable to communicate their agony, are all too common: Every year in the United States, of the 21 million people who

undergo anesthesia, an estimated 2000 to 4000 wake up during the procedure. Because neuromuscular blockade can obscure depth of anesthesia, and because failure to maintain adequate anesthesia can result in true horror, the clinician administering anesthesia must be especially watchful to ensure that the anesthetic dosage is adequate.

28.1.8.3 Postanesthetic Medications

28.1.8.3.1 Analgesics.

Analgesics are needed to control postoperative pain. If pain is severe, opioids are indicated. For mild pain, aspirin-like drugs may suffice.

28.1.8.3.2 Antiemetics.

Patients recovering from anesthesia often experience nausea and vomiting. This can be suppressed with antiemetics. Among the most effective is *ondansetron* [Zofran], a drug developed to suppress nausea and vomiting in patients undergoing cancer chemotherapy. Other commonly used antiemetics are *promethazine* and *droperidol*.

28.1.8.3.3 Muscarinic Agonists.

Abdominal distention (from atony of the bowel) and urinary retention are potential postoperative complications. Both conditions can be relieved through activation of muscarinic receptors. The muscarinic agonist employed most often is *bethanechol*.

28.1.9 Dosage and Administration

Administration of inhalation anesthetics is performed only by anesthesiologists (physicians) and anesthesiologists (nurses). Clinicians who lack the training of these specialists have no authority to administer anesthesia. Since knowledge of anesthetic dosage and administration is the responsibility of specialists, and since this text is designed for beginning students, details on dosage and administration are not presented. If you need this information, consult a textbook of anesthesiology.

28.1.10 Classification of Inhalation Anesthetics

Inhalation anesthetics fall into two basic categories: *gases* and *volatile liquids*. The gases, as their name implies, exist in a gaseous state at atmospheric pressure. The volatile liquids exist in a liquid state at atmospheric pressure, but can be easily volatilized (converted to a vapor) for administration by inhalation. The inhalation anesthetics in current use are listed in [Table 27-2](#). The

volatile liquids—halothane, enflurane, isoflurane, desflurane, and sevoflurane—are similar to one another in structure and function. The only gas in current use is nitrous oxide.

28.2 PROPERTIES OF INDIVIDUAL INHALATION ANESTHETICS

28.2.1 Halothane

Halothane [Fluothane] is the prototype of the volatile inhalation anesthetics. The drug was introduced in 1956 and remains the standard against which the newer volatile liquids are compared. Halothane is commonly used in children. However, because of concerns about liver failure (see below), use in adults has sharply declined.

28.2.1.1 Anesthetic Properties

Halothane is an effective anesthetic. For some procedures, anesthesia may be produced with halothane alone. Other procedures require adjunctive drugs.

28.2.1.1.1 Potency.

Halothane is a high-potency anesthetic, and hence has a low MAC (0.75%), indicating that unconsciousness can be produced when the drug's concentration in alveolar air is only 0.75%.

28.2.1.1.2 Time Course.

Induction of anesthesia is smooth and relatively rapid. However, although halothane can act quickly, in actual practice, induction is usually produced with thiopental, a rapid-acting barbiturate. Once the patient is unconscious, depth of anesthesia can be raised or lowered with ease. Patients awaken about 1 hour after ceasing halothane inhalation.

28.2.1.1.3 Analgesia.

Halothane is a weak analgesic. Consequently, when the drug is used for surgical anesthesia, coadministration of a strong analgesic is usually required. The analgesics most commonly employed are opioids (eg, morphine) and nitrous oxide.

28.2.1.1.4 Muscle Relaxation.

Although halothane has muscle relaxant actions, the degree of relaxation is generally inadequate for surgery. Accordingly, concurrent use of a neuromuscular blocking agent (eg, pancuronium) is usually required. Although relaxation of skeletal muscle is only moderate, halothane does promote significant relaxation of uterine smooth muscle. Consequently, when

used in obstetrics, halothane may inhibit uterine contractions, thereby delaying delivery and possibly increasing postpartum bleeding.

28.2.1.2 Adverse Effects

28.2.1.2.1 Hypotension.

Halothane causes a dose-dependent reduction in blood pressure. Doses only twice those needed for surgical anesthesia can produce complete circulatory failure and death. Halothane promotes hypotension by two mechanisms. First, the drug depresses myocardial contractility, and can thereby reduce cardiac output by 20% to 50%. Second, halothane increases vagal tone, which slows heart rate and thereby reduces cardiac output even further.

28.2.1.2.2 Respiratory Depression.

Halothane produces significant depression of respiration. To ensure adequate oxygenation, two measures are implemented: (1) mechanical or manual ventilatory support and (2) enrichment of the inspired gas mixture with oxygen.

28.2.1.2.3 Promotion of Dysrhythmias.

Halothane promotes dysrhythmias in two ways. First, the drug sensitizes the myocardium to catecholamines. Second, it prolongs the QT interval (see discussion of QT interval drugs in [Chapter 7](#)). To reduce the risk of dysrhythmias, epinephrine and other catecholamines should be used with caution. Also, caution is required in patients with existing QT prolongation and in those taking other drugs known to prolong the QT interval.

28.2.1.2.4 Malignant Hyperthermia.

Genetically predisposed patients may experience malignant hyperthermia. Accordingly, patients with a personal or familial history of malignant hyperthermia should not receive halothane, unless there is no other option. If halothane is employed, it must not be combined with succinylcholine, which would further increase the risk of malignant hyperthermia.

28.2.1.2.5 Hepatotoxicity.

Rarely, halothane produces hepatitis, sometimes progressing to massive hepatic necrosis and death. The incidence of fulminant hepatic failure is 1 in 30,000. Hepatotoxicity is thought to result from an autoimmune process triggered by metabolites of halothane that have formed complexes with liver proteins. Halothane-induced liver failure has occurred in adults only—

never in children. Because of concerns about liver damage, halothane is rarely given to adults. However, the drug still enjoys widespread use in children.

28.2.1.2.5.1 Other Adverse Effects.

Postoperative *nausea* and *vomiting* may occur, but these reactions are less common with halothane than with older anesthetics (eg, ether). By decreasing blood flow to the kidney, halothane can cause a substantial *decrease in urine output*.

28.2.1.3 Elimination

The majority (60% to 80%) of an administered dose is eliminated intact in the exhaled breath. Hepatic metabolism accounts for about 20% of elimination.

28.2.2 Isoflurane

Isoflurane [Forane] is widely used. The drug is potent (MAC = 1.15%) and has properties much like those of halothane. Induction of anesthesia is smooth and rapid, depth of anesthesia can be adjusted with speed and ease, and patients emerge from anesthesia rapidly. Like other volatile liquids, isoflurane causes respiratory depression and hypotension. With isoflurane, hypotension results from vasodilation rather than from reduced cardiac output. Isoflurane is a better muscle relaxant than halothane, but nonetheless is usually employed with a neuromuscular blocker. Like halothane, isoflurane suppresses uterine contraction. In contrast to halothane, isoflurane is not associated with renal or hepatic toxicity. Isoflurane is eliminated almost entirely in the expired breath; only 0.2% undergoes metabolism.

The cardiac actions of isoflurane differ significantly from those of halothane. Unlike halothane, isoflurane does not cause myocardial depression. Hence, cardiac output is not decreased. Furthermore, isoflurane does not sensitize the myocardium to catecholamines. Hence, patients can be given epinephrine and other catecholamines with little fear of precipitating a dysrhythmia. Finally, isoflurane is not associated with QT prolongation.

28.2.3 Enflurane

Enflurane [Ethrane] has pharmacologic properties very similar to those of halothane. Enflurane was introduced in 1973 and became quite popular. However, with the introduction of newer agents with preferable kinetics and fewer risks, use of the drug has declined.

Comparison of enflurane with halothane reveals important similarities and a few significant differences. Both anesthetics are very potent: the MAC of enflurane is 1.68%, compared with 0.75% for halothane. As with halothane, induction of anesthesia is smooth and rapid, and depth of

anesthesia can be changed quickly and easily. Like halothane, enflurane produces substantial depression of respiration. Accordingly, patients are likely to need ventilatory support; the concentration of inspired oxygen should be at least 35%. Muscle relaxation induced by enflurane is greater than with halothane. However, despite this action, a neuromuscular blocker is usually employed (to permit a reduction of enflurane dosage). Like halothane, enflurane can suppress uterine contractions, thereby impeding labor. Significantly, sensitization of the myocardium to catecholamines is less than with halothane. As a result, patients can be given catecholamines with relative safety. High doses of enflurane can induce seizures, a response not seen with halothane. Obviously, enflurane should be avoided in patients with a history of seizure disorders. Like halothane, enflurane is eliminated primarily in the exhaled breath as the intact parent compound. About 2% is eliminated by hepatic metabolism.

256

28.2.4 Desflurane

257

Desflurane [Suprane] is nearly identical in structure to isoflurane. Induction occurs more rapidly than with any other volatile anesthetic; depth of anesthesia can be changed quickly; and recovery occurs only minutes after ceasing administration. Desflurane is indicated for *maintenance* of anesthesia in adults and children and for *induction* of anesthesia in adults. The drug is not approved for induction in children and infants because of a high incidence of respiratory difficulties (laryngospasm, apnea, increased secretions), which are caused by the drug's pungency. Like isoflurane, desflurane can cause respiratory depression and hypotension secondary to vasodilation. During induction, or in response to an abrupt increase in desflurane blood levels, heart rate and blood pressure may increase, causing tachycardia and hypertension. Postoperative nausea and vomiting are possible. Malignant hypertension has occurred in experimental animals. Desflurane undergoes even less metabolism than isoflurane. Hence, the risk of postoperative organ injury is probably low.

28.2.5 Sevoflurane

Sevoflurane [Ultane] is similar to desflurane. The drug is approved for induction and maintenance of anesthesia in adults and children. As with desflurane, induction is rapid, depth of anesthesia can be adjusted easily, and recovery occurs minutes after ceasing inhalation. Because onset and recovery occur quickly, sevoflurane is widely used for outpatient procedures. In contrast to desflurane, sevoflurane has a pleasant odor and is not a respiratory irritant. Accordingly, the drug is suitable for mask induction in children. Sevoflurane has a MAC of 1.71% and is eliminated primarily in the exhaled breath; about 3% gets metabolized. Adverse effects are minimal. The most common problem is postoperative nausea and vomiting. In contrast to desflurane, sevoflurane does not cause tachycardia or hypertension. Occasionally, sevoflurane produces

extreme heat and even fire in the administration apparatus, usually when the CO₂ adsorbent in the apparatus has become desiccated.

28.2.6 Nitrous Oxide

Nitrous oxide (aka “laughing gas”) differs from the volatile liquid anesthetics with respect to pharmacologic properties and uses. Pharmacologically, nitrous oxide is unique in two ways: (1) it has very low *anesthetic* potency, whereas the anesthetic potency of the other inhalation agents is high, and (2) it has very high *analgesic* potency, whereas the analgesic potency of other inhalation agents is low. Because of these properties, nitrous oxide has a unique pattern of use: owing to its low anesthetic potency, nitrous oxide is never employed as a primary anesthetic. However, owing to its high analgesic potency, nitrous oxide is frequently combined with other inhalation agents to enhance analgesia.

Because nitrous oxide has such low anesthetic potency, *it is virtually impossible to produce surgical anesthesia employing nitrous oxide alone*. The MAC of nitrous oxide is very high—greater than 100%. This tells us that, even if it were possible to administer 100% nitrous oxide (ie, inspired gas that contains only nitrous oxide and no oxygen), this would still be insufficient to produce surgical anesthesia. Because practical considerations (ie, the need to administer at least 30% oxygen) limit the maximum usable concentration of nitrous oxide to 70%, and because much higher concentrations are needed to produce surgical anesthesia, it is clear that full anesthesia cannot be achieved with nitrous oxide alone.

Despite its low anesthetic potency, nitrous oxide is one of our most widely used inhalation agents: *Many patients undergoing general anesthesia receive nitrous oxide to supplement the analgesic effects of the primary anesthetic*. As indicated in [Table 27-1](#), the analgesic effects of nitrous oxide are substantially greater than those of the other inhalation agents. In fact, nitrous oxide is such a potent analgesic that inhaling 20% nitrous oxide can produce pain relief equivalent to that of morphine. The advantage of providing analgesia with nitrous oxide, rather than relying entirely on the primary anesthetic, is that the dosage of the primary anesthetic can be significantly decreased—usually by 50% or more. As a result, respiratory and cardiac depression are reduced, and emergence from anesthesia is accelerated. When employed in combination with other inhalation anesthetics, nitrous oxide is administered at a concentration of 70%.

At therapeutic concentrations, nitrous oxide has no serious adverse effects. The drug is not toxic to the CNS, and does not cause cardiovascular or respiratory depression. Furthermore, the drug is not likely to precipitate malignant hyperthermia. The major concern with nitrous oxide is postoperative *nausea* and *vomiting*, which occur more often with this agent than with any other inhalation anesthetic.

In certain settings, nitrous oxide can be used alone—but only for *analgesia*, not anesthesia. Nitrous oxide alone is used for analgesia in dentistry and during delivery.

28.2.7 Obsolete Inhalation Anesthetics

Several once-popular anesthetics are now obsolete. Five of these agents—*ethylene*, *cyclopropane*, *diethyl ether (ether)*, *vinyl ether*, and *ethyl chloride*—are gases. They were abandoned because they are explosive and because they offer no advantages over newer, less hazardous anesthetics. Only one volatile liquid—*methoxyflurane*—has become obsolete. The reason is concern about kidney damage.

28.3 INTRAVENOUS ANESTHETICS

Intravenous anesthetics may be used alone or to supplement the effects of inhalation agents. When combined with an inhalation anesthetic, IV agents offer two potential benefits: (1) they permit dosage of the inhalation agent to be reduced and (2) they produce effects that cannot be achieved with an inhalation agent alone. Three of the drug families discussed in this section—opioids, barbiturates, and benzodiazepines—are considered at length in other chapters. Discussion here is limited to their use in anesthesia.

28.3.1 Short-Acting Barbiturates (Thiobarbiturates)

Short-acting barbiturates, administered intravenously, are employed for *induction of anesthesia*. Two agents are available: *thiopental sodium* [Pentothal] and *methohexital sodium* [Brevital]. Almost every time an inhalation anesthetic is used, a short-acting barbiturate is administered first for induction.

28.3.1.1 Thiopental.

Thiopental [Pentothal] was the first short-acting barbiturate and is the prototype for the group. This drug acts rapidly to produce unconsciousness. Analgesic and muscle-relaxant effects are weak.

Thiopental has a rapid onset and short duration. Unconsciousness occurs 10 to 20 seconds after IV injection. If thiopental is not followed by inhalation anesthesia, the patient will wake up in about 10 minutes.

The time course of anesthesia is determined by thiopental's pattern of distribution. Thiopental is highly lipid soluble, and therefore enters the brain rapidly to begin its effects. Anesthesia is terminated as thiopental undergoes redistribution from the brain and blood to other tissues.

Practically no metabolism of the drug takes place between the time of administration and the time of awakening.

257

Like most of the inhalation anesthetics, thiopental causes cardiovascular and respiratory depression. If administered too rapidly, the drug may cause apnea.

258

28.3.2 Benzodiazepines

When administered in large doses, benzodiazepines produce unconsciousness and amnesia. Because of this ability, IV benzodiazepines are occasionally given to induce anesthesia. However, short-acting barbiturates are generally preferred. Three benzodiazepines—diazepam, lorazepam, and midazolam—are administered IV for induction. Diazepam is the prototype for the group. The basic pharmacology of the benzodiazepines is discussed in [Chapter 34](#).

28.3.2.1 Diazepam.

Induction with IV diazepam [Valium] is slower than with barbiturates. Unconsciousness develops in about 1 minute. Diazepam causes very little muscle relaxation and no analgesia. Cardiovascular and respiratory depression are usually only moderate. However, on occasion respiratory depression is severe. Therefore, whenever diazepam is administered IV, facilities for respiratory support must be immediately available.

28.3.2.2 Midazolam.

Intravenous midazolam [Versed] may be used for *induction of anesthesia* and to produce *conscious sedation*. When used for induction, midazolam is usually combined with a short-acting barbiturate. Unconsciousness develops in 80 seconds.

Conscious sedation can be produced by combining midazolam with an opioid analgesic (eg, morphine, fentanyl). The state is characterized by sedation, analgesia, amnesia, and lack of anxiety. The patient is unperturbed and passive, but responsive to commands, such as “open your eyes.” Conscious sedation persists for an hour or so and is suitable for minor surgeries and endoscopic procedures.

Midazolam can cause dangerous cardiorespiratory effects, including respiratory depression and respiratory and cardiac arrest. Accordingly, the drug should be used only in a setting that permits constant monitoring of cardiac and respiratory status. Facilities for resuscitation must be immediately available. The risk of adverse effects can be minimized by injecting midazolam slowly (over 2 or more minutes) and by waiting another 2 or more minutes for full effects to develop before dosing again.

28.3.3 Propofol

28.3.3.1 Actions and Uses.

Propofol [Diprivan] is an IV sedative-hypnotic used for induction and maintenance of anesthesia. In addition, propofol can be used to sedate patients undergoing mechanical ventilation and certain noninvasive procedures (eg, radiation therapy, endoscopy, magnetic resonance imaging). Like thiopental, propofol has a rapid onset and short duration of action. Unconsciousness develops within 60 seconds and lasts for 3 to 5 minutes following a single injection. As with thiopental, redistribution from the brain to other tissues explains the speed of awakening. For extended effects, a continuous, low-dose infusion is used.

28.3.3.2 Adverse Effects.

Propofol can cause profound *respiratory depression* (including apnea) and *hypotension*. Accordingly, the drug should be used with caution in elderly patients, hypovolemic patients, and patients with compromised cardiac function. With all patients, facilities for respiratory support should be immediately available.

Propofol poses a high risk of *bacterial infection*. Why? Because the drug is supplied in a mixture of soybean oil, glycerol, and egg lecithin—an excellent medium for bacterial growth. In surgical patients, use of preparations that have become contaminated after opening has caused sepsis and death. To minimize the risk of infection, propofol solutions and opened vials should be discarded within 6 hours. Unopened vials should be stored at 22°C (72°F).

Propofol can cause transient pain at the site of IV injection. This can be minimized by using a large vein and by injecting IV lidocaine (a local anesthetic) at the site just prior to injecting propofol.

28.3.4 Etomidate

Etomidate [Amidate] is a potent hypnotic agent used for induction of surgical anesthesia. Unconsciousness develops rapidly and lasts about 5 minutes. The drug has no analgesic actions. Adverse effects associated with single injections include transient apnea, venous pain at the injection site, and suppression of plasma cortisol levels for 6 to 8 hours. Repeated administration can cause hypotension, oliguria, electrolyte disturbances, and a high incidence (50%) of postoperative nausea and vomiting. Cardiovascular effects are less than with barbiturates, and hence the drug is preferred for patients with cardiovascular disorders.

28.3.5 Ketamine

28.3.5.1 Anesthetic Effects.

Ketamine [Ketalar] produces a state known as *dissociative anesthesia* in which the patient feels dissociated from his or her environment. In addition, the drug causes sedation, immobility, analgesia, and amnesia; responsiveness to pain is lost. Induction is rapid and emergence begins within 10 to 15 minutes. Full recovery, however, may take several hours.

28.3.5.2 Adverse Psychologic Reactions.

During recovery from ketamine, unpleasant psychologic reactions may occur, including hallucinations, disturbing dreams, and delirium. In some cases, these reactions recur days or even weeks after ketamine was used. To minimize these effects, the patient should be kept in a soothing, stimulus-free environment until recovery is complete. Premedication with diazepam or midazolam reduces the risk of an adverse reaction. Psychologic reactions are least likely in children under the age of 15 years and in adults over the age of 65. Despite its adverse psychologic effects, ketamine has become a popular drug of abuse (see [Chapter 39](#)).

28.3.5.3 Therapeutic Uses.

Ketamine is especially valuable for anesthesia in young children undergoing minor surgical and diagnostic procedures. The drug is frequently used to facilitate changing of burn dressings. Because of its potential for adverse psychologic effects, ketamine should generally be avoided in patients with a history of psychiatric illness, although the drug has produced short-term relief in patients with intractable depression.

28.3.6 Neuroleptic-Opioid Combination: Droperidol Plus Fentanyl

A unique state, known as *neurolept analgesia*, can be produced with a combination of fentanyl, a potent opioid, plus droperidol, a neuroleptic (antipsychotic) agent. In the past, the combination was available premixed under the trade name *Innovar*.

Neurolept analgesia is characterized by quiescence, indifference to surroundings, and insensitivity to pain. The patient appears to be asleep but is not (ie, complete loss of consciousness does not occur). In large part, neurolept analgesia is similar to the dissociative anesthesia produced by ketamine. Neurolept analgesia is employed for diagnostic and minor surgical procedures (eg, bronchoscopy, repeated changing of burn dressings).

258

259

Droperidol prolongs the QT interval on the electrocardiogram, indicating that it can cause potentially fatal dysrhythmias. Accordingly, droperidol should be used only when safer drugs are ineffective or intolerable. Droperidol is contraindicated for patients with existing QT prolongation, and should be used with great caution in those at risk of developing QT prolongation. The issue of drug-induced QT prolongation is discussed at length in [Chapter 7](#) (Adverse Drug Reactions and Medication Errors).

Other adverse effects include hypotension and respiratory depression. Respiratory depression can be severe and may persist for hours. Respiratory assistance is usually required. Like other neuroleptics, droperidol blocks receptors for dopamine, and hence should not be given to patients with Parkinson's disease.

For some procedures, the combination of fentanyl plus droperidol is supplemented with nitrous oxide. The state produced by this threedrug regimen is called *neurolept anesthesia*. Neurolept anesthesia produces more analgesia and a greater reduction of consciousness than does *neurolept analgesia*. Neurolept anesthesia can be used for major surgical procedures.

28.3.6.1

KEY POINTS

- General anesthetics produce unconsciousness and insensitivity to painful stimuli. In contrast, analgesics reduce sensitivity to pain but need not reduce consciousness.
- The term *balanced anesthesia* refers to the use of several drugs to ensure that induction of anesthesia is smooth and rapid and that analgesia and muscle relaxation are adequate.
- The minimum alveolar concentration (MAC) of an inhalation anesthetic is defined as the minimum concentration of drug in alveolar air that will produce immobility in 50% of patients exposed to a painful stimulus. A *low* MAC indicates *high* anesthetic potency!
- Inhalation agents work by enhancing transmission at inhibitory synapses and by inhibiting transmission at excitatory synapses.
- Inhalation anesthetics are eliminated almost entirely in the expired air. As a rule, they undergo minimal hepatic metabolism.
- The principal adverse effects of general anesthetics are depression of respiration and cardiac performance.

- Malignant hyperthermia is a rare, genetically determined, life-threatening reaction to general anesthetics. Coadministration of succinylcholine, a neuromuscular blocker, increases the risk of the reaction.
- By enhancing analgesia, opioids reduce the required dosage of general anesthetic.
- By enhancing muscle relaxation, neuromuscular blockers reduce the required dosage of general anesthetic.
- Nitrous oxide differs from other general anesthetics in two important ways: (1) it has a very high MAC, and therefore cannot be used alone to produce general anesthesia; and (2) it has high analgesic potency, and therefore is frequently combined with other general anesthetics to supplement their analgesic effects.
- Induction of anesthesia is usually accomplished with a short-acting barbiturate, such as thiopental.
- Ketamine is an IV anesthetic that produces a state known as dissociative anesthesia. Patients recovering from ketamine may experience adverse psychologic reactions.

28.3.6.2

Summary of Major Nursing Implications

28.3.6.2.1

ALL GENERAL ANESTHETICS

Desflurane

Enflurane

Halothane

Isoflurane

Nitrous oxide

Sevoflurane

Nursing management of the patient receiving general anesthesia is almost exclusively preoperative and postoperative; intraoperative management is the responsibility of

	anesthesiologists and anesthesiologists. Accordingly, our summary of anesthesia-related nursing implications is divided into two sections: (1) implications that pertain to the preoperative patient and (2) implications that pertain to the postoperative patient. Intraoperative implications are not considered. The nursing implications summarized here are limited to ones that are directly related to anesthesia. Nursing implications regarding the overall management of the surgical patient (ie, implications unrelated to anesthesia) are not presented. (Overall nursing management of the surgical patient is discussed fully—and appropriately—in medical-surgical texts.) Nursing implications for drugs employed as adjuncts to anesthesia (barbiturates, benzodiazepines, anticholinergic agents, opioids, neuromuscular blocking agents) are summarized in other chapters. Only those implications that apply specifically to their adjunctive use are addressed here.	
28.3.6.2...	Preoperative Patients: Counseling, Assessment, and Medicating	
28.3.6.2...	Counseling Anxiety is common among patients anticipating surgery: the patient may fear the surgery itself, or may be concerned about the possibility of waking up or experiencing pain during the procedure. Since excessive anxiety can disrupt the smoothness of the surgical course (in addition to being distressing to the patient), you should attempt to dispel preoperative fears. To some extent, fear can be allayed by reassuring the patient that anesthesia will keep him or her asleep for the entire procedure, will prevent pain, and will create amnesia about the experience.	259 260
28.3.6.2...	Assessment	
28.3.6.2...	Medication History. The patient may be taking drugs that can affect responses to anesthetics. Drugs that act on the respiratory and cardiovascular systems are of particular concern. To decrease the risk of adverse interactions, obtain a thorough history of drug use. <i>All</i> drugs—prescription medications, over-the-counter preparations, and illicit agents—should be considered. With illicit drugs (eg, heroin, barbiturates) and with alcohol, it is important to determine both the duration of use and the amount used per day.	

28.3.6.2...

Respiratory and Cardiovascular Function.

Most general anesthetics produce cardiovascular and respiratory depression. In order to evaluate the effects of anesthesia, baseline values for blood pressure, heart rate, and respiration are required. Also, any disease of the cardiovascular and respiratory systems should be noted.

28.3.6.2...

Preoperative Medication

Preoperative medications (eg, benzodiazepines, opioids, anticholinergic agents) are employed to (1) calm the patient, (2) provide analgesia, and (3) counteract adverse effects of general anesthetics. As a rule, the nurse is responsible for administering these drugs. Since preoperative medication can have a significant impact on the overall response to anesthesia, it is important that these drugs be given at an appropriate time—typically 30 to 60 minutes before surgery. Because preoperative medication may produce drowsiness or hypotension, the patient should remain in bed. A calm environment will complement the effect of sedatives.

28.3.6.2...

Postoperative Patients: Ongoing Evaluation and Interventions

When receiving a patient for postoperative care, you should know all of the drugs the patient has received in the hospital (anesthetics and adjunctive medications). In addition, you should know what medications the patient was taking at home, especially drugs for hypertension. With this information, you will be able to anticipate the time course of emergence from anesthesia as well as potential drug-related postoperative complications.

28.3.6.2...

Evaluations and Interventions That Pertain to Specific Organ Systems

28.3.6.2...

Cardiovascular and Respiratory Systems.

Anesthetics depress cardiovascular and respiratory function. Monitor vital signs until they return to baseline. Determine blood pressure, pulse rate, and respiration immediately upon receipt of the patient, and repeat monitoring at brief intervals until recovery is complete. During the recovery period, observe the patient for respiratory and cardiovascular distress. Be alert for (1) reductions in blood pressure; (2) altered cardiac rhythm; and (3) shallow, slow, or noisy breathing. Ensure that the airway remains patent. Have facilities for respiratory support available.

28.3.6.2...

Central Nervous System.

Return of CNS function is gradual, and precautions are needed until recovery is complete. When appropriate, employ side rails or straps to avoid accidental falls. Assist ambulation until the patient is able to stand steadily. During the early stage of emergence, the patient may be able to hear, even though he or she may appear unconscious. Accordingly, exercise discretion in conversation.

28.3.6.2...

Gastrointestinal Tract.

Bowel function may be compromised by the surgery itself or by the drugs employed as adjuncts to anesthesia (eg, opioids, anticholinergics). Constipation or atony of the bowel may occur. Monitor bowel function. A muscarinic agonist (eg, bethanechol) may be needed to restore peristalsis. Determine bowel sounds before giving oral medications.

Nausea and vomiting are potential postanesthetic reactions. To reduce the risk of aspiration, position the patient with his or her head to the side. Have equipment for suctioning available. Antiemetic medication may be needed.

28.3.6.2...

Urinary Tract.

Anesthetics and their adjuncts can disrupt urinary tract function. Anesthetics can decrease urine production by reducing renal blood flow. Opioids and anticholinergic drugs can cause urinary retention. Monitor urine output. If the patient fails to void, follow hospital protocol. Catheterization or medication (eg, bethanechol) may be needed.

28.3.6.2...

Management of Postoperative Pain

As anesthesia wears off, the patient may experience postoperative pain. An opioid may be required. Since respiratory depression from opioids will add to residual respiratory depression from anesthesia, use opioids with caution; balance the need to relieve pain against the need to maintain ventilation.

28.3.6.2...

Implications for Ketamine

Adverse psychologic reactions can develop as the patient emerges from ketamine-induced anesthesia. To minimize these reactions, provide a calm and stimulus-free environment until recovery is complete.

²⁹CHAPTER 28 Opioid (Narcotic) Analgesics, Opioid Antagonists, and Nonopioid Centrally Acting Analgesics

Analgesics are drugs that relieve pain without causing loss of consciousness. In this chapter, we focus mainly on the opioid analgesics—the most effective pain relievers available. The opioid family, whose name derives from *opium*, includes such widely used agents as morphine, fentanyl, codeine, oxycodone [Oxy-Contin], and propoxyphene [Darvon].

^{29.1} INTRODUCTION TO THE OPIOIDS

^{29.1.1} Terminology

Opioid is a general term defined as any drug, natural or synthetic, that has actions similar to those of morphine. The term *opiate* is more specific and applies only to compounds present in opium (eg, morphine, codeine).

The term *narcotic* has had so many definitions that it cannot be used with precision. *Narcotic* has been used to mean an analgesic, a central nervous system (CNS) depressant, and any drug capable of causing physical dependence. *Narcotic* has also been employed in a legal context to designate not only the opioids but also such diverse drugs as cocaine, marijuana, and lysergic acid diethylamide (LSD). Because of its more precise definition, *opioid* is clearly preferable to *narcotic* as a label for a discrete family of pharmacologic agents.

^{29.1.2} Endogenous Opioid Peptides

The body has three families of peptides—*enkephalins*, *endorphins*, and *dynorphins*—that have opioid-like properties. Although we know that endogenous opioid peptides serve as neurotransmitters, neurohormones, and neuromodulators, their precise physiologic role is not fully understood. Endogenous opioid peptides are found in the CNS and in peripheral tissues.

^{29.1.3} Opioid Receptors

There are three main classes of opioid receptors, designated *mu*, *kappa*, and *delta*. From a pharmacologic perspective, mu receptors are the most important. Why? Because opioid analgesics act primarily by activating mu receptors, although they also produce weak activation of kappa receptors. As a rule, opioid analgesics do not interact with delta receptors. In contrast to opioid analgesics, endogenous opioid peptides act through all three types of opioid receptors, including

delta receptors. Important responses to activation of mu and kappa receptors are summarized in [Table 28-1](#).

29.1.3.1 Mu Receptors.

Responses to activation of mu receptors include analgesia, respiratory depression, euphoria, and sedation. In addition, mu activation is related to physical dependence.

A study in genetically engineered mice underscores the importance of mu receptors in drug action. In this study, researchers studied mice that lacked the gene for mu receptors. When these mice were given morphine, the drug had no effect. It did not produce analgesia, it did not produce physical dependence, and it did not reinforce social behaviors that are thought to indicate subjective effects. Hence, at least in mice, mu receptors appear both necessary and sufficient to mediate the major actions of opioid drugs.

261
262

TABLE 28-1 Important Responses to Activation of Mu and Kappa Receptors

Response	Receptor Type	
	Mu	Kappa
Analgesia	✓	✓
Respiratory depression	✓	
Sedation	✓	✓
Euphoria	✓	
Physical dependence	✓	
Decreased GI motility	✓	✓

29.1.3.2 Kappa Receptors.

As with mu receptors, activation of kappa receptors can produce analgesia and sedation. In addition, kappa activation may underlie psychotomimetic effects seen with certain opioids.

29.1.4 Classification of Drugs That Act at Opioid Receptors

Drugs that act at opioid receptors are classified on the basis of how they affect receptor function. At each type of receptor, a drug can act in one of three ways: as an *agonist*, *partial agonist*, or

antagonist. (Recall from [Chapter 5](#) that a partial agonist is a drug that produces low to moderate receptor activation when administered alone, but will block the actions of a full agonist if the two are given together.) Based on these actions, drugs that bind opioid receptors fall into three major groups: (1) pure opioid agonists, (2) agonist-antagonist opioids, and (3) pure opioid antagonists. The actions of drugs in these groups at mu and kappa receptors are summarized in [Table 28-2](#).

29.1.4.1 Pure Opioid Agonists.

The pure opioid agonists activate mu receptors and kappa receptors. By doing so, the pure agonists can produce analgesia, euphoria, sedation, respiratory depression, physical dependence, constipation, and other effects. As indicated in [Table 28-3](#), the pure agonists can be subdivided into two groups: *strong opioid agonists* and *moderate to strong opioid agonists*. Morphine is the prototype of the strong agonists. Codeine is the prototype of the moderate to strong agonists.

29.1.4.2 Agonist-Antagonist Opioids.

Four agonist-antagonist opioids are available: pentazocine, nalbuphine, butorphanol, and buprenorphine. The actions of these drugs at mu and kappa receptors are summarized in [Table 28-2](#). When administered alone, the agonist-antagonist opioids produce analgesia. However, if given to a patient who is taking a pure opioid agonist, these drugs can *antagonize* analgesia caused by the pure agonist. Pentazocine [Talwin] is the prototype of the agonist-antagonists.

29.1.4.3 Pure Opioid Antagonists.

The pure opioid antagonists act as antagonists at mu and kappa receptors. These drugs do not produce analgesia or any of the other effects caused by opioid agonists. Their principal use is reversal of respiratory and CNS depression caused by overdose with opioid agonists. In addition, one of these drugs—methylnaltrexone—is used to treat opioid-induced constipation. Naloxone [Narcan] is the prototype of the pure opioid antagonists.

TABLE 28-2 Drug Actions At Mu and Kappa Receptors

Drugs	Receptor Type	
	Mu	Kappa
Pure Opioid Agonists		
Morphine, codeine, meperidine, and other morphine-like drugs	Agonist	Agonist
Agonist-Antagonist Opioids		
Pentazocine, nalbuphine, butorphanol	Antagonist	Agonist
Buprenorphine	Partial agonist	Antagonist
Pure Opioid Antagonists		
Naloxone, naltrexone, nalmeferne	Antagonist	Antagonist

29.2 BASIC PHARMACOLOGY OF THE OPIOIDS

29.2.1 Morphine

Morphine is the prototype of the strong opioid analgesics and remains the standard by which newer opioids are measured. Morphine has multiple pharmacologic effects, including analgesia, sedation, euphoria, respiratory depression, cough suppression, and suppression of bowel motility. The drug is named after Morpheus, the Greek god of dreams.

29.2.1.1 Source

Morphine is found in the seedpod of the poppy plant, *Papaver somniferum*. The drug is prepared by extraction from opium (the dried juice of the poppy seedpod). In addition to morphine, opium contains two other medicinal compounds: codeine (an analgesic) and papaverine (a smooth muscle relaxant).

29.2.1.2 Overview of Pharmacologic Actions

Morphine has multiple pharmacologic actions. In addition to relieving pain, the drug causes drowsiness, mental clouding, anxiety reduction, and a sense of well-being. Through actions in the CNS and periphery, morphine can cause respiratory depression, constipation, urinary

retention, orthostatic hypotension, emesis, miosis, cough suppression, and biliary colic. With prolonged use, the drug produces tolerance and physical dependence.

Individual effects of morphine may be beneficial, detrimental, or both. For example, analgesia is clearly beneficial, whereas respiratory depression and urinary retention are clearly detrimental. Certain other effects, such as sedation and reduced bowel motility, may be beneficial or detrimental, depending on the circumstances of drug use.

29.2.1.3 Therapeutic Use: Relief of Pain

The principal indication for morphine is relief of moderate to severe pain. The drug can relieve postoperative pain, chronic pain of cancer, and pain associated with labor and delivery. In addition, morphine can be used to relieve pain of myocardial infarction and dyspnea associated with left ventricular failure and pulmonary edema—although it is no longer the drug of choice for these disorders. Morphine may also be administered preoperatively for sedation and anxiety reduction.

Morphine relieves pain without affecting other senses (eg, sight, touch, smell, hearing) and without causing loss of consciousness. The drug is more effective against constant, dull pain than against sharp, intermittent pain. However, even sharp pain can be relieved by large doses. The ability of morphine to cause mental clouding, sedation, euphoria, and anxiety reduction can contribute to relief of pain.

262

263

TABLE 28-3 Opioid Analgesics: Abuse Liability and Maximal Pain Relief

Drug and Category	CSA* Schedule	Abuse Liability	Maximal Pain Relief
Strong Opioid Agonists			
Alfentanil	II	High	High
Fentanyl	II	High	High
Hydromorphone	II	High	High
Levorphanol	II	High	High
Meperidine	II	High	High
Methadone	II	High	High
Morphine	II	High	High
Oxymorphone	II	High	High
Remifentanyl	II	—	High
Sufentanil	II	High	High
Moderate to Strong Opioid Agonists			
Codeine	II	Moderate	Low
Hydrocodone	III†	Moderate	Moderate
Oxycodone	II	Moderate	Moderate
Propoxyphene	IV	Low	Low
Agonist-Antagonist Opioids			
Buprenorphine	V	Low	Moderate to high
Butorphanol	IV	Low	Moderate to high
Nalbuphine	NR‡	Low	Moderate to high
Pentazocine	IV	Low	Moderate

* CSA = Controlled Substances Act.

† In the United States, hydrocodone is available only in combination with aspirin or acetaminophen. These combination products are classified under Schedule III.

‡ NR = not regulated under the Controlled Substances Act.

The use of morphine and other opioids to relieve pain is discussed further in [Chapter 29](#) and under *Clinical Use of Opioids* in this chapter.

29.2.1.3.1 Mechanism of Analgesic Action.

Morphine and other opioid agonists are thought to relieve pain by mimicking the actions of endogenous opioid peptides, primarily at mu receptors. This hypothesis is based on the following observations:

- Opioid peptides and morphine-like drugs both produce analgesia when administered to experimental subjects.
- Opioid peptides and morphine-like drugs share structural similarities ([Fig. 28-1](#)).
- Opioid peptides and morphine-like drugs bind to the same receptors in the CNS.
- The receptors to which opioid peptides and morphine-like drugs bind are located in regions of the brain and spinal cord associated with perception of pain.
- Subjects rendered tolerant to analgesia from morphine-like drugs show cross-tolerance to analgesia from opioid peptides.
- The analgesic effects of opioid peptides and morphine-like drugs can both be blocked by the same antagonist: naloxone.

263

Figure 28-1 **Structural similarity between morphine and met-enkephalin.** In the morphine structural formula, highlighting indicates the part of the molecule thought responsible for interaction with opioid receptors. In the met-enkephalin structural formula, highlighting indicates the region of structural similarity with morphine.

From these data we can postulate that (1) opioid peptides serve a physiologic role as modulators of pain perception, and (2) morphine-like drugs produce analgesia by mimicking the actions of endogenous opioid peptides.

29.2.1.4 Adverse Effects

29.2.1.4.1 Respiratory Depression.

Respiratory depression is the most serious adverse effect of the opioids. At equianalgesic doses, all of the pure opioid agonists depress respiration to the same extent. Death following overdose is almost always from respiratory arrest. Opioids depress respiration primarily through activation of mu receptors, although activation of kappa receptors also contributes.

The time course of respiratory depression varies with route of administration. Depressant effects begin about 7 minutes after IV injection, 30 minutes after IM injection, and up to 90 minutes after subQ injection. With all three routes, significant depression may persist for 4 to 5 hours. When morphine is administered by spinal injection, onset of respiratory depression may be delayed for hours; be alert to this possibility.

With prolonged use of opioids, tolerance develops to respiratory depression. Huge doses that would be lethal to nontolerant individuals have been taken by opioid addicts without noticeable effect. Similarly, tolerance to respiratory depression develops during long-term clinical use of opioids (eg, in patients with cancer).

When administered at usual therapeutic doses, opioids rarely cause significant respiratory depression. However, although uncommon, substantial respiratory depression can occur. Accordingly, respiratory rate should be determined prior to opioid administration. If the rate is 12 breaths per minute or less, the opioid should be withheld and the prescriber notified. Certain patients, including the very young, the elderly, and those with respiratory disease (eg, asthma, emphysema) are especially sensitive to respiratory depression and must be monitored closely. Outpatients should be informed about the risk of respiratory depression and instructed to notify the prescriber if respiratory distress occurs.

Respiratory depression is increased by concurrent use of other drugs that have CNS-depressant actions (eg, alcohol, barbiturates, benzodiazepines). Accordingly, these drugs should be avoided. Outpatients should be warned against use of alcohol and all other CNS depressants.

29.2.1.4.2 Constipation.

Opioids promote constipation through actions in the CNS and GI tract. Specifically, these drugs can suppress propulsive intestinal contractions, intensify nonpropulsive contractions, increase the tone of the anal sphincter, and inhibit secretion of fluids into the intestinal lumen. As a result, constipation can develop after a few days of opioid use.

The risk of opioid-induced constipation can be reduced with a combination of pharmacologic and nonpharmacologic measures. The goal is to produce a soft, formed stool every 1 to 2 days. Principal nondrug measures are physical activity and increased intake of fiber and fluids. Most patients also require prophylactic drugs. A stimulant laxative, such as senna, is given to counteract reduced bowel motility. A stool softener, such as docusate [Colace, others], provides additional benefit. As discussed later in the chapter, a new drug—*methylnaltrexone* [Relistor]—helps by blocking opioid receptors in the intestine. The drug can't cross the blood-brain barrier, and hence does not reduce analgesia. Severe constipation can be managed with an osmotic laxative, such as sodium phosphate.

Because of their effects on the intestine, opioids are highly effective for treating diarrhea. In fact, antidiarrheal use of these drugs preceded analgesic use by centuries. The effect of opioids on intestinal function is an interesting example of how an effect can be detrimental (constipation) or beneficial (relief of diarrhea) depending on who is taking the medication. Opioids employed specifically to treat diarrhea are discussed in [Chapter 78](#).

29.2.1.4.3 Orthostatic Hypotension.

Morphine-like drugs lower blood pressure by blunting the baroreceptor reflex and by dilating peripheral arterioles and veins. Peripheral vasodilation results primarily from morphine-induced release of histamine. Hypotension is mild in the recumbent patient but can be substantial when the patient stands up. Patients should be informed about symptoms of hypotension (lightheadedness, dizziness) and instructed to sit or lie down if they occur. Also, patients should be informed that hypotension can be minimized by moving slowly when changing from a supine or seated position to an upright position. Patients should be warned against walking if hypotension is significant. Hospitalized patients may require ambulatory assistance. Hypotensive drugs can exacerbate opioid-induced hypotension.

29.2.1.4.4 Urinary Retention.

Morphine can cause urinary hesitancy and urinary retention by increasing tone in the bladder sphincter. Also, by increasing tone in the detrusor muscle, the drug can elevate pressure within the bladder, causing urinary urgency. In addition to its direct effects on the urinary tract, morphine may interfere with voiding by suppressing awareness of bladder stimuli. Accordingly, patients should be encouraged to void every 4 hours. Urinary hesitancy or retention is especially likely in patients with prostatic hypertrophy. Drugs with anticholinergic properties (eg, tricyclic antidepressants, antihistamines) can exacerbate the problem.

Urinary retention should be assessed by monitoring intake and output and by palpating the lower abdomen every 4 to 6 hours for bladder distention. If a change in intake/output ratio develops, or if bladder distention is detected, or if the patient reports difficulty voiding, the prescriber should be notified. Catheterization may be required.

In addition to causing urinary retention, morphine may decrease urine production. How? Largely by decreasing renal blood flow, and partly by promoting release of antidiuretic hormone.

29.2.1.4.5 Cough Suppression.

Morphine-like drugs act at opioid receptors in the medulla to suppress cough. Suppression of spontaneous cough may lead to accumulation of secretions in the airway. Accordingly, patients should be instructed to actively cough at regular intervals. Lung status should be assessed by auscultation for rales. The ability of opioids to suppress cough is put to clinical use in the form of codeine- and hydrocodone-based cough remedies.

29.2.1.4.6 Biliary Colic.

Morphine can induce spasm of the common bile duct, causing pressure within the biliary tract to rise dramatically. Symptoms range from epigastric distress to biliary colic. In patients with pre-existing biliary colic, morphine may intensify pain rather than relieve pain. Certain opioids (eg, meperidine) cause less smooth muscle spasm than morphine, and hence are less likely to exacerbate biliary colic.

29.2.1.4.7 Emesis.

Morphine promotes nausea and vomiting through direct stimulation of the chemoreceptor trigger zone of the medulla. Emetic reactions are greatest with the initial dose and diminish with subsequent doses. Nausea and vomiting are uncommon in recumbent patients, but occur in 15% to 40% of ambulatory patients, suggesting a vestibular component. Nausea and vomiting can be reduced by pretreatment with an antiemetic (eg, prochlorperazine) and by having the patient remain still.

264

265

29.2.1.4.8 Elevation of Intracranial Pressure.

Morphine can elevate intracranial pressure (ICP). The mechanism is indirect: By suppressing respiration, morphine increases the CO₂ content of blood, which dilates the cerebral vasculature, causing ICP to rise. Accordingly, if respiration is maintained at a normal rate, ICP will remain normal too.

29.2.1.4.9 Euphoria/Dysphoria.

Euphoria is defined as an exaggerated sense of well-being. Morphine often produces euphoria when given to patients in pain. Although euphoria can enhance pain relief, it also contributes to the drug's potential for abuse. Euphoria is caused by activation of mu receptors.

In some individuals, morphine causes *dysphoria* (a sense of anxiety and unease). Dysphoria is uncommon among patients in pain, but may occur when morphine is taken in the absence of pain.

29.2.1.4.10 Sedation.

When administered to relieve pain, morphine is likely to cause drowsiness and some mental clouding. Although these effects can complement analgesic actions, they can also be detrimental. Outpatients should be warned about CNS depression and advised to avoid hazardous activities (eg, driving) if sedation is significant. Sedation can be minimized by (1) taking smaller doses more often, (2) using opioids that have short half-lives, and (3) giving small doses of a CNS stimulant (methylphenidate or dextroamphetamine) in the morning and early afternoon.

29.2.1.4.11 Miosis.

Morphine and other opioids cause pupillary constriction (miosis). In response to toxic doses, the pupils may constrict to “pinpoint” size. Since miosis can impair vision in dim light, room light should be kept bright during waking hours.

29.2.1.4.12 Neurotoxicity.

Opioid-induced neurotoxicity can cause delirium, agitation, myoclonus, hyperalgesia, and other symptoms. Primary risk factors are renal impairment, pre-existing cognitive impairment, and prolonged, high-dose opioid use. Management consists of hydration and dose reduction. For patients who must take opioids long term, opioid rotation (periodically switching from one opioid to another) may reduce neurotoxicity development.

29.2.1.4.13 Adverse Effects from Prolonged Use.

Clinical and preclinical studies indicate that prolonged use of opioids can cause hormonal changes and can alter immune function. Hormonal changes include a progressive decline in cortisol levels, an increase in prolactin levels, and a decrease in levels of luteinizing hormone, follicle-stimulating hormone, testosterone, and estrogen. With prolonged opioid exposure, immune function is suppressed. We do not yet know the extent to which these changes are clinically relevant.

29.2.1.5 Pharmacokinetics

Morphine is administered by several routes: oral, IM, IV, subQ, epidural, and intrathecal. Onset of effects is slower with oral administration than with parenteral administration. With three routes—IM, IV, and subQ—analgesia lasts 4 to 5 hours. With two routes—epidural and intrathecal—analgesia may persist up to 24 hours. With oral therapy, duration depends on the formulation. For example, with immediate-release tablets, effects last 4 to 5 hours, whereas with extended-release capsules, effects last 24 hours.

In order to relieve pain, morphine must cross the blood-brain barrier and enter the CNS. Because the drug is not very lipid soluble, it does not cross the barrier easily. Consequently, only a small fraction of each dose reaches sites of analgesic action. Since the blood-brain barrier is not well developed in infants, these patients generally require lower doses than do older children and adults.

Morphine is inactivated by hepatic metabolism. When taken by mouth, the drug must pass through the liver on its way to the systemic circulation. Much of an oral dose is inactivated during this first pass through the liver. Consequently, oral doses need to be substantially larger than parenteral doses to produce equivalent analgesic effects. In patients with liver disease, analgesia and other effects may be intensified and prolonged. Accordingly, it may be necessary to reduce the dosage or lengthen the dosing interval.

29.2.1.6 Tolerance and Physical Dependence

With continuous use, morphine can cause tolerance and physical dependence. These phenomena, which are generally inseparable, reflect cellular adaptations that occur in response to prolonged opioid exposure.

29.2.1.6.1 Tolerance.

Tolerance can be defined as a state in which a larger dose is required to produce the same response that could formerly be elicited by a smaller dose. Alternatively, tolerance can be defined as a condition in which a particular dose now produces a smaller response than it did when treatment began. Because of tolerance, dosage must be increased to maintain analgesic effects.

Tolerance develops to many—but not all—of morphine's actions. With prolonged treatment, tolerance develops to *analgesia*, *euphoria*, and *sedation*. As a result, with long-term therapy, an increase in dosage may be required to maintain these desirable effects. Fortunately, as tolerance develops to these therapeutic effects, tolerance also develops to *respiratory depression*. As a result, the high doses needed to control pain in the tolerant individual are not associated with increased respiratory depression.

Very little tolerance develops to *constipation* and *miosis*. Even in highly tolerant addicts, constipation remains a chronic problem, and constricted pupils are characteristic.

Cross-tolerance exists among the opioid agonists (eg, oxycodone, methadone, fentanyl, codeine, heroin). Accordingly, individuals tolerant to one of these agents will be tolerant to the others. No cross-tolerance exists between opioids and general CNS depressants (eg, barbiturates, ethanol, benzodiazepines, general anesthetics).

29.2.1.6.2 Physical Dependence.

Physical dependence is defined as a state in which an abstinence syndrome will occur if drug use is abruptly stopped. Opioid dependence results from adaptive cellular changes that occur in response to the continuous presence of these drugs. Although the exact nature of these changes is unknown, it is clear that, once these compensatory changes have taken place, the body requires the continued presence of opioids to function normally. If opioids are withdrawn, an abstinence syndrome will follow.

The intensity and duration of the opioid abstinence syndrome depends on two factors: the half-life of the drug being used and the degree of physical dependence. With opioids that have relatively short half-lives (eg, morphine), symptoms of abstinence are intense but brief. In contrast, with opioids that have long half-lives (eg, methadone), symptoms are less intense but more prolonged. With any opioid, the intensity of withdrawal symptoms parallels the degree of physical dependence.

265

266

For individuals who are highly dependent, the abstinence syndrome can be extremely unpleasant. Initial reactions include yawning, rhinorrhea, and sweating. Onset occurs about 10 hours after the last dose. These early responses are followed by anorexia, irritability, tremor, and “gooseflesh”—hence the term *cold turkey*. At its peak, the syndrome manifests as violent sneezing, weakness, nausea, vomiting, diarrhea, abdominal cramps, bone and muscle pain, muscle spasm, and kicking movements—hence, “kicking the habit.” Giving an opioid at any time during withdrawal rapidly reverses all signs and symptoms. Left untreated, the morphine withdrawal syndrome runs its course in 7 to 10 days. It should be emphasized that, although withdrawal from opioids is unpleasant, the syndrome is rarely dangerous. In contrast, withdrawal from general CNS depressants (eg, barbiturates, alcohol) can be lethal (see [Chapter 34](#)).

To minimize the abstinence syndrome, opioids should be withdrawn gradually. When the degree of dependence is moderate, symptoms can be avoided by administering progressively smaller doses over 3 days. When the patient is highly dependent, dosage should be tapered more slowly—over 7 to 10 days. With a proper withdrawal procedure, withdrawal symptoms will resemble those of a mild case of flu—even when the degree of dependence is high.

It is important to note that physical dependence is rarely a complication when opioids are taken *acutely* to treat pain. Hospitalized patients receiving morphine 2 to 3 times a day for up

to 2 weeks show no significant signs of dependence. If morphine is withheld from these patients, no significant signs of withdrawal can be detected. The issue of physical dependence as a clinical concern is discussed further later in the chapter.

Infants exposed to opioids *in utero* may be born drug dependent. If the infant is not provided with opioids, an abstinence syndrome will ensue. Signs of withdrawal include excessive crying, sneezing, tremor, hyperreflexia, fever, and diarrhea. The infant can be weaned from drug dependence by administering dilute paregoric in progressively smaller doses.

Cross-dependence exists among pure opioid agonists. As a result, any pure agonist will prevent withdrawal in a patient who is physically dependent on any other pure agonist.

29.2.1.7 Abuse Liability

Morphine and the other opioids are subject to abuse, largely because of their ability to cause pleasurable experiences (eg, euphoria, sedation, a sensation in the lower abdomen resembling orgasm). Physical dependence contributes to abuse: Once dependence exists, the ability of opioids to ward off withdrawal serves to reinforce their desirability in the mind of the abuser.

The abuse liability of the opioids is reflected in their classification under the Controlled Substances Act. (The provisions of this act are discussed in [Chapter 37](#).) As shown in [Table 28-3](#), morphine and all other strong opioid agonists are classified under Schedule II. This classification reflects a moderate to high abuse liability. The agonist-antagonist opioids have a lower abuse liability and hence are classified under Schedule IV (butorphanol, pentazocine) or Schedule V (buprenorphine), or have no classification at all (nalbuphine). Healthcare personnel who prescribe, dispense, and administer opioids must adhere to the procedures set forth in the Controlled Substances Act.

Fortunately, abuse is rare when opioids are employed to treat pain. The issue of abuse as a clinical concern is addressed in depth later in the chapter.

29.2.1.8 Precautions

Some patients are more likely than others to experience adverse effects. Common sense dictates that opioids be used with special caution in these people. Conditions that can predispose patients to adverse reactions are discussed immediately below.

29.2.1.8.1 Decreased Respiratory Reserve.

Because morphine depresses respiration, it can further compromise respiration in patients with impaired pulmonary function. Accordingly, the drug should be used with caution in patients with asthma, emphysema, kyphoscoliosis, chronic cor pulmonale, and extreme obesity. Caution is also needed in patients taking other drugs that can depress respiration (eg, barbiturates, benzodiazepines, general anesthetics).

29.2.1.8.2 Pregnancy.

Morphine does not cause birth defects in humans. However, regular use of opioids during pregnancy *can* cause physical dependence in the fetus. Accordingly, prolonged use by pregnant women should be avoided if possible.

29.2.1.8.3 Labor and Delivery.

Use of morphine during delivery can suppress uterine contractions and cause respiratory depression in the neonate. Following delivery, respiration in the neonate should be monitored closely. Respiratory depression can be reversed with naloxone. The use of opioids in obstetrics is discussed further later in the chapter.

29.2.1.8.4 Head Injury.

Morphine and other opioids must be used with caution in patients with head injury. Head injury can cause respiratory depression accompanied by elevation of ICP. Morphine can exacerbate these symptoms. In addition, since miosis, mental clouding, and vomiting can be valuable diagnostic signs following head injury, and since morphine can cause these same effects, use of opioids can confound diagnosis.

29.2.1.8.5 Other Precautions.

Infants and elderly patients are especially sensitive to morphine-induced respiratory depression. In patients with *inflammatory bowel disease*, morphine may cause toxic megacolon or paralytic ileus. Since morphine and all other opioids are inactivated by liver enzymes, effects may be intensified and prolonged in patients with *liver impairment*. Severe hypotension may occur in patients with preexisting *hypotension* or *reduced blood volume*. In

patients with *prostatic hypertrophy*, opioids may cause acute urinary retention; repeated catheterization may be required.

29.2.1.9 Drug Interactions

The major interactions between morphine and other drugs are summarized in [Table 28-4](#). Some interactions are adverse, and some are beneficial.

29.2.1.9.1 CNS Depressants.

All drugs with CNS-depressant actions (eg, barbiturates, benzodiazepines, alcohol) can intensify sedation and respiratory depression caused by morphine and other opioids. Outpatients should be warned against use of alcohol and all other CNS depressants.

29.2.1.9.2 Anticholinergic Drugs.

These agents (eg, antihistamines, tricyclic antidepressants, atropine-like drugs) can exacerbate morphine-induced constipation and urinary retention.

29.2.1.9.3 Hypotensive Drugs.

Antihypertensive drugs and other drugs that lower blood pressure can exacerbate morphine-induced hypotension.

29.2.1.9.4 Monoamine Oxidase Inhibitors.

The combination of meperidine (a morphine-like drug) with a monoamine oxidase (MAO) inhibitor has produced a syndrome characterized by excitation, delirium, hyperpyrexia, convulsions, and severe respiratory depression. Deaths have occurred. Although this reaction has not been reported with combined use of an MAO inhibitor and morphine, prudence suggests that the combination nonetheless be avoided.

266

267

TABLE 28-4 Interactions of Morphine-like Drugs with Other Drugs

Interacting Drugs	Outcome of the Interaction
Adverse Interactions	
CNS depressants	Increased respiratory depression and sedation
Barbiturates	
Benzodiazepines	
Alcohol	
General anesthetics	
Antihistamines	
Phenothiazines	
Agonist-antagonist opioids	Precipitation of a withdrawal reaction
Anticholinergic drugs	Increased constipation and urinary retention
Atropine-like drugs	
Antihistamines	
Phenothiazines	
Tricyclic antidepressants	
Hypotensive agents	Increased hypotension
Monoamine oxidase inhibitors	Hyperpyrexia coma
Beneficial Interactions	
Amphetamines	Increased analgesia and decreased sedation
Antiemetics	Suppression of nausea and vomiting
Naloxone	Suppression of symptoms of opioid overdose
Dextromethorphan	Increased analgesia; possible reduction in tolerance

29.2.1.9.5 Agonist-Antagonist Opioids.

These drugs (eg, pentazocine, buprenorphine) can precipitate a withdrawal syndrome if given to an individual physically dependent on a pure opioid agonist. The basis of this reaction is

considered later in the chapter. Patients taking pure opioid agonists should be weaned from these drugs before beginning treatment with an agonist-antagonist.

29.2.1.9.6 Opioid Antagonists.

Opioid antagonists (eg, naloxone) can counteract most actions of morphine and other pure opioid agonists. Opioid antagonists are employed primarily to treat opioid overdose. The actions and uses of the opioid antagonists are discussed in detail later in the chapter.

29.2.1.9.7 Other Interactions.

Antiemetics of the phenothiazine type (eg, promethazine [Phenergan]) may be combined with opioids to reduce nausea and vomiting. *Amphetamines*, *clonidine*, and *dextromethorphan* can enhance opioid-induced analgesia. *Amphetamines* can also offset sedation.

29.2.1.10 Toxicity

29.2.1.10.1 Clinical Manifestations.

Opioid overdose produces a classic triad of signs: *coma*, *respiratory depression*, and *pinpoint pupils*. Coma is profound, and the patient cannot be aroused. Respiratory rate may be as low as 2 to 4 breaths per minute. Although the pupils are constricted initially, they may dilate as hypoxia sets in (secondary to respiratory depression). Hypoxia may cause blood pressure to fall. Prolonged hypoxia may result in shock. When death occurs, respiratory arrest is almost always the immediate cause.

29.2.1.10.2 Treatment.

Treatment consists primarily of *ventilatory support* and giving an *opioid antagonist*. Traditionally, naloxone [Narcan] has been the antagonist of choice. However, nalmefene [Revex], a newer and longer acting antagonist, may be preferred for many patients. The pharmacology of the opioid antagonists is discussed later.

29.2.1.11 Preparations, Dosage, and Administration

29.2.1.11.1 General Guidelines on Dosage and Administration.

Dosage must be individualized. High doses are required for patients with a low tolerance to pain or with extremely painful disorders. Patients with sharp, stabbing pain need higher doses

than patients with dull pain. Elderly adults generally require lower doses than younger adults. Neonates require relatively low doses because their blood-brain barrier is not fully developed. For all patients, dosage should be reduced as pain subsides. Outpatients should be warned not to increase dosage without consulting the physician.

Before an opioid is administered, respiratory rate, blood pressure, and pulse rate should be determined. The drug should be withheld and the prescriber notified if respiratory rate is at or below 12 breaths per minute, if blood pressure is significantly below the pretreatment value, or if pulse rate is significantly above or below the pretreatment value.

As a rule, *opioids should be administered on a fixed schedule—not PRN*. With a fixed schedule, medication is given before intense pain returns. As a result, the patient is spared needless discomfort. Furthermore, anxiety about recurrence of pain is reduced. If breakthrough pain occurs, supplemental doses of a short-acting preparation should be given.

Morphine and practically all other opioid agonists are classified under Schedule II of the Controlled Substances Act and must be dispensed accordingly.

29.2.1.11.2 Preparations.

Morphine sulfate is available in 11 formulations: *immediate-release tablets* (15 and 30 mg); *controlled-release tablets* [MS Contin] (15, 30, 60, 100, and 200 mg) and [Oramorph SR] (15, 30, 60, and 100 mg); *extended-release tablets* (15, 30, 60, 100, and 200 mg); *sustained-release capsules* [Kadian] (10, 20, 30, 50, 60, 80, 100, and 200 mg); *extended-release capsules* [Avinza] (30, 60, 90, and 120 mg); *standard oral solution* [MSIR] (2 and 4 mg/mL); *concentrated oral solution* [MSIR, Roxanol] (20 mg/mL); *rectal suppositories* [RMS] (5, 10, 20, and 30 mg); *soluble tablets for injection* (10, 15, and 30 mg); *standard solution for injection* [Astramorph PF, Duramorph, Infumorph] (0.5, 1, 2, 4, 5, 8, 10, 15, 25, and 50 mg/mL); and *extended-release liposomal solution for injection* [DepoDur] (10 mg/mL).

29.2.1.11.3 Dosage and Routes of Administration. Oral.

Oral administration is generally reserved for patients with chronic, severe pain, such as that associated with cancer. Because oral morphine undergoes extensive metabolism on its first pass through the liver, oral doses are usually higher than parenteral doses. A typical dosage is 10 to 30 mg repeated every 4 hours as needed. However, oral dosing is highly individualized, and hence some patients may require 75 mg or more. Controlled-release formulations may be administered every 8 to 12 hours, and the extended-release formulation [Avinza] is given

every 24 hours. Patients should be instructed to swallow these products intact, without crushing or chewing. Also, *warn patients using Avinza not to drink alcohol*, which can accelerate release of morphine from this formulation.

29.2.1.11.3.1 Intramuscular and Subcutaneous.

Both routes are painful and unreliable, and hence should generally be avoided. For adults, dosing is initiated at 5 to 10 mg every 4 hours, and then adjusted up or down as needed. The usual dosage for children is 0.1 to 0.2 mg/kg repeated every 4 hours as needed.

29.2.1.11.3.2 Intravenous.

Intravenous morphine should be injected slowly (over 4 to 5 minutes). Rapid IV injection can cause severe adverse effects (profound hypotension, cardiac arrest, respiratory arrest) and should be avoided. When IV injections are made, an opioid antagonist (eg, naloxone) and facilities for respiratory support should be available. Injections should be given with the patient lying down to minimize hypotension. The usual dose for adults is 4 to 10 mg (diluted in 4 to 5 mL of sterile water for injection). The usual pediatric dose is 0.05 to 0.1 mg/kg.

267

268

29.2.1.11.3.3 Epidural and Intrathecal.

When morphine is employed for spinal analgesia, epidural injection is preferred to intrathecal. With either route, onset of analgesia is rapid and the duration prolonged (up to 24 hours). The most troubling side effects are delayed respiratory depression and delayed cardiac depression. Be alert for possible late reactions. The usual adult epidural dose is 5 mg. Intrathecal doses are much smaller—about one-tenth the epidural dose.

The extended-release liposomal formulation [DepoDur] is intended for *epidural use only*. Inadvertent intrathecal and subarachnoid administration has been associated with profound and prolonged respiratory depression, which can be managed with a naloxone infusion.

29.2.2 Other Strong Opioid Agonists

In an effort to produce a strong analgesic with a low potential for respiratory depression and abuse, pharmaceutical scientists have created many new opioid analgesics. However, none of the newer pure opioid agonists can be considered truly superior to morphine: These drugs are essentially equal to morphine with respect to analgesic action, abuse liability, and the ability to

cause respiratory depression. Also, to varying degrees, they all cause sedation, euphoria, constipation, urinary retention, cough suppression, hypotension, and miosis. However, despite their similarities to morphine, the newer drugs do have unique qualities. Hence one agent may be more desirable than another in a particular clinical situation. With all of the newer pure opioid agonists, toxicity can be reversed with an opioid antagonist (eg, naloxone). Important differences between morphine and the newer strong opioid analgesics are discussed below. [Table 28-5](#) summarizes dosages, routes, and time courses for morphine and the newer agents.

29.2.2.1 Fentanyl

Fentanyl [Sublimaze, Duragesic, Fentora, Actiq, Ionsys] is a strong opioid analgesic with a high milligram potency (about 100 times that of morphine). Like other strong opioids, fentanyl overdose poses a risk of fatal respiratory depression. Fentanyl is metabolized by CYP3A4 (the 3A4 isozyme of cytochrome P450), and hence fentanyl levels can be increased by CYP3A4 inhibitors (eg, ritonavir, ketoconazole). Patients taking these inhibitors should be closely monitored for severe respiratory depression and other signs of toxicity. Fentanyl is available in five formulations for administration by three routes: parenteral, transdermal, and transmucosal. All preparations are regulated under Schedule II of the Controlled Substances Act.

29.2.2.1.1 Parenteral.

Parenteral fentanyl [Sublimaze], administered IM or IV, is employed primarily for induction and maintenance of surgical anesthesia. The drug is well suited for these applications because it has a rapid onset and short duration. Most effects are like those of morphine. In addition, fentanyl can cause muscle rigidity, which can interfere with induction of anesthesia. As discussed in [Chapter 27](#) (General Anesthetics), the combination of fentanyl plus droperidol is used to produce a state known as “neurolept analgesia.”

29.2.2.1.2 Transdermal.

Fentanyl for transdermal administration is available in two formulations: (1) a patch [Duragesic] that releases fentanyl slowly over an extended time and (2) an iontophoretic system [Ionsys] that releases a small dose each time the system is activated. The iontophoretic system is indicated only for *postoperative pain* in hospitalized patients. In contrast, the patch is indicated for *persistent pain* in patients who are already opioid tolerant, and is specifically *contraindicated* for postoperative pain.

29.2.2.1.2.1 Standard Transdermal System (Patch)

The standard fentanyl transdermal system [Duragesic] consists of a fentanyl-containing patch that is applied to the skin of the upper torso. The drug is slowly released from the patch and absorbed through the skin, reaching effective levels in 24 hours. Levels remain steady for another 48 hours, after which the patch should be replaced. If a new patch is not applied, effects will nonetheless persist for several hours, owing to continued absorption of residual fentanyl remaining in the skin.

Transdermal fentanyl is indicated only for persistent severe pain in patients who are already opioid tolerant. Use in nontolerant patients can cause fatal respiratory depression. The patch should not be used in children under 2 years old, or in anyone under 18 who weighs less than 110 pounds. Also, the patch should not be used for postoperative pain, intermittent pain, or pain that responds to a less powerful analgesic.

Transdermal fentanyl has the same adverse effects as other opioids: respiratory depression, sedation, constipation, urinary retention, nausea, and so forth. Of these, respiratory depression is the greatest concern. Adverse effects may persist for hours following patch removal owing to continued absorption from the skin. Signs of toxicity can be reversed with an opioid antagonist (eg, naloxone). Used or damaged patches should be flushed down the toilet. Unused patches should be stored out of reach of children.

Heat can accelerate fentanyl release from the patch, thereby increasing the risk of toxicity. Accordingly, patients should be advised to avoid exposing the patch to external heat sources, including heating pads, electric blankets, heat lamps, saunas, hot tubs, and heated water beds. Sunbathing and hot baths should be avoided as well. Patients with fever should be monitored for signs of increased drug levels and, if toxicity develops, fentanyl dosage should be reduced.

Fentanyl patches are available in five sizes, which deliver fentanyl to the systemic circulation at rates of 12.5, 25, 50, 75, and 100 mcg/hr. The smallest effective patch should be used. If a dosage greater than 100 mcg/hr is required, a combination of patches can be applied. When the patch is in place, it must not be exposed to direct heat (eg, heating pads, hot baths, electric blankets), because doing so can accelerate fentanyl release, as can fever, sunbathing, and strenuous exercise. Because full analgesic effects can take up to 24 hours to develop, PRN therapy with a short-acting opioid may be required until the patch takes

effect. As with other long-acting opioids, if breakthrough pain occurs, supplemental dosing with a short-acting opioid is indicated. For the majority of patients, patches can be replaced every 72 hours, although some may require a new patch in 48 hours.

29.2.2.1.2.2 Transdermal Iontophoretic System.

The transdermal iontophoretic system [Ionsys]—a self-contained credit card–sized device—is the first *needle-free* patient-activated system for on-demand delivery of analgesia. The device, which is applied to the skin, delivers fentanyl by iontophoresis, a process in which a low-intensity electrical field (generally imperceptible to the patient) drives the drug across the skin and into the systemic circulation. Ionsys is approved only for acute management of postoperative pain in hospitalized adult patients, and should be removed prior to discharge. Pain control is equivalent to that achieved with an IV patient-controlled analgesia pump. The most common adverse effect is nausea (38%).

268

TABLE 28-5 Clinical Pharmacology of Pure Opioid Agonists

a IM administration should be avoided whenever possible.

b Dose in milligrams that produces a degree of analgesia equivalent to that produced by a 10-mg IM dose of morphine.

c Data are for the transdermal patch, not the transdermal iontophoretic system.

d With repeated doses, methadone's duration of action may increase up to 48 hours.

e Effects of extended-release formulations may persist for 8 to 12 hours.

f A dose of propoxyphene equivalent to 10 mg of morphine would be too toxic to administer.

g Analgesia stops 5 to 10 minutes after stopping the infusion.

269

270

Ionsys consists of a plastic case that houses a 3-volt battery, control electronics, and a reservoir containing 10.8 mg of fentanyl hydrochloride. The upper surface of the device has a recessed dosing button and a red light; the lower surface has adhesive to hold the device to the skin. When pain relief is needed, the patient presses the dosing button twice (within 3 seconds), causing delivery of a 40-mcg dose over a 10-minute interval. An audible beep indicates the process has begun and the red light remains on while delivery takes place. One Ionsys device can be used for 24 hours or delivery of 80 doses, whichever comes first. Ionsys should be applied to intact, nonirritated, nonirradiated skin of the chest or outer upper arm. Excessive hair should be removed by clipping, not shaving. All patients should be titrated to comfort with an appropriate analgesic before Ionsys is employed.

29.2.2.1.3 Transmucosal.

Fentanyl for transmucosal administration is available in two formulations: lozenges on a stick [Actiq] and buccal tablets [Fentora]. Both products are approved only for breakthrough cancer pain in patients who are already taking opioids and who have developed some degree of tolerance, defined as needing more than 60 mg of morphine/day, at least 25 mcg of fentanyl/hr, or an equianalgesic dose of another opioid for a week or more. These products must not be used for acute pain, postoperative pain, headache, or athletic injuries. It is essential to appreciate that the dose of fentanyl in either formulation is sufficient to kill nontolerant individuals—especially children. Accordingly, these products must be stored in a secure, child-resistant location.

29.2.2.1.3.1 Lozenge on a Stick.

The fentanyl lozenge on a stick [Actiq]—also known as OTFC (oral transmucosal fentanyl citrate)—consists of a raspberry-flavored lozenge on a plastic handle, and looks much like a lollypop. Six strengths are available: 200, 400, 600, 800, 1200, and 1600 mcg. As noted, the Actiq system is approved only for *breakthrough cancer pain* in patients who are already opioid tolerant.

To administer the unit, patients place it between the cheek and the lower gum and actively suck it. Periodically, the unit should be moved from one side of the mouth to the other. Consumption of the entire lozenge should take 15 minutes. As the patient sucks, some of the drug is absorbed directly and rapidly through the oral mucosa, and some is swallowed

and absorbed slowly from the GI tract. Analgesia begins in 10 to 15 minutes, peaks in 20 minutes, and persists 1 to 2 hours.

Dosing should begin with a 200-mcg unit. If breakthrough pain persists, the patient can take another 200-mcg unit 15 minutes after finishing the first one (ie, 30 minutes after starting the first). Unit size should be gradually increased until an effective dose is determined. If the patient needs more than 4 units/day, it may be time to give a higher dose of his or her long-acting opioid.

Adverse effects of the Actiq system are like those of other opioids. The most common are dizziness, anxiety, confusion, nausea, vomiting, constipation, dyspnea, weakness, and headache. The biggest concerns are respiratory depression and shock. If dizziness, nausea, or signs of overdose develop, the unit should be removed from the patient's mouth and disposed of immediately.

To promote safe and effective use of the Actiq system, the manufacturer provides an Actiq Welcome Kit with the initial drug supply. The kit contains educational materials and safe storage containers for unused, partially used, and completely used units.

29.2.2.1.3.2

Buccal Tablets

Like the Actiq lozenges, fentanyl buccal tablets [Fentora] are indicated only for breakthrough cancer pain in patients who are already taking opioids and have developed some degree of tolerance. Administration to nontolerant patients could result in severe respiratory depression.

The buccal tablets are much like the lozenges, but with one very important difference: *absorption from the tablets is more complete than from the lozenges*, and hence the two formulations are not directly interchangeable. For example, a 100-mcg buccal tablet produces about the same fentanyl blood level as a 200-mcg lozenge. Hence, when patients are switched from the lozenge to the tablet, the dosage must be reduced (see below). Failure to do so could prove fatal.

Fentanyl buccal tablets are available in five strengths, identifiable by color: 100 mcg (blue), 200 mcg (orange), 400 mcg (green), 600 mcg (pink), and 800 mcg (yellow). Patients should be instructed to place the tablet above a rear molar between the cheek and the gum and let it dissolve in place, usually in 15 to 30 minutes. Remaining fragments should be swallowed with a glass of water. Whole tablets should never be split, chewed, sucked, or swallowed.

Dosage is based on current opioid use. For patients switching from Actiq, the initial Fentora tablet should be 100 mcg (for patients using 200 mcg or 400 mcg of Actiq), 200 mcg (for patients using 600 mcg or 800 mcg of Actiq), or 400 mcg (for patients using 1200 mcg or 1600 mcg of Actiq). For patients not using Actiq, the initial dose of Fentora should be 100 mcg. The dosage may then be titrated using up to four 100-mcg Fentora tablets per dose. If a higher dosage is needed, larger Fentora tablets should be used.

29.2.2.2 Alfentanil and Sufentanil

Alfentanil [Alfenta] and sufentanil [Sufenta] are intravenous opioids related to fentanyl. Both drugs are used for induction of anesthesia, for maintenance of anesthesia (in combination with other agents), and as sole anesthetic agents. Pharmacologic effects are like those of morphine. Sufentanil has an especially high milligram potency (about 1000 times that of morphine); alfentanil is about 10 times more potent than morphine. Both drugs have a rapid onset, and both are Schedule II agents.

29.2.2.3 Remifentanil

Remifentanil [Ultiva] is an intravenous opioid with a rapid onset and brief duration. The brief duration results from rapid metabolism by plasma and tissue esterases, and not from hepatic metabolism or renal excretion. Like fentanyl, remifentanil is about 100 times more potent than morphine. Remifentanil is approved for analgesia during surgery and during the immediate postoperative period. Administration is by continuous IV infusion. Effects begin in minutes, and terminate 5 to 10 minutes after the infusion is stopped. For surgical analgesia, the infusion rate is 0.05 to 2 mcg/kg/min. For postoperative analgesia, the infusion rate is 0.025 to 0.2 mcg/kg/min. Adverse effects during the infusion include respiratory depression, hypotension, bradycardia, and muscle rigidity sufficient to compromise breathing. Postinfusion effects include nausea (44%), vomiting (22%), and headache (18%). Remifentanil is regulated as a Schedule II substance.

29.2.2.4 Meperidine

Meperidine [Demerol] shares the major pharmacologic properties of morphine. With parenteral and oral administration, analgesia is strong. In the past, meperidine was considered a first-line drug for relief of moderate to severe pain. Now, however, use of meperidine is in decline. Why? First, the drug has a short half-life, and hence dosing must be repeated at short intervals. Second, meperidine interacts adversely with a number of drugs. Third, with continuous use,

there is a risk of harm owing to accumulation of a toxic metabolite. Accordingly, routine use of the drug should be avoided. However, meperidine may still be appropriate for patients who can't take other opioids, and for patients with drug-induced rigors or postanesthesia shivering.

Meperidine can interact with MAO inhibitors to cause excitation, delirium, hyperpyrexia, and convulsions. Coma and death can follow. The underlying mechanism appears to be excessive activation of serotonin receptors owing to meperidine-induced blockade of serotonin reuptake. Clearly, the combination of meperidine with an MAO inhibitor should be avoided. Other drugs that increase serotonin availability (eg, tricyclic antidepressants, selective serotonin reuptake inhibitors) may also pose a risk.

270

271

Repeated dosing results in accumulation of normeperidine, a toxic metabolite that can cause dysphoria, irritability, tremors, and seizures. To avoid toxicity, *treatment should not exceed 48 hours, and the dosage should not exceed 600 mg/24 hr.*

Meperidine is available in tablets (50 and 100 mg) and a syrup (10 mg/mL) for oral use, and in solution (25, 50, 75, and 100 mg/mL) for injection (IV, IM, or subQ). The usual adult dosage is 50 to 150 mg (IM, subQ, or PO) repeated every 3 to 4 hours as needed—up to a maximum of 600 mg/day. The usual dosage for children is 1 to 1.8 mg/kg (IM, subQ, or PO) repeated every 3 to 4 hours as needed. As noted, prolonged use must be avoided.

29.2.2.5 Methadone

Methadone [Diskets, Dolophine, Methadose] has pharmacologic properties very similar to those of morphine. The drug is effective orally and has a long duration of action. Repeated dosing can result in accumulation. Methadone is used to relieve pain and to treat opioid addicts. The use of methadone in drug-abuse treatment programs is discussed in [Chapter 39](#).

Methadone prolongs the QT interval, and hence may pose a risk of potentially fatal dysrhythmias. Torsades de pointes has developed in patients taking 65 to 400 mg/day. To reduce risk, methadone should be used with great caution—if at all—in patients with existing QT prolongation and in those taking other QT-prolonging drugs (eg, amiodarone, quinidine, erythromycin, tricyclic antidepressants).

In recent years, there have been increasing reports of deaths and life-threatening side effects (especially dysrhythmias and respiratory depression) among patients taking methadone to relieve pain. The presumed cause of toxicity is high drug levels, owing largely to excessive dosage. To reduce risk, patients should be warned against taking more methadone than was

prescribed, and should be cautioned to avoid other CNS depressants, including benzodiazepines, alcohol, and other opioids. Drugs that inhibit CYP3A4 (the enzyme that metabolizes methadone) can raise methadone levels, and hence should be used with care. Among these inhibitors are clarithromycin, fluvoxamine, fluconazole, and nelfinavir.

Methadone is supplied in standard tablets (5 and 10 mg) and solution (1, 2, and 10 mg/mL) for oral use, and in solution (10 mg/mL) for IM and subQ injection. In addition, the drug is available in dispersible 40-mg tablets for detoxification and maintenance of opioid addicts. Usual oral analgesic doses for adults range from 2.5 to 20 mg repeated every 3 to 4 hours as needed.

29.2.2.6 Heroin

Heroin is a strong opioid agonist very similar to morphine in structure and actions. The drug is an effective analgesic and is employed legally in Europe to relieve pain. In the United States, federal legislation prohibits the medical use of this drug. Why? Because heroin has a high abuse liability and is no better than other opioids at relieving pain.

What makes heroin so attractive as a drug of abuse? Pharmacokinetics: Heroin has greater lipid solubility than morphine, and therefore crosses the blood-brain barrier more readily. As a result, when heroin is injected IV, it accumulates in the brain more rapidly and to a higher level than would an equivalent dose of morphine. Once in the brain, heroin (diacetylmorphine) is rapidly converted into active metabolites: monoacetylmorphine and morphine ([Fig. 28-2](#)). It is these metabolites, and not heroin itself, that produce the subjective effects that follow heroin injection. In this regard, heroin can be viewed as a vehicle for facilitating transport of morphine into the brain.

29.2.2.7 Hydromorphone, Oxycodone, and Levorphanol

29.2.2.7.1 Basic Pharmacology.

All three drugs are strong opioid agonists with pharmacologic actions like those of morphine, and all three are indicated for moderate to severe pain. Dosages and time courses are summarized in [Table 28-5](#). Adverse effects include respiratory depression, sedation, cough suppression, constipation, urinary retention, nausea, and vomiting. Toxicity can be reversed with an opioid antagonist (eg, naloxone). All three drugs are Schedule II agents.

29.2.2.7.2 Preparations, Dosage, and Administration

29.2.2.7.2.1 Hydromorphone.

Hydromorphone [Dilaudid] is available in five formulations: (1) oral tablets (2, 4, and 8 mg); (2) oral liquid (1 mg/mL); (3) rectal suppositories (3 mg); (4) solutions (1, 2, 4, and 10 mg/mL) for IM and subQ injection; and (5) a powder (250 mg), to be reconstituted to a 10-mg/mL solution for IM and subQ injection. With the tablets, the usual adult dosage is 2 mg every 4 to 6 hours. With the oral liquid, the usual adult dosage is 2.5 to 10 mg every 3 to 6 hours. With the rectal suppositories, the usual dosage is 3 mg every

Figure 28-2 Biotransformation of heroin into morphine.

Heroin, as such, is biologically inactive. After crossing the blood-brain barrier, heroin is converted to monoacetylmorphine (MAM) and then into morphine itself. MAM and morphine are responsible for the effects elicited by injection of heroin.

6 to 8 hours. With subQ and IM injection, dosages range from 1 to 4 mg every 4 to 6 hours.

29.2.2.7.2.2 Oxymorphone.

Oxymorphone is available in three formulations: (1) immediate-release tablets (5 and 10 mg) sold as *Opana*; (2) extended-release tablets (5, 7.5, 10, 15, 20, 30, and 40 mg) sold as *Opana ER*; and (3) solution for IM, IV, or subQ injection (1 mg/mL) sold as *Opana*. All oxymorphone tablets should be taken on an empty stomach, because dosing with food can produce excessive peak levels. Also, alcohol should be avoided, since it can increase blood levels of oral oxymorphone. For IV therapy, the initial dose is 0.5 mg. Usual subQ and IM dosages are 1 to 1.5 mg every 4 to 6 hours as needed.

29.2.2.7.2.3 Levorphanol.

Levorphanol [Levo-Dromoran] is available in 2-mg oral tablets and in solution (2 mg/mL) for IM, IV, or subQ injection. The usual adult oral dosage is 2 mg, repeated in 6 to 8 hours as needed. For IV therapy, the usual dosage is 1 mg, repeated in 3 to 6 hours as needed, up to a maximum of 4 to 8 mg/24 hr. For IM or subQ therapy, the usual dosage is 1 to 2 mg, repeated in 6 to 8 hours as needed, up to a maximum of 3 to 8 mg/24 hr.

29.2.3 Moderate to Strong Opioid Agonists

The moderate to strong opioid agonists are similar to morphine in most respects. Like morphine, these drugs produce analgesia, sedation, and euphoria. In addition, they can cause respiratory depression, constipation, urinary retention, cough suppression, and miosis. Differences between the moderate to strong opioids and morphine are primarily quantitative: The moderate to strong opioids produce less analgesia and respiratory depression than morphine and have a somewhat lower potential for abuse. As with morphine, toxicity from the moderate to strong agonists can be reversed with naloxone.

271

272

29.2.3.1 Codeine

Codeine is indicated for relief of mild to moderate pain. The drug is usually administered by mouth. Side effects are dose limiting. As a result, although taking codeine can produce significant pain relief, the degree of pain relief that can be achieved *safely* is quite low—much lower than with morphine. When taken in its usual analgesic dose (30 mg), codeine produces about as much pain relief as 325 mg of aspirin or 325 mg of acetaminophen.

In the liver, about 10% of each codeine dose undergoes conversion to *morphine*, the active form of codeine. The enzyme responsible is CYP2D6 (the 2D6 isomer of cytochrome P450). Among people who lack an effective gene for CYP2D6, codeine cannot be converted to morphine, and hence codeine cannot produce analgesia. Conversely, among ultrarapid metabolizers, who carry multiple copies of the CYP2D6 gene, codeine is unusually effective. Ultrarapid metabolism occurs in 7% of whites, 3% of blacks, and 1% of Hispanics and Asians.

Very rarely, severe toxicity develops in breast-fed infants whose mothers are taking codeine. The cause is high levels of morphine in breast milk, owing to ultrarapid codeine metabolism. Nursing mothers who are taking codeine should be alert for signs of infant intoxication—excessive sleepiness, breathing difficulties, lethargy, poor feeding—and should seek medical attention if these develop.

For analgesic use, codeine is formulated alone and in combination with nonopioid analgesics (either aspirin or acetaminophen). Since codeine and nonopioid analgesics relieve pain by different mechanisms, the combinations can produce greater pain relief than either agent alone. Codeine alone is classified under Schedule II of the Controlled Substances Act. The combination preparations are classified under Schedule III. Although codeine is classified along with morphine in Schedule II, the abuse liability of codeine appears to be significantly lower.

Codeine is an extremely effective cough suppressant and is widely used for this action. The antitussive dose (10 mg) is lower than analgesic doses. Codeine is formulated in combination with various agents to suppress cough. These mixtures are classified under Schedule V.

29.2.3.1.1 Preparations, Dosage, and Administration.

Codeine is administered orally and parenterally (IV, IM, and subQ). For oral therapy, the drug is available in tablets (15, 30, and 60 mg) and in solution (3 mg/mL). For parenteral therapy, the drug is available in solution (15 and 30 mg/mL).

The usual analgesic dosage for adults is 15 to 60 mg (PO, IV, IM, or subQ) every 3 to 6 hours (to a maximum of 120 mg/24 hr). The usual analgesic dosage for children 1 year and older is 0.5 mg/kg (PO, IM, or subQ) every 4 to 6 hours (to a maximum of 60 mg/24 hr).

29.2.3.2 Oxycodone

Oxycodone [OxyContin, Roxicodone, Combunox, Percodan, Percocet, others] has analgesic actions equivalent to those of codeine. Administration is oral. Oxycodone is available by itself

in immediate-release tablets (5, 10, 15, 20, and 30 mg), immediate-release capsules (5 mg), controlled-release tablets (10, 15, 20, 30, 40, 60, and 80 mg), and oral solution (1 and 20 mg/mL). In addition, the drug is available in combination with aspirin (as Percodan), acetaminophen (as Percocet, Roxicet, others), and ibuprofen (as Combunox). All formulations are classified under Schedule II.

Controlled-release oxycodone [OxyContin] is a longacting analgesic designed to relieve moderate to severe pain around-the-clock for an extended time. Dosing is done every 12 hours—not PRN. If breakthrough pain occurs, supplemental dosing with a short-acting analgesic is indicated.

Owing to increasing reports of OxyContin abuse, safety warnings have been strengthened. When prescribed and used properly, controlled-release oxycodone tablets are safe and effective. However, abusers do not take them properly. Rather, they crush the tablets and then “snort” the resulting powder, or dissolve the powder in water and inject it IV. Both practices allow *immediate* absorption of the entire dose, and thereby produce drug blood levels that are much higher than those produced when the tablets are ingested whole and absorbed gradually. The result can be an intense “high” coupled with a risk of fatal respiratory depression. At least 39 deaths have been reported. To prevent the immediate release of a potentially fatal dose, the controlled-release tablets must be swallowed whole, without breaking, crushing, or chewing. Furthermore, the 80-mg formulation must be reserved for patients who are already opioid tolerant. OxyContin tablets should never be dissolved and injected. Why? Because the tablets contain insoluble particulate matter (especially talc) that can cause local tissue necrosis, pulmonary granulomas, endocarditis, and valvular heart injury. As with all other opioids, concerns about abuse and addiction should not interfere with using OxyContin to manage pain. Rather, the drug must simply be prescribed appropriately and then used as prescribed.

29.2.3.3 Hydrocodone

Hydrocodone is the most widely prescribed drug in the United States. In 2007, more than 108 million prescriptions were written—far more than the 65 million for atorvastatin (a cholesterol-lowering drug) or the 34 million for amoxicillin (an antibiotic). Hydrocodone has analgesic actions equivalent to those of codeine. The drug is taken orally to relieve pain and to suppress cough. The usual dosage is 5 mg. Hydrocodone is available only in combination with other drugs. For analgesic use, hydrocodone is combined with aspirin, acetaminophen, or ibuprofen. For cough suppression, the drug is combined with antihistamines and nasal decongestants. All of these combination products are currently classified under Schedule III. However, owing to

widespread abuse of hydrocodone-containing products, the Drug Enforcement Agency (DEA) would like the classification changed to Schedule II. Trade names for combination products containing hydrocodone include *Vicodin*, *Vicoprofin*, and *Lortab*.

29.2.3.4 Propoxyphene

Propoxyphene [Darvon] has analgesic effects about equal to those of aspirin. The drug is frequently prescribed in combination with a nonopioid analgesic, either aspirin or acetaminophen. These combinations can produce greater pain relief than either propoxyphene or the nonopioid alone. Propoxyphene has a low potential for abuse, primarily because large doses cause toxic psychosis. Furthermore, excessive doses often prove fatal. Accordingly, the drug should not be prescribed for patients with suicidal tendencies. Physical dependence is minimal. Propoxyphene—alone or in combination with a nonopioid analgesic—is classified under Schedule IV.

Propoxyphene is available as two salts: propoxyphene hydrochloride and propoxyphene napsylate. Both are administered orally. Propoxyphene hydrochloride is available in 65-mg capsules (as *Darvon Pulvules*); the usual adult dosage is 65 mg repeated every 4 hours as needed. Propoxyphene napsylate is available in 100-mg tablets (as *Darvon-N*); the usual adult dosage is 100 mg repeated every 4 hours as needed. In addition to these single-ingredient products, propoxyphene napsylate is available in combinations with acetaminophen, sold as *Darvocet* and *Propacet*.

272

273

29.2.4 Agonist-Antagonist Opioids

Four agonist-antagonist opioids are available: pentazocine, nalbuphine, butorphanol, and buprenorphine. With the exception of buprenorphine, these drugs act as antagonists at mu receptors and agonists at kappa receptors (see [Table 28-2](#)). Compared with pure opioid agonists, the agonist-antagonists have a low potential for abuse, produce less respiratory depression, and generally have less powerful analgesic effects. If given to a patient who is physically dependent on a pure opioid agonist, these drugs can precipitate withdrawal. The clinical pharmacology of the agonist-antagonists is summarized in [Table 28-6](#).

29.2.4.1 Pentazocine

29.2.4.1.1 Actions and Uses.

Pentazocine [Talwin] was the first agonist-antagonist opioid available and can be considered the prototype for the group. The drug is indicated for mild to moderate pain. Pentazocine is much less effective than morphine against severe pain.

Pentazocine acts as an *agonist* at kappa receptors and as an *antagonist* at mu receptors. By activating kappa receptors, the drug produces analgesia, sedation, and respiratory depression. However, unlike the respiratory depression caused by morphine, *respiratory depression caused by pentazocine is limited*. Beyond a certain dose, no further depression occurs. Because it lacks agonist actions at mu receptors, pentazocine produces little or no euphoria. In fact, at supratherapeutic doses, pentazocine produces unpleasant reactions (anxiety, strange thoughts, nightmares, hallucinations). These psychotomimetic effects may result from activation of kappa receptors. Because of its subjective effects, pentazocine has a low potential for abuse and is classified under Schedule IV.

Adverse effects are generally like those of morphine. However, in contrast to the pure opioid agonists, pentazocine increases cardiac work. Accordingly, a pure agonist (eg, morphine) is preferred to pentazocine for relieving pain in patients with myocardial infarction.

If administered to a patient who is physically dependent on a pure opioid agonist, pentazocine can precipitate withdrawal. Recall that mu receptors mediate physical dependence on pure opioid agonists and that pentazocine acts as an antagonist at these receptors. By blocking access of the pure agonist to mu receptors, pentazocine will prevent receptor activation, thereby triggering withdrawal. Accordingly, *pentazocine and other drugs that block mu receptors should never be administered to a person who is physically dependent on a pure opioid agonist.* If a pentazocine-like agent is to be used, the pure opioid agonist must first be withdrawn.

Physical dependence can occur with pentazocine, but symptoms of withdrawal are generally mild (eg, cramps, fever, anxiety, restlessness). Treatment is rarely required. As with pure opioid agonists, toxicity from pentazocine can be reversed with naloxone.

29.2.4.1.2 Preparations, Dosage, and Administration.

Pentazocine is administered orally. A formulation for parenteral use has been withdrawn.

Pentazocine [Talwin NX] is formulated in 50-mg tablets that also contain 0.5 mg of naloxone (to prevent abuse). The usual adult dosage is 50 mg every 3 to 4 hours as needed. The drug is also available in combination with aspirin [Talwin Compound] and with acetaminophen [Talacen].

29.2.4.2 Nalbuphine

Nalbuphine [Nubain] has pharmacologic actions similar to those of pentazocine. The drug is an agonist at kappa receptors and an antagonist at mu receptors. At low doses, nalbuphine has analgesic actions equal to those of morphine. However, as dosage increases, a ceiling to analgesia is reached. As a result, the maximal pain relief that can be produced with nalbuphine is much lower than with morphine. As with pain relief, there is also a ceiling to respiratory depression. Like pentazocine, nalbuphine can cause psychotomimetic reactions. With prolonged treatment, physical dependence can develop. Symptoms of abstinence are less intense than with morphine but more intense than with pentazocine. When used during labor and delivery, nalbuphine has caused serious adverse effects, including bradycardia in the fetus and apnea, cyanosis, and hypotonia in the neonate. Accordingly, use during labor and delivery should be avoided, if possible. Nalbuphine has a low abuse potential and is not regulated under the Controlled Substances Act. As with the pure opioid agonists, toxicity can be reversed with naloxone. Like pentazocine, nalbuphine will precipitate a withdrawal reaction if administered to an individual physically dependent on a pure opioid agonist. Nalbuphine is supplied in solution (10 and 20 mg/mL) for IV, IM, and subQ injection. The usual adult dosage is 10 mg repeated every 3 to 6 hours as needed.

273

274

TABLE 28-6 Clinical Pharmacology of Opioid Agonists-Antagonists

Drug and Route [*]	Equianalgesic Dose (mg) [†]	Time Course of Analgesic Effects		
		Onset (min)	Peak (min)	Duration (hr)
Buprenorphine				
IM	0.3	15	60	Up to 6
IV	0.3	Under 15	Under 60	Up to 6
Butorphanol				
IM	2–3	10	30–60	3–4
IV	2–3	2–3	30–60	3–4
Intranasal	2–3	Within 15	60–120	4–5
Nalbuphine				
IM	10	Within 15	60	3–6
IV	10	2–3	30	3–6
SubQ	10	Within 15	60	3–6
Pentazocine				
PO	—	15–30	60–90	3 [‡]
IM	30	15–20	30–60	4–6 [‡]
IV	30	2–3	15–30	4–6 [‡]
SubQ	30	15–20	30–60	4–6 [‡]

* IM administration should be avoided whenever possible.

† Dose in milligrams that produces a degree of analgesia equivalent to that produced by a 10-mg IM dose of morphine.

‡ Duration may increase greatly in patients with liver disease.

29.2.4.3 Butorphanol

Butorphanol [Stadol] has actions similar to those of pentazocine. The drug is an agonist at kappa receptors and an antagonist at mu receptors. Analgesic effects are less than those of morphine.

As with pentazocine, there is a “ceiling” to respiratory depression. The drug can cause

psychotomimetic reactions, but these are rare. Butorphanol increases cardiac work and should not be given to patients with myocardial infarction. Physical dependence can occur, but symptoms of withdrawal are relatively mild. The drug may induce a withdrawal reaction in patients physically dependent on a pure opioid agonist. Butorphanol has a low potential for abuse and is regulated under Schedule IV of the Controlled Substances Act. Toxicity can be reversed with naloxone.

Butorphanol is administered parenterally (IM and IV) and by nasal spray (primarily to treat migraine). The usual adult IV dosage is 1 mg every 3 to 4 hours as needed. The usual IM dosage is 2 mg every 3 to 4 hours as needed. The usual intranasal dosage is 1 mg (1 spray from the metered-dose spray device) repeated in 60 to 90 minutes if needed. The two-dose sequence may then be repeated every 3 to 4 hours as needed.

29.2.4.4 Buprenorphine

Buprenorphine [Buprenex, Subutex, Suboxone] differs significantly from other opioid agonist-antagonists. The drug is a partial agonist at mu receptors and an antagonist at kappa receptors. Analgesic effects are like those of morphine, but significant tolerance has not been observed. Although buprenorphine can depress respiration, severe respiratory depression has not been reported. Like pentazocine, buprenorphine can precipitate a withdrawal reaction in persons physically dependent on a pure opioid agonist. Psychotomimetic reactions can occur but are rare. Physical dependence develops but symptoms of abstinence are delayed; peak responses may not occur until 2 weeks after the last dose was taken. Prolonged use may pose a risk of liver damage. Buprenorphine is currently classified as a Schedule III substance. In addition to its use for analgesia, buprenorphine is used to treat opioid addiction (see [Chapter 39](#)).

Although pretreatment with naloxone can prevent toxicity from buprenorphine, naloxone cannot readily reverse toxicity that has already developed. It appears that buprenorphine binds very tightly to its receptors, and hence cannot be readily displaced by naloxone.

To manage *pain*, buprenorphine [Buprenex] is supplied in solution (0.3 mg/mL) for administration by IM or slow IV injection. The usual dosage for patients age 13 years and older is 0.3 mg repeated every 6 hours as needed.

To manage *opioid addiction*, buprenorphine is available in two sublingual formulations. One [Subutex] contains buprenorphine alone, and the other [Suboxone] contains buprenorphine plus naloxone (see [Chapter 39](#)).

29.3 CLINICAL USE OF OPIOIDS

29.3.1 Dosing Guidelines

29.3.1.1 Pain Assessment

Assessment is an essential component of pain management. Pain status should be evaluated prior to opioid administration and about 1 hour after. Unfortunately, because pain is a subjective experience, affected by multiple factors (eg, cultural influences, patient expectations, associated disease), there is no reliable objective method for determining just how much discomfort the patient is feeling. That is, we cannot measure pain with instruments equivalent to those employed to monitor blood pressure, cardiac performance, and other physiologic parameters. As a result, assessment must ultimately be based on the patient's description of his or her experience. Accordingly, you should ask the patient where the pain is located, what type of pain is present (eg, dull, sharp, stabbing), how the pain changes with time, what makes the pain better, and what makes it worse. In addition, you should assess for psychologic factors that can reduce pain threshold (anxiety, depression, fear, anger).

When attempting to assess pain, keep in mind that, on occasion, what the patient says may not accurately reflect his or her experience. For example, a few patients who are pain free may claim to feel pain so as to receive medication for its euphoriant effects. Conversely, some patients may claim to feel fine even though they are experiencing considerable discomfort. Reasons for under-reporting pain include fear of addiction, fear of needles, and a need to be stoic and bear the pain. Patients suspected of under-reporting pain must be listened to with care if their true pain status is to be evaluated.

Pain assessment is discussed at length in [Chapter 29](#) (Pain Management in Patients with Cancer).

29.3.1.2 Dosage Determination

Dosage of opioid analgesics must be adjusted to accommodate individual variation. “Standard” doses cannot be relied upon as appropriate for all patients. For example, if a “standard” 10-mg dose of morphine were employed for all adults, only 70% would receive adequate relief; the other 30% would be undertreated. Not all patients have the same tolerance for pain, and hence some need larger doses than others for the same disorder. Some conditions hurt more than others. For example, patients recovering from open chest surgery are likely to experience

greater pain and need larger doses than patients recovering from an appendectomy. Elderly patients metabolize opioids slowly, and therefore require lower doses than younger adults. Because the blood-brain barrier of newborns is poorly developed, these patients are especially sensitive to opioids; therefore, they generally require smaller doses (on a milligram-per-kilogram basis) than older infants and young children.

29.3.1.3 Dosing Schedule

As a rule, *opioids should be administered on a fixed schedule* (eg, every 4 hours) rather than PRN. With a fixed schedule, each dose is given before pain returns, thereby sparing the patient needless discomfort. In contrast, when PRN dosing is employed, there can be a long delay between onset of pain and production of relief: Each time pain returns, the patient must call the nurse, wait for the nurse to respond, wait for the nurse to evaluate the pain, wait for the nurse to sign out medication, wait for the nurse to prepare and administer the injection, and then wait for the drug to undergo absorption and finally produce analgesia. This delay causes unnecessary discomfort and creates anxiety about pain recurrence. Use of a fixed dosing schedule reduces these problems. As discussed below, allowing the patient to self-administer opioids with a patient-controlled analgesia (PCA) device can provide even greater protection against pain recurrence than can be achieved by having you administer opioids on a fixed schedule. The differ

274

275

Figure 28-3 Fluctuation in opioid blood levels seen with three dosing procedures. Note that with PRN dosing, opioid levels can fluctuate widely, going from subtherapeutic to excessive and back again. In contrast, when opioids are administered with a PCA device or on a fixed schedule, levels stay within the therapeutic range, allowing continuous pain relief with minimal adverse effects.

ences between PRN dosing, fixed-schedule dosing, and use of a PCA device are shown graphically in [Figure 28-3](#).

29.3.1.4 Avoiding a Withdrawal Reaction

When opioids are administered in high doses for 20 days or more, clinically significant physical dependence may develop. Under these conditions, abrupt withdrawal will precipitate an abstinence syndrome. To minimize symptoms of abstinence, opioids should be withdrawn slowly, tapering the dosage over 3 days. If the degree of dependence is especially high, as can occur in opioid addicts, dosage should be tapered over 7 to 10 days.

29.3.2 Physical Dependence, Abuse, and Addiction as Clinical Concerns

Most people in our society, including many health professionals, harbor strong fears about the ability of “narcotics” to cause “addiction.” In a clinical setting, such excessive concern is both unwarranted and counterproductive. Because of inappropriate fears, physicians frequently prescribe less pain medication than patients need, and nurses frequently administer less than was prescribed. The result, according to one estimate, is that only 25% of patients receive doses of opioids that are sufficient to relieve suffering. One pain specialist described this unacceptable situation as follows: “The excessive and unrealistic concern about the dangers of addiction in the hospitalized medical patient is a significant and potent force for the undertreatment with narcotics [opioids].”

When treating a patient for pain, you may have to decide how much opioid to give and when to give it. If you are excessively concerned about the ability of opioids to cause physical dependence and addiction, you will be unable to make a rational decision. Furthermore, in your role as patient advocate, it is your responsibility to intervene and request an increase in dosage if the prescribed dosage has proved inadequate. If you fear that dosage escalation may cause “addiction,” you are less likely to make the request.

The object of the following discussion is to dispel excessive concerns about dependence, abuse, and addiction in the medical patient so these concerns do not result in undermedication and needless suffering.

29.3.2.1 Definitions

Before we can discuss the clinical implications of physical dependence, abuse, and addiction, we need to define these terms.

29.3.2.1.1 Physical Dependence.

As noted, physical dependence is a state in which an abstinence syndrome will occur if the dependence-producing drug is abruptly withdrawn. *Physical dependence should NOT be equated with addiction.*

29.3.2.1.2 Abuse.

Abuse can be broadly defined as *drug use that is inconsistent with medical or social norms*. By this definition, abuse is determined primarily by the reason for drug use and by the setting in which that use occurs—and not by the pharmacologic properties of the drug itself. For example, whereas it is *not* considered abuse to administer 20 mg of morphine in a hospital to relieve pain, it *is* considered abuse to administer the same dose of the same drug on the street to produce euphoria. The concept of abuse is discussed at length in [Chapter 37](#).

29.3.2.1.3 Addiction.

Addiction can be defined as *a behavior pattern characterized by continued use of a psychoactive substance despite physical, psychologic, or social harm*. Note that nowhere in this definition is addiction equated with physical dependence. In fact, physical dependence is not even part of the definition. The concept of addiction is discussed further in [Chapter 37](#).

Although physical dependence is not required for addiction to occur, physical dependence *can* contribute to addictive behavior. If an individual has already established a pattern of compulsive drug use, physical dependence can reinforce that pattern. For the individual with a marginal resolve to discontinue opioid use, the desire to avoid symptoms of withdrawal may be sufficient to promote continued drug use. However, in the presence of a strong desire to become drug free, physical dependence, by itself, is insufficient to motivate continued addictive behavior.

275

29.3.2.2 Minimizing Fears About Physical Dependence

276

For two important reasons, there is little to fear regarding physical dependence on opioids in the hospitalized patient:

- Development of significant physical dependence is extremely rare when opioids are given acutely to relieve pain. For most patients, the doses employed and the duration of treatment are insufficient to cause significant dependence.

- Even when physical dependence *does* occur, patients rarely develop addictive behavior and continue opioid administration after their pain has subsided. The vast majority of patients who become physically dependent in a clinical setting simply go through gradual withdrawal and never take opioids again. This observation emphasizes the point that physical dependence per se is insufficient to cause addiction.

From the preceding, we can see there is little to fear regarding physical dependence during the therapeutic use of opioids. We can conclude, therefore, that there is no justification for withholding opioids from patients in pain on the basis of concerns about physical dependence.

29.3.2.3 Minimizing Fears About Addiction

The principal reason for abandoning fears about opioid addiction in patients is simple: *Development of addiction to opioids as a result of clinical exposure to these drugs is extremely rare.* Results of the Boston Collaborative Drug Study showed that, of 12,000 hospitalized patients taking opioids, only 4 became drug abusers. Furthermore, as discussed below, if abuse or addiction *does* occur, it is probable that these behaviors reflect tendencies that existed before the patient entered the hospital, and hence are not the result of inappropriate medical use of opioids during the hospital stay.

For the purpose of this discussion, the population can be divided into two groups: individuals who are prone to drug abuse and individuals who are not. One source estimates that about 8% of the population is prone to drug abuse, whereas the other 92% is not. Individuals who are prone to drug abuse have a tendency to abuse drugs inside the hospital and out. Nonabusers, on the other hand, will not abuse drugs in a clinical setting or anywhere else. Withholding analgesics from abuse-prone individuals is not going to reverse their tendency to abuse drugs. Conversely, administering opioids to non-abuse-prone persons will not convert them into “drug fiends.”

If a patient who did not formerly abuse opioids does abuse these drugs following therapeutic exposure, you should not feel responsible for having created an addict. That is, if a patient tries to continue opioid use after leaving the hospital, it is probable that the patient was abuse prone before you met him or her. Therefore, the pattern of abuse that emerged during clinical exposure to opioids was the result of factors that existed before the patient ever entered the hospital—and not the consequence of therapy. The only action that might have prevented opioid abuse by such a patient would have been to withhold opioids entirely—an action that would not have been feasible.

29.3.2.4 Balancing the Need to Provide Pain Relief with the Desire to Minimize Abuse

Although concerns about opioid abuse in the clinical setting are small, they cannot be dismissed entirely. You are still obliged to administer opioids with discretion in an effort to minimize abuse. Some reasonable attempt must be made to determine who is likely to abuse drugs and who is not. As a rule, distinguishing abusers from nonabusers can be done with some confidence. When nonabusers say they need more pain relief, believe them and provide it. In contrast, when an obvious abuser requests more analgesic, some healthy skepticism is in order. When there is doubt as to whether a patient is abuse prone or not, logic dictates giving the patient the benefit of the doubt and providing the medication. If the patient is an abuser, little harm will result from giving unneeded medication. However, if the patient is a nonabuser, failure to provide medication would intensify suffering for no justifiable reason.

In order to minimize physical dependence and abuse, opioid analgesics should be administered in the lowest effective dosages for the shortest time needed. Be aware, however, that larger doses are needed for patients who have more intense pain and for those who have developed tolerance. As pain diminishes, opioid dosage should be reduced. As soon as possible, the patient should be switched to a nonopioid analgesic, such as aspirin or acetaminophen.

In summary, when working with opioids, as with any other drugs, you must balance the risks of therapy against the benefits. The risk of addiction from therapeutic use of opioids is real but very small. Consequently, concerns about addiction should play a real but secondary role in making decisions about giving these drugs. Dosages should be sufficient to relieve pain. Suffering because of insufficient dosage is unacceptable. However, it is also unacceptable to promote possible abuse through failure to exercise good judgment.

29.3.3 Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) is a method of drug delivery that permits the patient to self-administer parenteral (transdermal, IV, subQ, epidural) opioids on an “as-needed” basis. PCA has been employed primarily for relief of pain in postoperative patients. Other candidates include patients experiencing pain caused by cancer, trauma, myocardial infarction, vaso-occlusive sickle cell crisis, and labor. As discussed below, PCA offers several advantages over opioids administered by the nurse.

29.3.3.1 PCA Devices.

PCA was made possible by the development of reliable PCA devices. Two kinds are available: traditional PCA pumps and the fentanyl iontophoretic system [Ionsys]. The PCA pumps consist of an electronically controlled infusion pump that can be activated by the patient to deliver a preset bolus dose of an opioid, which is delivered through an indwelling catheter. In addition to providing bolus doses on demand, some PCA pumps can deliver a basal infusion of opioid. As discussed above, the Ionsys device uses iontophoresis, not a pump, to deliver a transdermal dose of opioid (fentanyl).

An essential feature of all PCA pumps is a timing control. This control limits the total dose that can be administered each hour, thereby minimizing the risk of overdose. In addition, the timing control regulates the minimum interval (eg, 10 minutes) between doses. This interval, referred to as the “lock-out” or “delay” interval, prevents the patient from administering a second dose before the first has had time to produce its full effect.

29.3.3.2 Drug Selection and Dosage Regulation.

The opioid used most extensively for PCA is morphine. Other pure opioid agonists (eg, methadone, hydromorphone, fentanyl) have also been employed, as have agonist-antagonist opioids (eg, nalbuphine, buprenorphine).

276

277

Prior to starting PCA, the postoperative patient should be given an opioid loading dose (eg, 2 to 10 mg of morphine). Once effective opioid levels have been established with the loading dose, PCA can be initiated, provided the patient has recovered sufficiently from anesthesia. For PCA with morphine, initial bolus doses of 1 mg are typical. The size of the bolus should be increased if analgesia is inadequate, and decreased if excessive sedation occurs. The size of the bolus dose is usually increased during sleeping hours, thereby promoting rest by prolonging the interval between doses.

29.3.3.3 Comparison of PCA with Traditional IM Therapy.

The objective of therapy with analgesics is to provide comfort while minimizing sedation and other side effects, especially respiratory depression. This objective is best achieved by maintaining plasma levels of opioids that have minimal fluctuations. In this manner, side effects from excessively high levels can be avoided, as can the return of severe pain when levels dip too low.

In the traditional management of postoperative pain, patients are given an IM injection of an opioid every 3 to 4 hours. With this dosing schedule, plasma drug levels can vary widely. Shortly after the injection, plasma levels may rise very high, causing excessive sedation and possibly respiratory depression. Late in the dosing interval, pain may return as plasma levels drop to their lowest point.

In contrast to traditional therapy, PCA is ideally suited to maintain steady levels of opioids. Why? Because PCA relies on small doses given frequently (eg, 1 mg of morphine every 10 minutes) rather than on large doses given infrequently (eg, 20 mg of morphine every 3 hours). Maintenance of steady drug levels can be facilitated further if the PCA device is capable of delivering a basal infusion. Because plasma drug levels remain relatively steady, PCA can provide continuous control of pain while avoiding the adverse effects associated with excessive drug levels.

An additional advantage of PCA is rapid relief of pain. Because the patient can self-administer a parenteral dose of opioid as soon as pain begins to return, there is minimal delay between detection of pain and restoration of an adequate drug level. With traditional therapy, the patient must wait for the nurse to respond to a request for more drug; this delay allows pain to grow more intense.

Studies indicate that PCA is associated with accelerated recovery. When compared with patients receiving traditional IM analgesia, postoperative patients receiving PCA show improved early mobilization, greater cooperation during physical therapy, and a shorter hospital stay.

29.3.3.4 Patient Education.

Patient education is essential for successful PCA. Surgical patients should be educated preoperatively. Education should include an explanation of what PCA is, along with instruction on how to activate the PCA device.

Patients should be told not to fear overdose; the PCA device will not permit self-administration of excessive doses. Patients should be informed that there is a time lag (about 10 minutes) between activation of the device and production of maximal analgesia. To reduce discomfort associated with physical therapy, changing of dressings, ambulation, and other potentially painful activities, patients should be taught to activate the pump prophylactically (eg, 10 minutes prior to the anticipated activity). Patients should be informed that, at night, the PCA

device will be adjusted to deliver larger doses than during waking hours. This will prolong the interval between doses and thereby facilitate sleep.

29.3.4 Using Opioids for Specific Kinds of Pain

29.3.4.1 Postoperative Pain.

Opioid analgesics offer several benefits to the postoperative patient. The most obvious is increased comfort through reduction of pain. In addition, by reducing painful sensation, opioids can facilitate early movement and intentional cough. In patients who have undergone thoracic surgery, opioids permit chest movement that would otherwise be too uncomfortable to allow adequate ventilation. By promoting ventilation, opioids can reduce the risk of hypoxia and pneumonitis.

Opioids are not without drawbacks for the postoperative patient. These agents can cause constipation and urinary retention. Suppression of reflex cough can result in respiratory tract complications. In addition, analgesia may delay diagnosis of postoperative complications—because pain will not be present to signal their development.

29.3.4.2 Obstetric Analgesia.

When administered to relieve pain during delivery, opioids may depress fetal respiration and uterine contractions. Since these effects are less likely with meperidine than with other strong opioids, *meperidine* is often the preferred opioid for obstetric use. Dosage should be high enough to reduce maternal discomfort to a tolerable level, but not so high as to cause pronounced respiratory depression in the neonate. Because opioids cross the blood-brain barrier of the infant more readily than that of the mother, doses that have little effect on maternal respiration may nonetheless cause profound respiratory depression in the infant. For meperidine, the usual dosage is 50 to 100 mg every 2 to 3 hours. Administration should be parenteral (IV or IM). Timing of administration is important: if the drug is given too early, it can inhibit or delay the progress of uterine contractions; if given too late, it can cause excessive neonatal sedation and respiratory depression. Following delivery, respiration in the neonate should be monitored closely. Naloxone can reverse respiratory depression and should be on hand.

29.3.4.3 Myocardial Infarction.

Morphine is the opioid of choice for decreasing pain of myocardial infarction. With careful control of dosage, morphine can reduce discomfort without causing excessive respiratory

depression and adverse cardiovascular effects. In addition, by lowering blood pressure, morphine can decrease cardiac work. If excessive hypotension or respiratory depression occurs, it can be reversed with naloxone. Because *pentazocine* and *butorphanol* increase cardiac work and oxygen demand, these agonist-antagonist opioids should generally be avoided.

29.3.4.4 Head Injury.

Opioids must be employed with caution in patients with head injury. Head injury can cause respiratory depression accompanied by elevation of ICP; opioids can exacerbate these symptoms. In addition, since miosis, mental clouding, and vomiting can be valuable diagnostic signs following head injury, and since opioids can cause these same effects, use of opioids can complicate diagnosis.

29.3.4.5 Cancer-Related Pain.

Treating chronic pain of cancer differs substantially from treating acute pain of other disorders. When treating cancer pain, the objective is to maximize comfort. Psychologic and physical dependence are minimal concerns. Patients should be given as much medication as needed to relieve pain. In the words of one pain specialist, “No patient should wish for death because of the physician's reluctance to use adequate amounts of opioids.” With proper therapy, cancer pain can be effectively managed in about 90% of patients. Cancer pain is discussed fully in [Chapter 29](#).

277

278

29.3.4.6 Chronic Noncancer Pain.

In many patients with chronic pain of nonmalignant origin, opioids can reduce discomfort, improve mood, and enhance function. Accordingly, pain experts generally recommend that opioids not be withheld from these people. Nonetheless, because of concerns about addiction, tolerance, adverse effects, diversion to street use, and regulatory action, physicians and nurse practitioners are often reluctant to prescribe these drugs. To some degree, all of these concerns are legitimate. However, patients still have a right to effective treatment. Hence there is a need to balance patient's rights with prescribers' concerns. To help achieve that balance, the American Academy of Pain Medicine and the American Pain Society issued guidelines for using opioids in patients with chronic noncancer pain. Provisions include

- Using opioids only after nonopioid analgesics have failed
- Discussing the benefits and risks of long-term opioids with the patient

- When possible, using only one prescriber and one pharmacy
- Ensuring comprehensive follow-up to assess efficacy and side effects of treatment, and to monitor for signs of opioid abuse
- Stopping opioids if they don't work
- Fully documenting the entire process

29.4 OPIOID ANTAGONISTS

Opioid antagonists are drugs that block the effects of opioid agonists. Principal uses are treatment of opioid overdose, relief of opioid-induced constipation, reversal of postoperative opioid effects (eg, respiratory depression, ileus), and management of opioid addiction. Five pure antagonists are available: naloxone [Narcan], methylnaltrexone [Relistor], alvimopan [Entereg], nalmefene [Revex], and naltrexone [ReVia, Depade].

29.4.1 Naloxone

29.4.1.1 Mechanism of Action

Naloxone [Narcan] is a structural analog of morphine that acts as a competitive antagonist at opioid receptors, thereby blocking opioid actions. Naloxone can reverse most effects of the opioid agonists, including respiratory depression, coma, and analgesia.

29.4.1.2 Pharmacologic Effects

When administered in the absence of opioids, naloxone has no significant effects. If administered prior to giving an opioid, naloxone will block opioid actions. If administered to a patient who is already receiving opioids, naloxone will reverse analgesia, sedation, euphoria, and respiratory depression. If administered to an individual who is physically dependent on opioids, naloxone will precipitate an immediate withdrawal reaction.

29.4.1.3 Pharmacokinetics

Naloxone may be administered IV, IM, or subQ. Following IV injection, effects begin almost immediately and persist about 1 hour. Following IM or subQ injection, effects begin within 2 to 5 minutes and persist several hours. Elimination is by hepatic metabolism. The half-life is approximately 2 hours. Naloxone cannot be used orally because of rapid first-pass inactivation.

29.4.1.4 Therapeutic Uses

29.4.1.4.1 Reversal of Opioid Overdose.

Naloxone is the drug of choice for treating overdose with pure opioid agonists. The drug reverses respiratory depression, coma, and other signs of opioid toxicity. Naloxone can also reverse toxicity from agonist-antagonist opioids (eg, pentazocine, nalbuphine). However, the doses required may be higher than those needed to reverse poisoning by pure agonists.

Dosage must be carefully titrated when treating toxicity in opioid addicts. Because the degree of physical dependence in these individuals is usually high, if dosage is excessive, naloxone can transport the patient from a state of poisoning to one of acute withdrawal. Accordingly, treatment should be initiated with a series of small doses rather than one large dose. Because the half-life of naloxone is shorter than that of most opioids, repeated dosing is required until the crisis has passed.

In some cases of accidental poisoning, there may be uncertainty as to whether unconsciousness is due to opioid overdose or to overdose with a general CNS depressant (eg, barbiturate, alcohol, benzodiazepine). When uncertainty exists, naloxone is nonetheless indicated. If the cause of poisoning is a barbiturate or another general CNS depressant, naloxone will be of no benefit—but neither will it cause any harm. If a cumulative dose of 10 mg fails to elicit a response, it is unlikely that opioids are involved, and hence other intoxicants should be suspected.

29.4.1.4.2 Reversal of Postoperative Opioid Effects.

Following surgery, naloxone may be employed to reverse excessive respiratory and CNS depression caused by opioids given preoperatively or intraoperatively. Dosage should be titrated with care; the objective is to achieve adequate ventilation and alertness without reversing opioid actions to the point of unmasking pain.

29.4.1.4.3 Reversal of Neonatal Respiratory Depression.

When opioids are given for analgesia during labor and delivery, respiratory depression may occur in the neonate. If respiratory depression is substantial, naloxone should be administered to restore ventilation.

29.4.1.5 Preparations, Dosage, and Administration

29.4.1.5.1 Preparations and Routes.

Naloxone [Narcan] is available in solution (0.4 mg/mL) for IV, IM, and subQ injection.

29.4.1.5.2 Opioid Overdose.

The initial dose is 0.4 mg for adults and 10 mcg/kg for children. The preferred route is IV. However, if IV administration is not possible, then IM or subQ injection may be employed. Dosing is repeated at 2- to 3-minute intervals until a satisfactory response has been achieved. Additional doses may be needed at 1- to 2-hour intervals for up to 72 hours, depending on the duration of action of the offending opioid.

29.4.1.5.3 Postoperative Opioid Effects.

Initial therapy for adults consists of 0.1 to 0.2 mg IV repeated every 2 to 3 minutes until an adequate response has been achieved. Additional doses may be required at 1- to 2-hour intervals.

29.4.1.5.4 Neonatal Respiratory Depression.

The initial dose is 10 mcg/kg (IV, IM, or subQ). This dose is repeated every 2 to 3 minutes until respiration is satisfactory.

29.4.2 Other Opioid Antagonists

29.4.2.1 Methylnaltrexone

29.4.2.1.1 Actions and Therapeutic Use.

Methylnaltrexone [Relistor], approved in 2008, is a selective mu opioid antagonist indicated for opioid-induced constipation in patients with late-stage disease who are taking opioids continuously to relieve pain, and who have not responded to standard laxative therapy. Benefits derive from blocking mu opioid receptors in the GI tract. In clinical trials, the drug worked in about half of those treated: within 4 hours of receiving subQ methylnaltrexone, defecation occurred in 48% of patients, compared with only 15% of those receiving placebo. In about 30% of methylnaltrexone recipients, defecation occurred rapidly—within 30 minutes.

278

279

Because it contains a methyl group, methylnaltrexone cannot readily cross membranes, including those of the blood-brain barrier, and hence does not block opioid receptors in the CNS. Accordingly, the drug does not decrease analgesia and cannot precipitate opioid withdrawal.

29.4.2.1.2 Pharmacokinetics.

Methylnaltrexone is rapidly absorbed following subQ injection, reaching peak plasma levels within 30 minutes. Because membrane passage is restricted, distribution of the drug is limited. Methylnaltrexone undergoes minimal metabolism and is excreted in the urine (50%) and feces (50%), primarily as unchanged drug. The terminal half-life is 8 hours.

29.4.2.1.3 Adverse Effects, Precautions, and Drug Interactions.

Methylnaltrexone is generally well tolerated. The most common adverse effects are *abdominal pain* (28.5%), *flatulence* (13.3%), *nausea* (11.5%), *dizziness* (4.3%), and *diarrhea* (5.5%). In the event of severe or persistent diarrhea, the drug should be discontinued. In patients with known or suspected mechanical GI obstruction, methylnaltrexone should be avoided. No significant drug interactions have been reported.

29.4.2.1.4 Preparations, Dosage, and Administration.

Methylnaltrexone [Relistor] is available in solution (12 mg/0.6 mL) for subQ injection into the upper arm, abdomen, or thigh. Because defecation can occur rapidly, a bathroom should be immediately available. Dosing is usually done once every 48 hours, and should not exceed once every 24 hours. Dosage is based on weight as follows: 8 mg for patients from 38 kg to under 62 kg (84 lb to under 136 lb); 12 mg for patients 62 to 114 kg (136 to 251 lb); and 0.15 mg/kg for patients under 38 kg or over 114 kg. In patients with severe renal impairment, defined as creatinine clearance below 30 mL/min, dosage should be reduced by 50%. Methylnaltrexone should be stored at room temperature and protected from light.

29.4.2.2 Alvimopan

Like methylnaltrexone, alvimopan [Entereg] is a selective, peripherally acting mu opioid antagonist developed to counteract the adverse effects of opioids on bowel function. At therapeutic doses, alvimopan does not reduce opioid-mediated analgesia, in part because of limited ability to cross the blood-brain barrier. In contrast to methylnaltrexone, which is approved for long-term therapy of constipation in patients taking opioids for chronic pain,

alvimopan is approved only for short-term therapy of opioid-induced ileus following partial small or large bowel resection with primary anastomosis. The goal of treatment is to accelerate time to recovery of upper and lower bowel function, which can be impaired by opioids used for analgesia during and after surgery. Alvimopan was approved in 2008.

When used short term in postoperative patients, alvimopan is very well tolerated. However, when used long term in patients taking opioids for chronic pain, the drug has been associated with an increased incidence of myocardial infarction, although a causal relationship has not been established. Because myocardial infarction may be a risk with prolonged dosing, the drug is approved only for short-term (7-day) use, and only for hospitalized patients. Furthermore, hospitals that dispense the drug must enroll in the Entereg Access Support and Education program, designed to minimize risk of myocardial infarction.

Alvimopan is available in 12-mg capsules for oral dosing. The regimen consists of 12 mg given 0.5 to 5 hours before surgery, followed by 12 mg twice daily (beginning the day after surgery) for a total of 15 or fewer doses.

29.4.2.3 Naltrexone

Naltrexone [ReVia, Vivitrol] is a pure opioid antagonist approved for opioid and alcohol abuse. In opioid abuse, the objective is to prevent euphoria if the abuser should take an opioid. Since naltrexone can precipitate a withdrawal reaction in persons who are physically dependent on opioids, candidates for treatment must be rendered opioid-free before naltrexone is given. Although naltrexone can block opioid-induced euphoria, the drug does not prevent craving for opioids. As a result, many addicts fail to comply with treatment. Therapy with naltrexone has been considerably less successful than with methadone, a drug that eliminates craving for opioids while blocking euphoria. Use of naltrexone in alcoholism and opioid addiction is discussed further in [Chapters 38](#) and [39](#), respectively.

When dosage is excessive, naltrexone can cause hepatocellular injury. Accordingly, the drug is contraindicated for patients with acute hepatitis or liver failure. Warn patients about the possibility of liver injury, and advise them to discontinue the drug if signs of hepatitis develop.

Naltrexone is available in two formulations: (1) 50-mg tablets, marketed as *ReVia*, for oral dosing; and (2) an extended-release suspension (380 mg/vial), marketed as *Vivitrol*, for IM dosing. For oral therapy, a typical dosing schedule consists of 100 mg on Monday and

Wednesday and 150 mg on Friday. Alternatively, the drug can be administered daily in 50-mg doses. For IM dosing, the usual regimen is 380 mg once a month.

29.4.2.4 Nalmefene

29.4.2.4.1 Uses.

Nalmefene [Revex] is a *long-acting* analog of naltrexone. The drug is approved for reversing postoperative opioid effects and treating opioid overdose. Nalmefene must be used with caution when treating overdose in patients suspected of being opioid dependent, because too much nalmefene could precipitate prolonged withdrawal.

29.4.2.4.2 Pharmacokinetics.

Effects begin 2 minutes after IV injection (the usual route) and peak within 5 minutes. Duration of action depends on dosage: Effects may fade within 30 to 60 minutes after a small dose, and may last many hours after a large dose. Most importantly, when nalmefene dosage is adequate, effects persist longer than those of most opioids. Nalmefene undergoes complete but slow hepatic metabolism, followed by renal excretion. The half-life is 11 hours—considerably longer than that of naloxone.

29.4.2.4.3 Preparations, Dosage, and Administration.

Nalmefene [Revex] is available in two concentrations. The low concentration (100 mcg/mL), supplied in blue-labeled ampules, is used to reverse postoperative opioid effects. The high concentration (1 mg/mL), supplied in green-labeled ampules, is used for opioid overdose.

The usual route is IV. However, if IV access is impossible, nalmefene may be given IM or subQ. Dosages are the same for all routes. However, with IM or subQ administration, onset is delayed.

For *postoperative* use, the initial dose is 0.25 mcg/kg. This dose is repeated at 2- to 5-minute intervals (for a maximum of four total doses) until the desired degree of opioid reversal has been achieved.

Treatment of *opioid overdose* depends on whether the patient is opioid dependent. If the patient is not dependent, treatment consists of two doses: 0.5 mg/70 kg initially, followed by 1 mg/70 kg 2 to 5 minutes later. If opioid dependency is suspected, a small challenge dose (0.1

mg/70 kg) is given. If the challenge dose does not precipitate withdrawal, then treatment continues as for patients who are not dependent.

29.5 NONOPIOID CENTRALLY ACTING ANALGESICS

Four centrally acting analgesics—tramadol [Ultram], clonidine [Duraclon], ziconotide [Prialt], and dexmedetomidine [Precedex]—relieve pain by mechanisms largely or completely unrelated to opioid receptors. These drugs do not cause respiratory depression, physical dependence, or abuse, and are not regulated under the Controlled Substances Act.

29.5.1 Tramadol

Tramadol [Ultram, Ultram ER] is a moderately strong analgesic with minimal potential for dependence, abuse, or respiratory depression. The drug relieves pain through a combination of opioid and nonopioid mechanisms.

29.5.1.1 Mechanism of Action.

Tramadol is an analog of codeine that relieves pain in part through weak agonist activity at mu opioid receptors. However, it seems to work primarily by blocking uptake of norepinephrine and serotonin, thereby activating monoaminergic spinal inhibition of pain. Naloxone, an opioid antagonist, only partially blocks tramadol's effects.

29.5.1.2 Therapeutic Use.

Tramadol is approved for moderate to moderately severe pain. The drug is less effective than morphine and no more effective than codeine combined with aspirin or acetaminophen. Analgesia begins 1 hour after oral dosing, is maximal at 2 hours, and continues for 6 hours.

29.5.1.3 Pharmacokinetics.

Tramadol is administered by mouth and reaches peak plasma levels in 2 hours. Elimination is by hepatic metabolism and renal excretion. The half-life is 5 to 6 hours.

279

29.5.1.4 Adverse Effects.

Tramadol has been used by millions of patients, and serious adverse effects have been rare. The most common side effects are *sedation, dizziness, headache, dry mouth, and constipation*.

Respiratory depression is minimal. *Seizures* have been reported in over 280 patients, and hence

280

the drug should be avoided in patients with epilepsy and other neurologic disorders. Severe allergic reactions occur rarely.

29.5.1.5 Drug Interactions.

Tramadol can intensify responses to *CNS depressants* (eg, alcohol, benzodiazepines), and therefore should not be combined with these drugs.

By inhibiting uptake of norepinephrine, tramadol can precipitate a hypertensive crisis if combined with an *MAO inhibitor*. Accordingly, the combination is absolutely contraindicated.

By inhibiting uptake of serotonin, tramadol can cause *serotonin syndrome* in patients taking *drugs that enhance serotonergic transmission*. Among these are selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, MAO inhibitors, and triptans. If these drugs must be combined with tramadol, the patient should be monitored carefully, especially during initial therapy and times of dosage escalation.

29.5.1.6 Abuse Liability.

Abuse liability is very low, and hence tramadol is not regulated under the Controlled Substances Act. Nonetheless, there have been a few reports of abuse, dependence, withdrawal, and intentional overdose, presumably for subjective effects. Consequently, tramadol should not be given to patients with a history of drug abuse, and the recommended dosage should not be exceeded.

29.5.1.7 Preparations, Dosage, and Administration.

Tramadol is available alone (as Ultram and Ultram ER) and in combination with acetaminophen (as Ultracet).

Tramadol *alone* is available in two formulations: (1) 50-mg immediate-release (IR) tablets, sold as Ultram; and (2) extended-release tablets (100, 200, and 300 mg), sold as Ultram ER. Dosages are as follows:

- *Immediate-release tablets [Ultram]*—The recommended adult dosage is 50 to 100 mg every 4 to 6 hours as needed, up to a maximum of 400 mg/day. In patients with significant renal or hepatic impairment, the dosing interval should be increased to 12 hours, and the total daily dose should not exceed 200 mg (with renal impairment) or 100 mg (with hepatic impairment).

- *Extended-release tablets [Ultram ER]*—For patients who are not currently taking IR tramadol, the dosage is 100 mg once a day initially, and then titrated every 5 days in 100-mg increments to a maximum of 300 mg once a day. For patients currently taking IR tramadol, the initial once-daily dosage should equal the total daily dosage of IR tramadol (rounded *down* to the nearest 100 mg). Dosage can then be titrated up or down as needed. Extended-release tramadol should not be used by patients with severe hepatic or renal impairment.

Tramadol *combined with acetaminophen* [Ultracet] is indicated for short-term therapy of acute pain. Each tablet contains 37.5 mg tramadol and 325 mg acetaminophen. The recommended dosage is 2 tablets every 4 to 6 hours (but should not exceed 8 tablets/day). Treatment duration should not exceed 5 days.

29.5.2 Clonidine

Clonidine [Duraclon] has two approved applications: treatment of hypertension and relief of severe pain. To relieve pain, clonidine is administered by continuous epidural infusion. To treat hypertension, the drug is given by mouth or as a transdermal patch. Because the antihypertensive pharmacology of clonidine differs dramatically from its analgesic pharmacology, antihypertensive pharmacology is discussed separately (in [Chapters 19](#) and [46](#)). To avoid errors, you should know that the trade name employed for clonidine depends on the application: When used for pain relief, clonidine is marketed as *Duraclon*; when used for hypertension, the drug is marketed as *Catapres*. Clonidine has no abuse potential and is not regulated under the Controlled Substances Act.

29.5.2.1 Mechanism of Pain Relief.

As discussed in [Chapter 19](#), clonidine is an α_2 -adrenergic agonist. The drug appears to relieve pain by binding to presynaptic and postsynaptic α_2 receptors in the spinal cord. The result is blockade of nerve traffic in pathways that transmit pain signals from the periphery to the brain. Pain relief is not blocked by opioid antagonists.

29.5.2.2 Analgesic Use.

Clonidine, in combination with an opioid analgesic, is approved for treating severe cancer pain that cannot be relieved by an opioid alone. Administration is by continuous infusion through an implanted epidural catheter. The drug is more effective against neuropathic pain (electrical, burning, or shooting in nature) than diffuse (unlocalized) visceral pain. Pain relief occurs only in

regions innervated by sensory nerves that come from the part of the spinal cord where clonidine is present in high concentration.

29.5.2.3 Pharmacokinetics.

Clonidine is highly lipid soluble, and hence readily moves from the spinal cord to the blood. About half of each dose undergoes hepatic metabolism. The rest is excreted unchanged in the urine. Because urinary excretion is substantial, dosage should be reduced in patients with significant renal impairment.

29.5.2.4 Adverse Effects. Hypotension.

The greatest concern is severe hypotension secondary to massive vasodilation. The cause of vasodilation is activation of α_2 receptors in the CNS. Hypotension is most likely during the first 4 days of treatment—and is most intense following infusion into the upper thoracic region of the spinal cord. Because of the risk of hypotension, vital signs should be monitored closely, especially during the first few days of treatment. Hypotension can be managed by infusing IV fluids. If necessary, IV ephedrine can be used to promote vasoconstriction.

29.5.2.4.1 Bradycardia.

Clonidine can slow heart rate. The underlying mechanism is activation of α_2 receptors in the CNS. Severe bradycardia can be managed with atropine.

29.5.2.4.2 Rebound Hypertension.

As discussed in [Chapter 19](#), abrupt discontinuation of clonidine can cause rebound hypertension. Accordingly, when the drug is withdrawn, dosage should be tapered over 2 to 4 days. Rebound hypertension can be managed with IV clonidine or phentolamine.

29.5.2.4.3 Catheter-Related Infection.

Infection is common with implanted epidural catheters. If the patient develops a fever of unknown origin, infection should be suspected.

29.5.2.4.4 Other Adverse Effects.

As with oral clonidine, epidural clonidine can cause *dry mouth*, *dizziness*, *sedation*, *anxiety*, and *depression*.

29.5.2.5 Contraindications.

Because of the risk of severe hypotension and bradycardia, epidural clonidine is contraindicated for patients who are hemodynamically unstable, and for obstetric, postpartum, or surgical patients. Additional contraindications are infection at the site of infusion, administration above the C4 dermatome, and use by patients receiving anticoagulants.

29.5.2.6 Preparations, Dosage, and Administration.

Clonidine [Duraclon] is available in 10-mL vials containing 100 or 500 mcg/mL. The drug is administered through an implanted epidural catheter using a continuous infusion device. The initial infusion rate is 30 mcg/hr.

29.5.3 Ziconotide

Ziconotide [Prialt], approved in 2004, is a centrally acting analgesic with a novel structure and mechanism. Administration is intrathecal (IT). The drug is indicated only for severe, chronic pain in patients for whom IT therapy is warranted, and who are intolerant of or refractory to other treatments, including systemic and IT morphine. In clinical trials, analgesic responses were modest (at least in opioid-resistant patients), and adverse effects (eg, hallucinations, confusion, muscle injury) were common. Accordingly, ziconotide cannot be considered a first-choice drug.

29.5.3.1 Mechanism of Action.

Ziconotide is a small synthetic peptide equivalent to a peptide found naturally in *Conus magus*, a marine snail. The drug is a selective antagonist at N-type voltage-sensitive calcium channels on neurons. Benefits derive from blocking calcium channels on primary nociceptive afferent neurons in the dorsal horn of the spinal cord, an action that prevents transmission of pain signals from the periphery to the brain. To maximize analgesia and minimize effects on peripheral nerves, ziconotide must be administered by IT infusion. The drug does not interact with opioid receptors, and does not cause tolerance, physical dependence, or respiratory depression. Abrupt discontinuation does not cause a withdrawal syndrome.

29.5.3.2 Clinical Trials.

Ziconotide was evaluated in three randomized, placebo-controlled trials involving patients with severe, intractable pain. In all three trials, pain relief was modest. In one trial, for example,

patients had severe pain that was unresponsive to IT morphine, IT clonidine, and/or IT bupivacaine. At baseline, mean pain scores were 81, as measured with a Visual Analog Scale of Pain Intensity (where 100 mm equals the worst pain possible and 0 mm equals no pain). Patients were randomized to receive IT ziconotide or IT placebo. The result? At the end of 3 weeks, the mean improvement in pain scores was only 12% in the ziconotide group, compared with 5% in the placebo group. Only 16% of ziconotide recipients improved by 30% or more, and nearly 50% did not respond at all. Keep in mind, however, that none of these patients responded to IT morphine either. Hence, before concluding that ziconotide is not very effective, it would be nice to see if the drug works well in patients who *do* respond to morphine.

29.5.3.3 Pharmacokinetics.

Following IT infusion, ziconotide distributes throughout the cerebrospinal fluid (CSF) and spinal cord, and then undergoes transport to the systemic circulation, followed by uptake into most tissues of the body, where it undergoes cleavage by peptidases at multiple sites on the molecule. The resulting fragments have not been identified, nor has their biologic activity been assessed. Little or no proteolytic cleavage takes place in the CSF or blood. The drug's half-life in CSF is 4.6 hours.

280

281

29.5.3.4 Adverse Effects.

Adverse CNS effects—mainly cognitive impairment and psychiatric symptoms—are common. In clinical trials, patients reported the following cognitive effects: *confusion* (33%), *memory impairment* (22%), *speech impairment* (14%), *aphasia* (12%), and *abnormal thinking* (8%). As a rule, these resolved within 2 weeks after stopping treatment. The most common psychiatric effect—*hallucinations*—developed in 12% of patients. Ziconotide can also cause *paranoid reactions* and *depression*. Patients with a history of psychiatric disorders should probably avoid this drug.

Ziconotide can cause *muscle injury*. In clinical trials, 40% of patients had abnormally high serum levels of creatine kinase (CK), a marker for muscle breakdown. However, serious muscle pain, soreness, or weakness was uncommon. Because of the risk of muscle injury, serum CK should be monitored. In patients with high CK levels combined with symptoms of muscle injury, the prescriber should consider reducing ziconotide dosage or discontinuing treatment.

29.5.3.5 Drug Interactions.

Formal studies on drug interactions have not been conducted. However, given that ziconotide is a peptide that is not metabolized by CYP450 enzymes, the drug is unlikely to affect the disposition of most other drugs, which *are* metabolized by CYP450 enzymes. Combined use with CNS depressants may increase the risk of adverse CNS events, such as dizziness and confusion. Combined use with *systemic* opioids appears safe, but combined use with *intrathecal* opioids is not recommended.

29.5.3.6 Preparations, Dosage, and Administration.

Ziconotide [Prialt] is available in single-use vials (25 and 100 mcg/mL) for IT infusion using a programmable microinfusion device, either external or implanted. The initial infusion rate is 0.1 mcg/hr (2.4 mcg/day). The rate may be gradually increased in steps of 0.1 mcg/hr every 2 to 3 days, up to a maximum of 0.8 mcg/hr (19.2 mcg/day) at the end of 3 weeks. Dosage adjustments are based on pain relief and tolerability of side effects.

29.5.4 Dexmedetomidine

29.5.4.1 Actions and Therapeutic Use.

Dexmedetomidine [Precedex], like clonidine, is a selective α_2 -adrenergic agonist. The drug acts in the CNS to cause sedation and analgesia. At this time dexmedetomidine is approved only for short-term sedation in critically ill patients who are initially intubated and undergoing mechanical ventilation. However, in addition to this approved use, the drug has a variety of off-label uses, including enhancement of sedation and analgesia in patients undergoing general anesthesia. In contrast to clonidine, which is administered by epidural infusion, dexmedetomidine is administered by IV infusion.

29.5.4.2 Pharmacokinetics.

With IV infusion, dexmedetomidine undergoes wide distribution to tissues. In the blood, the drug is 94% protein bound. Dexmedetomidine undergoes rapid and complete hepatic metabolism, followed by excretion in the urine. The elimination half-life is 2 hours.

29.5.4.3 Adverse Effects.

The most common adverse effects are *hypotension* and *bradycardia*. The mechanism is activation of α_2 -adrenergic receptors in the CNS and periphery, which results in decreased release of norepinephrine from sympathetic neurons innervating the heart and blood vessels. If these cardiovascular effects are too intense, they can be managed in several ways, including (1) decreasing or stopping the infusion, (2) infusing fluid, (3) and elevating the lower extremities. Giving a muscarinic antagonist (eg, atropine) can increase heart rate.

Additional adverse effects include *nausea*, *dry mouth*, and *transient hypertension*. Importantly, dexmedetomidine does *not* cause respiratory depression.

29.5.4.4 Drug Interactions.

Dexmedetomidine can enhance the actions of anesthetics, sedatives, hypnotics, and opioids. Excessive CNS depression can be managed by reducing the dosage of dexmedetomidine or the other agents.

29.5.4.5 Preparations, Dosage, and Administration.

Dexmedetomidine [Precedex] is supplied in solution (100 mcg/mL), which must be diluted to 4 mcg/mL prior to use. Administration is by IV infusion. Treatment consists of a loading dose (1 mcg/kg infused over 10 minutes) followed by a maintenance infusion of 0.2 to 0.7 mcg/kg/hr for no more than 24 hours.

29.5.4.5.1

KEY POINTS

- Analgesics are drugs that relieve pain without causing loss of consciousness.
- Opioids are the most effective analgesics available.
- There are three major classes of opioid receptors, designated mu, kappa, and delta.
- Morphine and other pure opioid agonists relieve pain by mimicking the actions of endogenous opioid peptides—primarily at mu receptors, and partly at kappa receptors.
- Opioid-induced sedation and euphoria can complement pain relief.

- Because opioids produce euphoria and other desirable subjective effects, they have a high liability for abuse.
- Respiratory depression is the most serious adverse effect of the opioids.
- Other important adverse effects are constipation, urinary retention, orthostatic hypotension, emesis, and elevation of ICP.
- Because of first-pass metabolism, oral doses of morphine must be larger than parenteral doses to produce equivalent analgesic effects.
- Because the blood-brain barrier is poorly developed in infants, these patients need smaller doses of opioids (adjusted for body weight) than do older children and adults.
- With prolonged opioid use, tolerance develops to analgesia, euphoria, sedation, and respiratory depression, but not to constipation and miosis.
- Cross-tolerance exists among the various opioid agonists, but not between opioid agonists and general CNS depressants.
- With prolonged opioid use, physical dependence develops. An abstinence syndrome will occur if the opioid is abruptly withdrawn.
- In contrast to the withdrawal syndrome associated with general CNS depressants, the withdrawal syndrome associated with opioids, although unpleasant, is not dangerous.
- To minimize symptoms of abstinence, opioids should be withdrawn gradually.
- Precautions to opioid use include pregnancy, labor and delivery, head injury, and decreased respiratory reserve.
- Patients taking opioids should avoid alcohol and other CNS depressants—because these drugs can intensify opioid-induced sedation and respiratory depression.
- Patients taking opioids should avoid anticholinergic drugs (eg, antihistamines, tricyclic antidepressants, atropine-like drugs)—because these drugs can exacerbate opioid-induced constipation and urinary retention.
- Opioid overdose produces a classic triad of signs: coma, respiratory depression, and pinpoint pupils.

- All strong opioid agonists are essentially equal to morphine with regard to analgesia, abuse liability, and respiratory depression.
- Use of meperidine [Demerol] should not exceed 48 hours—so as to avoid accumulation of normeperidine, a toxic metabolite.
- Like morphine, codeine and other moderate to strong opioid agonists produce analgesia, sedation, euphoria, respiratory depression, constipation, urinary retention, cough suppression, and miosis. These drugs differ from morphine in that they produce less analgesia and respiratory depression and have a lower potential for abuse.

281

- The combination of codeine with a nonopioid analgesic (eg, aspirin, acetaminophen) produces greater pain relief than can be achieved with either agent alone.
- Most agonist-antagonist opioids act as agonists at kappa receptors and antagonists at mu receptors.
- Pentazocine and other agonist-antagonist opioids produce less analgesia than morphine and have a lower potential for abuse.
- With agonist-antagonist opioids, there is a ceiling to respiratory depression.
- If given to a patient who is physically dependent on pure opioid agonists, an agonist-antagonist will precipitate withdrawal.
- Pure opioid antagonists act as antagonists at mu receptors and at kappa receptors.
- Naloxone and other pure opioid antagonists can reverse respiratory depression, coma, analgesia, and most other effects of pure opioid agonists. The only exception is methylnaltrexone, which doesn't cross the blood-brain barrier.
- Pure opioid antagonists are used primarily to treat opioid overdose. One agent—methylnaltrexone—is used for opioid-induced constipation, and another—alvimopan—for opioid-induced ileus.
- If administered in excessive dosage to an individual who is physically dependent on opioid agonists, naloxone will precipitate an immediate withdrawal reaction.

282

- Opioid dosage must be individualized. Patients with a low tolerance to pain or with extremely painful conditions need high doses. Patients with sharp, stabbing pain need higher doses than patients with dull pain. Elderly adults generally require lower doses than younger adults. Neonates require relatively low doses.
- As a rule, opioids should be administered on a fixed schedule (with supplemental doses for breakthrough pain) rather than PRN.
- Most PCA devices are electronically controlled pumps that can be activated by the patient to deliver a preset dose of opioid through an indwelling catheter. Some PCA devices also deliver a basal opioid infusion.
- PCA devices provide steady plasma drug levels, thereby maintaining continuous pain control while avoiding unnecessary sedation and respiratory depression.
- Use of parenteral opioids during delivery can suppress uterine contractions and cause respiratory depression in the neonate.
- Addiction is a behavior pattern characterized by continued use of a psychoactive substance despite physical, psychologic, or social harm. Physical dependence and addiction are not the same.
- Abuse is defined as drug use that is inconsistent with medical or social norms.
- Because of excessive and inappropriate fears about addiction and abuse, physicians frequently prescribe less pain medication than patients need, and nurses frequently administer less medication than was prescribed.
- Please! Dispel your concerns about abuse and addiction and give your patients the medication they need to relieve suffering. That's what opioids are for, after all.

29.5.4.5.2

Summary of Major Nursing Implications*

29.5.4.5.2.1

PURE OPIOID AGONISTS

Alfentanil

Codeine

Fentanyl

Hydrocodone

Hydromorphone

Levorphanol

Meperidine

Methadone

Morphine

Oxycodone

Oxymorphone

Propoxyphene

Remifentanyl

Sufentanyl

29.5.4.5.2....

Preadministration Assessment

29.5.4.5.2....

Therapeutic Goal

Relief or prevention of moderate to severe pain while causing minimal respiratory depression, constipation, urinary retention, and other adverse effects.

29.5.4.5.2....	Baseline Data	
29.5.4.5.2....	Pain Assessment. Assess pain before administration and 1 hour later. Determine the location, time of onset, and quality of pain (eg, sharp, stabbing, dull). Also, assess for psychologic factors that can lower pain threshold (anxiety, depression, fear, anger). Because pain is subjective and determined by multiple factors (eg, cultural influences, patient expectations, associated disease), there is no reliable objective method for determining how much discomfort the patient is experiencing. Ultimately, you must rely on your ability to interpret what patients have to say about their pain. When listening to patients, be aware that a few may claim discomfort when their pain is under control, and others may claim to feel fine when they actually hurt.	
29.5.4.5.2....	Vital Signs. Prior to administration, determine respiratory rate, blood pressure, and pulse rate.	
29.5.4.5.2....	Identifying High-Risk Patients All opioids are <i>contraindicated</i> for premature infants (both during and after delivery). <i>Morphine</i> is <i>contraindicated</i> following biliary tract surgery. <i>Meperidine</i> is <i>contraindicated</i> for patients taking MAO inhibitors.	282 283
29.5.4.5.2....	Use opioids with <i>caution</i> in patients with head injury, profound CNS depression, coma, respiratory depression, pulmonary disease (eg, emphysema, asthma), cardiovascular disease, hypotension, reduced blood volume, prostatic hypertrophy, urethral stricture, and liver impairment. <i>Caution</i> is also required when treating infants, elderly or debilitated patients, and patients receiving MAO inhibitors, CNS depressants, anticholinergic drugs, and hypotensive agents.	
29.5.4.5.2....	Implementation: Administration	
29.5.4.5.2....	Routes Oral, IM, IV, subQ, rectal, epidural, intrathecal, transdermal (fentanyl), and transmucosal (fentanyl). Routes for specific opioids are summarized in Tables 28-5 and 28-6.	

29.5.4.5.2....

Dosage

29.5.4.5.2....

General Guidelines.

Adjust dosage to meet individual needs. Higher doses are required for patients with low pain tolerance or with especially painful conditions. Patients with sharp, stabbing pain need higher doses than patients with dull, constant pain. Elderly patients generally require lower doses than younger adults. Neonates require relatively low doses because the blood-brain barrier is poorly developed. For all patients, dosage should be reduced as pain subsides.

Oral doses are larger than parenteral doses. Check to ensure that the dose is appropriate for the intended route.

Tolerance may develop with prolonged treatment, necessitating dosage escalation.

Warn outpatients not to increase dosage without consulting the prescriber.

29.5.4.5.2....

Dosage in Patients with Cancer.

Cancer is the principal disease for which opioids are used chronically. The objective is to maximize comfort. Physical dependence is a minor concern. Cancer patients should receive opioids on a fixed schedule around-the-clock—not PRN. If breakthrough pain occurs, fixed dosing should be supplemented PRN with a short-acting opioid. Because of tolerance to opioids or intensification of pain, dosage escalation may be required. Hence, patients should be re-evaluated on a regular basis to determine if pain control is adequate.

29.5.4.5.2....

Discontinuing Opioids.

Although significant dependence in hospitalized patients is rare, it can occur. To minimize symptoms of abstinence, withdraw opioids slowly, tapering the dosage over 3 days. **Warn outpatients against abrupt discontinuation of treatment.**

29.5.4.5.2....

Administration

Prior to administration, determine respiratory rate, blood pressure, and pulse rate. Withhold medication and notify the prescriber if respiratory rate is at or below 12

breaths per minute, if blood pressure is significantly below the pretreatment value, or if pulse rate is significantly above or below the pretreatment value.

As a rule, opioids should be administered on a fixed schedule, with supplemental doses as needed.

Perform IV injections slowly (over 4 to 5 minutes). Rapid injection may produce severe adverse effects (profound hypotension, respiratory arrest, cardiac arrest) and should be avoided. When making an IV injection, have an opioid antagonist (eg, naloxone) and facilities for respiratory support available.

Perform injections (especially IV) with the patient lying down to minimize hypotension.

Warn patients using fentanyl patches to avoid exposing the patch to direct heat (eg, heating pad, hot tub) because doing so can accelerate fentanyl release.

Opioid agonists are regulated under the Controlled Substances Act and must be dispensed accordingly. All of the pure agonists are Schedule II substances, except propoxyphene (Schedule IV) and hydrocodone (Schedule III).

29.5.4.5.2....

Concern for Opioid Abuse as a Factor in Dosage and Administration

Although opioids have a high potential for abuse, abuse is rare in the clinical setting. Consequently, when balancing the risk of abuse against the need to relieve pain, do not give excessive weight to concerns about abuse. The patient must not be allowed to suffer because of your unwarranted fears about abuse and dependence.

Although abuse is rare in the clinical setting, it can occur. To keep abuse to a minimum: (1) exercise clinical judgment when interpreting requests for opioid doses that seem excessive, (2) use opioids in the lowest effective doses for the shortest time required, (3) reserve opioid analgesics for patients with moderate to severe pain, and (4) switch to a nonopioid analgesic when the intensity of pain no longer justifies an opioid.

Responses to analgesics can be reinforced by nondrug measures, such as positioning the patient comfortably, showing concern and interest, and reassuring the patient that the medication will provide relief. Rest, mood elevation, and diversion can raise pain

	threshold and should be promoted. Conversely, anxiety, depression, fatigue, fear, and anger can lower pain threshold and should be minimized.	
29.5.4.5.2....	Ongoing Evaluation and Interventions	
29.5.4.5.2....	Evaluating Therapeutic Effects	
	Evaluate for pain control 1 hour after opioid administration. If analgesia is insufficient, consult the physician about an increase in dosage. Patients taking opioids chronically for suppression of cancer pain should be re-evaluated on a regular basis to determine if dosage is adequate.	
29.5.4.5.2....	Minimizing Adverse Effects	
29.5.4.5.2....	Respiratory Depression.	
	Monitor respiration in all patients. If respiratory rate is 12 breaths per minute or less, withhold medication and notify the prescriber. Warn outpatients about respiratory depression and instruct them to notify the prescriber if respiratory distress occurs.	
	Certain patients, including the very young, the elderly, and those with respiratory disease (eg, asthma, emphysema), are especially sensitive to respiratory depression and must be monitored closely.	283 284
	Delayed respiratory depression may develop following spinal administration of morphine. Be alert to this possibility.	
	When employed during labor and delivery, opioids may cause respiratory depression in the neonate. Monitor the infant closely. Have naloxone available to reverse opioid toxicity.	
29.5.4.5.2....	Sedation.	
	Inform patients that opioids may cause drowsiness. Warn them against doing hazardous activities (eg, driving) if sedation is significant. Sedation can be minimized by (1) using smaller doses given more frequently, (2) using opioids with short half-lives, and (3) giving small doses of a CNS stimulant (methylphenidate or dextroamphetamine) in the morning and early afternoon.	

29.5.4.5.2....

Orthostatic Hypotension.

Monitor blood pressure and pulse rate. **Inform patients about symptoms of hypotension (dizziness, lightheadedness), and advise them to sit or lie down if these occur. Inform patients that hypotension can be minimized by moving slowly when assuming an erect posture. Warn patients against walking if hypotension is significant.** If appropriate, assist hospitalized patients with ambulation.

29.5.4.5.2....

Constipation.

The risk of constipation can be reduced by maintaining physical activity, increasing intake of fiber and fluids, and prophylactic treatment with a stimulant laxative (eg, bisacodyl) plus a stool softener (eg, docusate). Methylnaltrexone, an opioid antagonist, may help too. Severe constipation can be managed with an osmotic laxative (eg, sodium phosphate).

29.5.4.5.2....

Urinary Retention.

To evaluate urinary retention, monitor intake and output, and palpate the lower abdomen for bladder distention every 4 to 6 hours. If there is a change in intake/output ratio, if bladder distention is detected, or if the patient reports difficulty voiding, notify the prescriber. Catheterization may be required. Difficulty with voiding is especially likely in patients with prostatic hypertrophy.

Because opioids may suppress awareness of bladder stimuli, encourage patients to void every 4 hours.

29.5.4.5.2....

Biliary Colic.

By constricting the common bile duct, morphine can increase pressure within the biliary tract, thereby causing severe pain. Biliary colic may be less pronounced with meperidine.

29.5.4.5.2....

Emesis.

Initial doses of opioids may cause nausea and vomiting. These reactions can be minimized by pretreatment with an antiemetic (eg, promethazine) and by having the patient remain still. Tolerance to emesis develops quickly.

29.5.4.5.2....

Cough Suppression.

Cough suppression may result in accumulation of secretions in the airway. **Instruct patients to cough at regular intervals. Auscultate the lungs for rales.**

29.5.4.5.2....

Miosis.

Miosis can impair vision in dim light. Keep hospital room lighting bright during waking hours.

29.5.4.5.2....

Neurotoxicity.

Neurotoxicity—delirium, agitation, myoclonus, hyperalgesia—can develop with prolonged high-dose therapy. Symptoms can be reduced with hydration, dose reduction, and opioid rotation.

29.5.4.5.2....

Opioid Dependence in the Neonate.

The infant whose mother abused opioids during pregnancy may be born drug dependent. Observe the infant for signs of withdrawal (eg, excessive crying, sneezing, tremor, hyperreflexia, fever, diarrhea) and notify the physician if these develop (usually within a few days after birth). The infant can be weaned from drug dependence by administering dilute paregoric in progressively smaller doses.

29.5.4.5.2....

Minimizing Adverse Interactions

29.5.4.5.2....

CNS Depressants.

Opioids can intensify responses to other CNS depressants (eg, barbiturates, benzodiazepines, alcohol, antihistamines), thereby presenting a risk of profound sedation and respiratory depression. **Warn patients against use of alcohol and other depressants.**

29.5.4.5.2....

Agonist-Antagonist Opioids.

These drugs (eg, pentazocine, nalbuphine) can precipitate an abstinence syndrome if administered to a patient who is physically dependent on a pure opioid agonist. Before administering an agonist-antagonist, make certain the patient has been withdrawn from opioid agonists.

29.5.4.5.2....

Anticholinergic Drugs.

These agents (eg, atropine-like drugs, tricyclic antidepressants, phenothiazines, antihistamines) can exacerbate opioid-induced constipation and urinary retention.

29.5.4.5.2....

Hypotensive Drugs.

Antihypertensive agents and other drugs that lower blood pressure can exacerbate opioid-induced orthostatic hypotension.

29.5.4.5.2....

Opioid Antagonists.

Opioid antagonists (eg, naloxone) can precipitate an abstinence syndrome if administered in excessive dosage to a patient who is physically dependent on opioids. To avoid this problem, carefully titrate the dosage of the antagonist.

29.5.4.5.2....

MAO Inhibitors.

Combining *meperidine* with an MAO inhibitor can cause delirium, hyperthermia, rigidity, convulsion, coma, and death. Obviously, the combination must be avoided.

29.5.4.5.2....

CYP3A4 Inhibitors.

Inhibitors of CYP3A4 (eg, ritonavir, ketoconazole) can increase levels of *fentanyl*, thereby posing a risk of fatal respiratory depression. Monitor patients using this combination with care.

29.5.4.5.2.2

AGONIST-ANTAGONIST OPIOIDS

Buprenorphine

29.5.4.5.2....	Butorphanol Nalbuphine Pentazocine Except for the differences presented below, the nursing implications for these drugs are much like those for the pure opioid agonists. Therapeutic Goal Relief of moderate to severe pain.	284
29.5.4.5.2....	Routes Oral, IV, IM, subQ, and intranasal (<i>butorphanol</i>). Routes for individual agents are summarized in Table 28-6.	285
29.5.4.5.2....	Differences from Pure Opioid Agonists Maximal pain relief with the agonist-antagonists is generally lower than with pure opioid agonists. Most agonist-antagonists have a ceiling to respiratory depression, thereby minimizing concerns about insufficient oxygenation. Agonist-antagonists cause little euphoria. Hence, abuse liability is low. Agonist-antagonists increase cardiac work and should not be given to patients with acute myocardial infarction. Because of their antagonist properties, agonist-antagonists can precipitate an abstinence syndrome in patients physically dependent on opioid agonists. Accordingly, patients must be withdrawn from pure opioid agonists before receiving an agonist-antagonist.	

29.5.4.5.2.3

NALOXONE

29.5.4.5.2....

Therapeutic Goal

Reversal of postoperative opioid effects, opioid-induced neonatal respiratory depression, and overdose with pure opioid agonists.

29.5.4.5.2....

Routes

Intravenous, IM, and subQ. For initial treatment, administer IV. Once opioid-induced CNS depression and respiratory depression have been reversed, IM or subQ administration may be employed.

29.5.4.5.2....

Dosage

Titrate dosage carefully. In opioid addicts, excessive doses can precipitate withdrawal. In postoperative patients, excessive doses can unmask pain by reversing opioid-mediated analgesia.

* Patient education information is highlighted as **blue text**.

³⁰CHAPTER 29 Pain Management in Patients with Cancer

Our topic for this chapter—cancer pain management—is of note both for its good news and bad news. The good news is that pain can be relieved with simple interventions in 90% of cancer patients. The bad news is that, despite the availability of effective treatments, pain goes unrelieved far too often. Multiple factors contribute to undertreatment ([Table 29-1](#)). Important among these are inadequate prescriber training in pain management; unfounded fears of addiction (shared by prescribers, patients, and families); and a healthcare system that focuses more on treating disease than relieving suffering.

Pain has a profound impact on both the patient and family. Pain undermines quality of life for the patient and puts a heavy burden on the family. Unrelieved pain compromises the patient's ability to work, enjoy leisure activities, and fulfill his or her role in the family and in society at large. Furthermore, pain can impede recovery, hasten death from cancer, and possibly even create a risk of suicide.

Every patient has the right to expect that pain management will be an integral part of treatment throughout the course of his or her disease. The goal is to minimize pain and thereby maintain a reasonable quality of life, including the ability to function at work and at play, and within the family and society. In addition, if the cancer is incurable, treatment should permit the patient a relatively painless death when that time comes.

TABLE 29-1 Barriers to Cancer Pain Management

Barriers Related to Healthcare Professionals

Inadequate knowledge of pain management
Poor assessment of pain
Concerns stemming from regulations on controlled substances
Fear of patient addiction
Concern about side effects of analgesics
Concern about tolerance to analgesics

Barriers Related to Patients

Reluctance to report pain
Fear of distracting physicians from treating the cancer
Fear that pain means the cancer is worse
Concern about not being a “good” patient
Reluctance to take pain medication
Fear of addiction or being thought of as an addict
Worries about unmanageable side effects
Concern about becoming tolerant to pain medications
Inability to pay for treatment

Barriers Related to the Healthcare System

Low priority given to cancer pain management
Inadequate reimbursement: The most appropriate treatment may not be reimbursed
Restrictive regulation of controlled substances
Treatment is unavailable or access is limited

Adapted from Jacox A, Carr DB, Payne R, et al: Management of Cancer Pain (Clinical Practice Guideline No. 9; AHCPR Publication No. 94-0592). Rockville, MD: Agency for Health Care Policy and Research, 1994.

30.1 PATHOPHYSIOLOGY OF PAIN

30.1.1 What Is Pain?

The International Association for the Study of Pain defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” Note that, by this definition, pain is not simply a sensory experience resulting from activation of pain receptors. Rather, it also includes the patient's emotional and cognitive responses to both the sensation of pain and the underlying cause (eg, tissue damage caused by cancer). Most importantly, we must appreciate that pain is inherently *personal and subjective*. Hence, when assessing pain, the most reliable method is to have the patient describe his or her experience.

286

30.1.2 Neurophysiologic Basis of Painful Sensations

287

The following discussion is a simplified version of how we perceive pain. Nonetheless, it should be adequate as a basis for understanding the interventions used for pain relief.

Sensation of pain is the net result of activity in two opposing neuronal pathways. The first pathway carries pain impulses from their site of origin to the brain, and thereby generates pain sensation. The second pathway, which originates in the brain, suppresses impulse conduction along the first pathway, and thereby diminishes pain sensation.

Pain impulses are initiated by activation of pain receptors, which are simply free nerve endings. These receptors can be activated by three types of stimuli: mechanical (eg, pressure), thermal, and chemical (eg, bradykinin, serotonin, histamine). In addition, *prostaglandins* and *substance P* can enhance the sensitivity of pain receptors to activation, although these compounds do not activate pain receptors directly.

Conduction of pain impulses from the periphery to the brain occurs by way of a multineuron pathway. The first neuron carries impulses from the periphery to a synapse in the spinal cord, where it releases either *glutamate* or *substance P* as a transmitter. The next neuron carries the impulse up the cord to a synapse in the thalamus. And the next neuron carries impulses from the thalamus to the cerebral cortex.

The brain is able to suppress pain conduction using endogenous opioid compounds, especially *enkephalins* and *beta-endorphin*. These compounds are released at synapses in the brain and spinal cord. Release within the spinal cord is controlled by a descending neuronal pathway that

originates in the brain. The opioids that we give as drugs (eg, morphine) produce analgesia by activating the same receptors that are activated by this endogenous pain-suppressing system.

30.1.3 Nociceptive Pain Versus Neuropathic Pain

In patients with cancer, pain has two major forms, referred to as *nociceptive* and *neuropathic*. Nociceptive pain results from injury to *tissues*, whereas neuropathic pain results from injury to *peripheral nerves*. These two forms of pain respond differently to analgesic drugs. Accordingly, it is important to differentiate between them. Among cancer patients, nociceptive pain is more common than neuropathic pain.

Nociceptive pain has two forms, known as *somatic* and *visceral*. Somatic pain results from injury to somatic tissues (eg, bones, joints, muscles), whereas visceral pain results from injury to visceral organs (eg, small intestine). Patients generally describe somatic pain as localized and sharp. In contrast, they describe visceral pain as vaguely localized with a diffuse, aching quality. Both forms of nociceptive pain respond well to *opioid analgesics* (eg, morphine). In addition, they may respond to *nonopioids* (eg, ibuprofen).

Neuropathic pain produces different sensations than nociceptive pain and responds to a different group of drugs. Patients describe neuropathic pain with such words as “burning,” “shooting,” “jabbing,” “tearing,” “numb,” “dead,” and “cold.” Unlike nociceptive pain, neuropathic pain responds poorly to opioid analgesics. However, it does respond to drugs known collectively as *adjuvant analgesics*. Among these are certain antidepressants (eg, imipramine), anticonvulsants (eg, carbamazepine, gabapentin), and local anesthetics/antidysrhythmics (eg, lidocaine).

30.1.4 Pain in Cancer Patients

Among patients with cancer, pain can be caused by the cancer itself and by therapeutic interventions. Cancer can cause pain through direct invasion of surrounding tissues (eg, nerves, muscles, visceral organs) and through metastatic invasion at distant sites. Metastases to bone are very common, causing pain in up to 50% of patients. Cancer can cause neuropathic pain through infiltration of nerves, and visceral pain through infiltration, obstruction, and compression of visceral structures.

The incidence and intensity of cancer-induced pain is a function of cancer type and the stage of disease progression. Among patients with advanced disease, about 75% experience significant pain. Of these, 40% to 50% report moderate to severe pain, and 25% to 30% report very severe pain.

Therapeutic interventions—especially chemotherapy, radiation, and surgery—cause significant pain in at least 25% of patients, and probably more. Chemotherapy can cause painful mucositis, diffuse neuropathies, and aseptic necrosis of joints. Radiation can cause osteonecrosis, chronic visceral pain, and peripheral neuropathy (secondary to causing fibrosis of nerves). Surgery can cause a variety of pain syndromes, including phantom limb syndrome and postmastectomy syndrome.

30.2 MANAGEMENT STRATEGY

Management of cancer pain is an ongoing process that involves repeating cycles of assessment, intervention, and reassessment. The goal is to create and implement a flexible treatment plan that can meet the changing needs of the individual patient. The flow chart in [Figure 29-1](#) summarizes the steps involved. Management begins with a comprehensive assessment. Once the nature of the pain has been determined, a treatment modality is selected. Analgesic drugs are preferred, and hence are usually tried first. If drugs are ineffective, other modalities can be implemented. Among these are radiation, surgery, and nerve blocks. After each intervention, pain is reassessed. Once relief has been achieved, the effective intervention is continued, accompanied by frequent reassessments. If severe pain returns or new pain develops, a new comprehensive assessment should be performed—followed by appropriate interventions and reassessment. Throughout this process, the healthcare team should make every effort to ensure active involvement of the patient and his or her family. Without their involvement, maximal benefits cannot be achieved. The importance of patient and family involvement is reflected in the clinical approach to pain management recommended by the Agency for Healthcare Research and Quality (AHRQ):

A **Ask** about pain regularly.

Assess pain systematically.

B **Believe** the patient and family in their reports of pain and what relieves it.

C **Choose** pain control options appropriate for the patient, family, and setting.

D **Deliver** interventions in a timely, logical, and coordinated fashion.

E **Empower** patients and their families.

Enable patients to control their treatment to the greatest extent possible.

287

Figure 29-1 **Flow chart for pain management in patients with cancer.** NSAID = nonsteroidal anti-inflammatory drug.

(Adapted from Jacox A, Carr DB, Payne R, et al: Management of Cancer Pain [Clinical Practice Guideline No. 9; AHCPR Publication No. 94-0592]. Rockville, MD: Agency for Health Care Policy and Research, 1994.)

30.3 ASSESSMENT AND ONGOING EVALUATION

Assessment is the foundation of treatment. In the absence of thorough assessment, effective pain management is impossible. Assessment begins with a comprehensive evaluation and then continues with regular follow-up evaluations. The initial assessment provides the basis for designing the treatment program. Follow-ups let us know how well treatment is working.

30.3.1 Comprehensive Initial Assessment

The initial assessment employs an extensive array of tests. The primary objective is to characterize the pain and identify its cause. This information provides the basis for designing a pain management plan. In addition, by documenting the patient's baseline pain status, the initial assessment provides a basis for evaluating the efficacy of treatment.

30.3.1.1 Assessment of Pain Intensity and Character: The Patient Self-Report

The patient's description of his or her pain is the cornerstone of pain assessment. No other component of assessment is more important! Remember, pain is a personal experience. Accordingly, if we want to assess pain, we must rely on the patient to tell us about it. Furthermore, we must act on what the patient says—even if we personally believe the patient may not be telling the truth.

The best way to ensure an accurate report is to ask the right questions and listen carefully to the answers. We cannot elicit comprehensive information by asking, “How do you feel?” Rather, we must ask a series of specific questions. The answers should be recorded on a pain inventory form. The following information should be obtained:

- *Onset and temporal pattern*—When did your pain begin? How often does it occur? Has the intensity increased, decreased, or remained constant? Does the intensity vary throughout the day?
- *Location*—Where is your pain? Do you feel pain in more than one place? Ask patients to point to the exact location of the pain, either on themselves, on you, or on a full-body drawing.
- *Quality*—What does your pain feel like? Is it sharp or dull? Does it ache? Is it shooting or stabbing? Burning or tingling? These questions can help distinguish neuropathic pain from nociceptive pain.

- *Intensity*—On a scale of 0 to 10, with 0 being no pain and 10 the most intense pain you can imagine, how would you rank your pain now? How would you rank your pain at its worst? And at its best? A pain intensity scale (see below) can be very helpful for this assessment.
- *Modulating factors*—What makes your pain worse? What makes it better?
- *Previous treatment*—What treatments have you tried to relieve your pain (eg, analgesics, acupuncture, relaxation techniques)? Are they effective now? If not, were they ever effective in the past?
- *Impact*—How does the pain affect your ability to function, both physically and socially? For example, does the pain interfere with your general mobility, work, eating, sleeping, socializing, or sex life?

30.3.1.2 Physical and Neurologic Examinations

The physical and neurologic examinations help to further characterize the pain, identify its source, and identify any complications related to the underlying pathology. The clinician should examine the site of pain and determine if palpation or manipulation makes it worse. Nonverbal cues (eg, protecting the painful area, limited movement in an arm or leg) that may indicate pain should be noted. Common patterns of referred pain should be assessed. For example, if the patient has hip pain, the assessment should determine if the pain actually originates in the hip or if it is referred pain caused by pathology in the lumbar spine. Potential neurologic complications should be considered. For example, patients with back pain should be evaluated for impaired motor and sensory function in the limbs, and for impaired rectal and urinary sphincter function.

30.3.1.3 Diagnostic Tests

Diagnostic tests are performed to identify the underlying cause of pain (eg, progression of cancer, tissue injury caused by cancer treatments). The repertoire of diagnostic tests includes imaging studies (eg, computed tomography scan, magnetic resonance imaging), neurophysiologic tests, and tests for tumor markers in blood. To ensure that abnormalities identified in the diagnostic tests really do explain the patient's pain, these findings should be correlated with findings from the physical and neurologic examinations.

30.3.1.4 Psychosocial Assessment

Psychosocial assessment is directed at both the patient and his or her family. The information is used in making pain management decisions. Some important issues to address include

- The impact of significant pain on the patient in the past
- The patient's usual coping responses to pain and stress
- The patient's preferences regarding pain management methods
- The patient's concerns about using opioids and other controlled substances (anxiolytics, stimulants)
- Changes in the patient's mood (anxiety, depression) brought on by cancer and pain
- The impact of cancer and its treatment on the family
- The level of care the family can provide and the potential need for outside help (eg, hospice)

30.3.1.5 Pain Intensity Scales

Pain intensity scales are useful tools for assessing pain intensity. Representative scales are shown in [Figures 29-2](#) and [29-3](#). The *descriptive scale* and *numeric scale* ([Fig. 29-2](#)) are used for adults and older children. The *pain affect FACES scale* ([Fig. 29-3](#)) is used for young children and for patients with cognitive impairment, who may have difficulty understanding the descriptive and numeric scales.

Pain intensity scales are valuable not only for assessing pain intensity, but also for *setting pain relief goals and evaluating treatment*. When setting goals, the patient and prescriber should agree on a target pain intensity rating that will permit the patient to participate in recovery activities, perform activities of daily living, and enjoy activities that contribute to quality of life. The objective of treatment is to reduce pain to the agreed-upon level—and lower, if possible.

289

30.3.2 Ongoing Evaluation

290

Once a treatment plan has been implemented, pain should be reassessed frequently. The objective is to determine the efficacy of treatment and to allow early diagnosis and treatment of new pain. Each time an analgesic drug is administered, pain should be evaluated after sufficient time has elapsed for the drug to take effect. Because most patients are treated at home, patients and

caregivers should be taught to conduct and document pain evaluations. The prescriber will use the documented record to make adjustments to the pain management plan.

Prescribers, patients, and caregivers should be alert for new pain. In the majority of cases, new pain results from a new cause (eg, metastasis, infection, fracture). Accordingly, whenever new pain occurs, a rigorous diagnostic work-up is indicated.

30.3.3 Barriers to Assessment

As stressed above, pain assessment relies heavily on a report from the patient. Unfortunately, the report is not always accurate: Some patients report more pain than they have, some

Figure 29-2 Linear pain intensity scales.*If used as a graphic rating scale, a 10-cm baseline is recommended.

(From Acute Pain Management Guideline Panel: Acute Pain Management: Operative or Medical Procedures and Trauma [Clinical Practice Guideline No. 1; AHCPR Publication No. 92-0032]. Rockville, MD: Agency for Health Care Policy and Research, 1992, with permission.)

Figure 29-3 **Wong-Baker FACES pain rating scale.** Explain to the patient that the first face represents a person who feels happy because he or she has no pain, and that the other faces represent people who feel sad because they have pain, ranging from a little to a lot. Explain that face 10 represents a person who hurts as much as you can imagine, but that you don't have to be crying to feel this bad. Ask the patient to choose the face that best reflects how he or she is feeling. The numbers below the faces correspond to the values in the numeric pain scale shown in [Figure 29-2](#).

(From Wong DL: Wong's Essentials of Pediatric Nursing, 6th ed. St. Louis: CV Mosby, 2003, with permission.)

report less, and some are unable to report at all. With other patients, cultural and language differences impede assessment. In all cases, reliance on behavioral cues and facial expression is a poor substitute for an accurate report by the patient.

Many patients under-report pain, frequently because of misconceptions. Some fear addiction to opioids, and hence want to minimize opioid use. Some believe they are expected to be stoic and “tough it out.” Some deny their pain because they fear pain signifies disease progression. When underreporting of pain is suspected, the patient should be interviewed in an effort to discover the reason. If a misconception is responsible for under-reporting, educating the patient can help fix the problem.

Some patients fear they may be denied sufficient pain medication, and hence, to ensure adequate dosing, report more pain than they actually have. When exaggeration is suspected, the patient

should be reassured that adequate pain relief will be provided, and should be taught that inaccurate reporting serves only to make appropriate treatment more difficult.

Language barriers and cultural barriers can impede pain assessment. For patients who do not speak English, a translator should be provided. Obtaining a pain rating scale in the patient's own language would obviously help. A *pain affect FACES scale* can be useful, since facial expressions reflecting discomfort are the same in all cultures. Cultural beliefs may cause some patients to hide overt expression of pain and report less pain than is present. The interviewer should be alert to this possibility.

When assessing pain, we must keep in mind that behavior and facial expression may be poor indicators of pain status. For example, in patients approaching the end of life, behavioral cues of pain (eg, vocalizing, grimacing) are often absent. Other patients may simply have good coping skills, and hence may smile and move around in apparent comfort, even though they are in considerable pain. Because appearances can be deceiving, we must not rely on them to assess pain.

Assessment in young children and other nonverbal patients is a special challenge. By definition, nonverbal patients are unable to self-report pain. Accordingly, we must use less reliable methods of assessment, including observing the patient for cues. Assessment in children is discussed further under *Pain Management in Special Populations*.

290

30.4 DRUG THERAPY

291

Analgesic drugs are the most powerful weapons we have for conquering cancer pain. With proper use, these agents can relieve pain in 90% of patients. Because analgesics are so effective, drug therapy is the principal modality for pain treatment. Three types of analgesics are employed:

- Nonopioid analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs] and acetaminophen)
- Opioid analgesics (eg, oxycodone, fentanyl, morphine)
- Adjuvant analgesics (eg, amitriptyline, carbamazepine, dextroamphetamine)

These classes differ in their abilities to relieve pain. With the nonopioid and adjuvant analgesics, there is a ceiling to how much relief we can achieve. In contrast, there is no ceiling to relief with the opioids.

Selection among the analgesics is based on pain intensity and pain type. To help guide drug selection, the World Health Organization (WHO) devised a drug selection ladder ([Fig. 29-4](#)). The

first step of the ladder—for mild to moderate pain—consists of nonopioid analgesics: NSAIDs and acetaminophen. The second step—for more severe pain—*adds* opioid analgesics of moderate strength (eg, oxycodone, hydrocodone). The top step—for severe pain—substitutes powerful opioids (eg, morphine, fentanyl) for the weaker ones. Adjuvant analgesics, which are especially effective against neuropathic pain, can be used on any step of the ladder. Specific drugs to *avoid* are listed in [Table 29-2](#).

Traditionally, patients have been given opioid analgesics only after a trial with nonopioids has failed. Guidelines from the National Comprehensive Cancer Network (NCCN) recommend a different approach, in which initial drug selection is based on pain intensity. Specifically, if the patient reports pain in the 4 to 10 range (as measured on a numeric rating scale), then treatment should start directly with an opioid; an initial trial with a non-opioid is considered unnecessary. If the patient reports pain in the 1 to 3 range, then treatment usually begins with a nonopioid, although starting with an opioid remains an alternative.

It is common practice to combine an opioid with a nonopioid. Why? Because the combination can be more effective than either drug alone. When pain is only moderate, opioids and nonopioids can be given in a fixed-dose combination formulation, thereby simplifying dosing. However, when pain is severe, these drugs must be given separately. Why? Because, with a fixed-dose combination, side effects of the nonopioid would become intolerable as the dosage grew large, and hence would limit how much opioid could be given.

Drug therapy of cancer pain should adhere to the following principles:

- Perform a comprehensive pretreatment assessment to identify pain intensity and the underlying cause.
- Individualize the treatment plan.
- Use the WHO analgesic ladder and NCCN guidelines to guide drug selection.
- Use oral therapy whenever possible.
- Avoid IM injections whenever possible.
- For persistent pain, administer analgesics on a fixed schedule around-the-clock (ATC), and provide additional rescue doses of a short-acting agent if breakthrough pain occurs.
- Evaluate the patient frequently for pain relief and drug side effects.

Figure 29-4 **The WHO analgesic ladder for cancer pain management.** Note that steps represent pain intensity. Accordingly, if a patient has intense pain at the outset, then treatment can be initiated with an opioid (step 2), rather than trying a nonopioid first (step 1).

(Adapted from Cancer Pain Relief, 2nd ed. Geneva: World Health Organization, 1996.)

30.4.1 Nonopioid Analgesics

The nonopioid analgesics—NSAIDs and acetaminophen—constitute the first rung of the WHO analgesic ladder. These agents are the initial drugs of choice for patients with mild pain. There is a ceiling to how much pain relief nonopioid drugs can provide. Hence, there is no benefit to exceeding recommended dosages ([Table 29-3](#)). Acetaminophen is about equal to the NSAIDs in *analgesic* efficacy but lacks *antiinflammatory* actions. Because of this difference and others, acetaminophen is considered separately below. The NSAIDs and acetaminophen are discussed at length in [Chapter 70](#). Accordingly, discussion here is brief.

30.4.1.1 Nonsteroidal Anti-inflammatory Drugs

NSAIDs (eg, aspirin, ibuprofen) can produce a variety of effects. Primary beneficial effects are pain relief, suppression of inflammation, and reduction of fever. Primary adverse effects are gastric ulceration, acute renal failure, and bleeding. In addition, all NSAIDs *except aspirin* increase the risk of thrombotic events (eg, myocardial infarction, stroke). In contrast to opioids, NSAIDs do not cause tolerance, physical dependence, or psychologic dependence.

NSAIDs are effective analgesics that can relieve mild to moderate pain. All of the NSAIDs have essentially equal analgesic efficacy, although individual patients may respond better to one NSAID than to another. NSAIDs relieve pain by a mechanism different from that of the opioids. As a result, combined use of an NSAID with an opioid can produce greater pain relief than either agent alone.

291

TABLE 29-2 Drugs That Are Not Recommended for Treating Cancer Pain

Drug Class	Drug	Why the Drug Is Not Recommended
Opioids		
Pure Agonists	Meperidine	A toxic metabolite accumulates with prolonged use
	Codeine	Maximal pain relief is limited owing to dose-limiting side effects
Agonist-Antagonists	Buprenorphine	Ceiling to analgesic effects; can precipitate withdrawal in opioid-dependent patients; cause psychotomimetic reactions
	Butorphanol	
	Nalbuphine	
	Pentazocine	
Opioid Antagonists	Naloxone	Can precipitate withdrawal in opioid-dependent patients; limit use to reversing life-threatening respiratory depression caused by opioid overdose
	Naltrexone	
	Nalmefene	
Benzodiazepines	Diazepam	Sedation from benzodiazepines limits opioid dosage; no demonstrated analgesic action
	Lorazepam others	
Barbiturates	Amobarbital	Sedation from barbiturates limits opioid dosage; no demonstrated analgesic action
	Secobarbital others	
Miscellaneous	Cocaine	No analgesic efficacy, either alone or in combination with an opioid
	Marijuana	
	Brompton's cocktail [*]	Side effects (dysphoria, drowsiness, hypotension, bradycardia) preclude routine use as an analgesic
		Analgesic efficacy is no better than that of a single opioid

* Brompton's cocktail consists of heroin (in variable amounts), 10 mg of cocaine, 2.5 mL of 98% ethanol, 5 mL of syrup, and chloroform water.

NSAIDs produce their effects—both good and bad—by inhibiting cyclooxygenase (COX), an enzyme that has two forms, known as COX-1 and COX-2. Most NSAIDs inhibit both COX-1 and COX-2, although a few are COX-2 selective. The selective COX-2 inhibitors (eg, celecoxib [Celebrex]) cause less GI damage than the nonselective inhibitors. Unfortunately, the selective

inhibitors pose a greater risk of thrombotic events, and hence long-term use of these drugs is not recommended.

For patients undergoing chemotherapy, inhibition of platelet aggregation by NSAIDs is a serious concern. Many anticancer drugs suppress bone marrow function, and thereby decrease platelet production. The resultant thrombocytopenia puts patients at risk of bruising and bleeding. Obviously, this risk will be increased by drugs that inhibit platelet function. Among the conventional NSAIDs, only one subclass—the nonacetylated salicylates (eg, magnesium salicylate)—does not inhibit platelet aggregation, and hence is safe for patients with thrombocytopenia. All other conventional NSAIDs should be avoided. *Aspirin* is especially dangerous because it causes *irreversible* inhibition of platelet aggregation. Hence, its effects persist for the life of the platelet (about 8 days). Because COX-2 inhibitors do not affect platelets, these drugs are safe for patients with thrombocytopenia.

30.4.1.2 Acetaminophen

Acetaminophen [Tylenol, others] is similar to the NSAIDs in some respects and different in others. Like the NSAIDs, acetaminophen is an effective analgesic, and hence can relieve mild to moderate pain. Benefits derive from inhibiting COX in the central nervous system (CNS), but not in the periphery. Combining acetaminophen with an opioid can produce greater analgesia than either drug alone (because acetaminophen and opioids relieve pain by different mechanisms).

Acetaminophen differs from the NSAIDs in several important ways. Because it does not inhibit COX in the periphery, acetaminophen lacks anti-inflammatory actions, does not inhibit platelet aggregation, and does not promote gastric ulceration, renal failure, or thrombotic events. Because acetaminophen does not affect platelets, the drug is safe for patients with thrombocytopenia.

Acetaminophen has important interactions with two other drugs: alcohol and warfarin (an anticoagulant). Combining acetaminophen with alcohol, even in moderate amounts, can result in potentially fatal liver damage. Accordingly, patients taking acetaminophen should minimize alcohol consumption. Acetaminophen also can increase the risk of bleeding in patients taking warfarin. The mechanism appears to be inhibition of warfarin metabolism, which causes warfarin to accumulate to dangerous levels.

30.4.2 Opioid Analgesics

Opioids are the most effective analgesics available, and hence are the primary drugs for treating moderate to severe cancer pain. With proper dosing, opioids can safely relieve pain in about 90% of cancer patients. Unfortunately, many patients are denied adequate doses, owing largely to unfounded fears of addiction. In the past, opioids were known as *narcotics*, a term that is now obsolete.

Opioids produce a variety of pharmacologic effects. In addition to analgesia, they can cause sedation, euphoria, constipation, respiratory depression, urinary retention, and miosis. With continuous use, tolerance develops to most of these effects, with the notable exception of constipation. Continuous use also results in physical dependence, which must not be equated with addiction.

292

293

TABLE 29-3 Dosages for Nonopioid Analgesics: Acetaminophen and Selected NSAIDs

Drug	Usual Adult Dosage [*]	
	Body Weight 50 kg or More	Body Weight Less Than 50 kg
Acetaminophen	650 mg q 4 h <i>or</i> 975 mg q 6 h <i>or</i> 1300 mg q8h	10–15 mg/kg q 4 h <i>or</i> 15–20 mg/kg q 4 h (rectal)
NSAIDs: Salicylates		
Aspirin	650 mg q 4 h <i>or</i> 975 mg q 6 h	10–15 mg/kg q 4 h <i>or</i> 15–20 mg/kg q 4 h (rectal)
Magnesium salicylate [Magan] [†]	650 mg q 4 h	—
Sodium salicylate [†]	325–650 mg q 3–4 h	—
NSAIDs: Propionic Acid Derivatives		
Fenoprofen	300–600 mg q 6 h	—
Ibuprofen [Motrin, Advil, others]	400–800 mg q 6 h	10 mg/kg q 6–8 h
Ketoprofen	25–60 mg q 6–8 h	—
Naproxen [Naprosyn]	250–275 mg q 6–8 h	5 mg/kg q 8 h
Naproxen sodium [Anaprox, Aleve, Naprelan, others]	275 mg q 6–8 h	—
NSAIDs: Miscellaneous		
Diflunisal	500 mg q 12 h	—
Etodolac	200–400 mg q 6–8 h	—
Meclofenamate sodium	50–100 mg q 6 h	—
Mefenamic acid [Ponstel]	250 mg q 6 h	—
NSAIDs: Selective COX-2 Inhibitors		
Celecoxib [Celebrex]	200 mg q 12 h	—

* All dosages are oral except where indicated.

† Magnesium salicylate and sodium salicylate are nonacetylated, and hence, unlike aspirin, are safe for patients with thrombocytopenia.

The opioids are discussed at length in [Chapter 28](#). Discussion here focuses on their use in patients with cancer.

30.4.2.1 Mechanism of Action and Classification

Opioid analgesics relieve pain by mimicking the actions of endogenous opioid peptides (enkephalins, dynorphins, endorphins), primarily at mu receptors and partly at kappa receptors.

Based on their actions at mu and kappa receptors, the opioids fall into two major groups: (1) *pure (full) agonists* (eg, morphine) and (2) *agonist-antagonists* (eg, butorphanol). The pure agonists can be subdivided into (1) agents for mild to moderate pain and (2) agents for moderate to severe pain. The pure agonists act as agonists at mu receptors *and* at kappa receptors. In contrast, the agonist-antagonists act as agonists only at kappa receptors; at mu receptors, these drugs act as *antagonists*. Because their agonist actions are limited to kappa receptors, the agonist-antagonists have a ceiling to their analgesic effects. Furthermore, because of their antagonist actions, the agonist-antagonists can block access of the pure agonists to mu receptors, and can thereby prevent the pure agonists from relieving pain. Accordingly, agonist-antagonists are not recommended for managing cancer pain.

30.4.2.2 Tolerance and Physical Dependence

Over time, opioids cause tolerance and physical dependence. These phenomena, which are generally inseparable, reflect neuronal adaptations to prolonged opioid exposure. Some degree of tolerance and physical dependence will develop after 1 to 2 weeks of opioid use.

30.4.2.2.1 Tolerance.

Tolerance can be defined as a state in which a specific dose (eg, 10 mg of morphine) produces a smaller effect than it could when treatment began. Put another way, tolerance is a state in which dosage must be increased to maintain the desired response. In patients with cancer, however, a need for larger doses isn't always a sign of tolerance. In fact, it's usually a sign that pain is getting worse (owing to disease progression).

Tolerance develops to some opioid effects but not to others. Tolerance does develop to analgesia, euphoria, respiratory depression, and sedation. In contrast, little or no tolerance develops to constipation.

There is cross-tolerance among opioids. Accordingly, significant tolerance to one opioid confers a similar degree of tolerance to all others.

30.4.2.2.2 Physical Dependence.

Physical dependence is a state in which an abstinence syndrome will occur if a drug is abruptly withdrawn. With opioids, the abstinence syndrome can be very unpleasant—but not dangerous. The intensity and duration of the abstinence syndrome are determined in part by the duration of drug use and in part by the half-life of the drug taken. Because drugs with a short half-life leave the body rapidly, the abstinence syndrome is brief but intense.

293

294

Conversely, for drugs with long half-lives, the syndrome is prolonged but relatively mild. The abstinence syndrome can be minimized by withdrawing opioids slowly (ie, by giving progressively smaller doses over several days). Please note that *physical dependence is not the same as addiction!*

30.4.2.3 Addiction

Opioid addiction is an important issue in pain management—not because addiction occurs (it rarely does), but because *inappropriate fears of addiction* are a major cause for undertreatment.

The American Society of Addiction Medicine defines addiction as *a disease process characterized by continued use of a psychoactive substance despite physical, psychologic, or social harm*. According to this definition, addiction is primarily a *behavior pattern*—and is *not* equated with physical dependence. Although it is true that physical dependence can contribute to addictive behavior, other factors—especially *psychologic dependence*—are the primary underlying cause. All cancer patients who take opioids chronically develop substantial physical dependence, but only a few (less than 1%) develop addictive behavior. Most patients, if their cancer were cured, would simply go through gradual withdrawal, and never think about or use opioids again. Clearly, these patients cannot be considered addicted, despite their physical dependence.

Because of misconceptions about opioid addiction, prescribers often order lower doses than patients need, nurses administer lower doses than were ordered, patients report less pain than they actually have, and family members discourage opioid use. The end result? The majority of cancer patients receive lower doses of opioids than they need. How can we improve this unacceptable situation? We must educate physicians, nurses, patients, and family members. Specifically, we must teach them about the nature of addiction and inform them that development of addiction in the therapeutic setting is very rare. Hopefully, this information will dispel unfounded fears of addiction, and will thereby help ensure delivery of opioids in doses that are sufficient to relieve suffering. After all, that *is* what opioids are for.

30.4.2.4 Drug Selection

30.4.2.4.1 Preferred Opioids.

For all cancer patients, *pure opioid agonists* are preferred to the agonist-antagonists. If pain is not too intense, a moderately strong opioid (eg, oxycodone) is appropriate. If pain is moderate to severe, a strong opioid (eg, morphine) should be used. Since morphine is inexpensive, available in multiple dosage forms, and clinically well understood, this opioid is used more than any other. Preferred opioids are listed in [Table 29-4](#).

30.4.2.4.2 Opioid Rotation.

Opioid rotation—switching from one opioid to another—has become an accepted practice. Because opioids have different side effect profiles, switching among them can help minimize adverse effects while maintaining good analgesia. To make the switch, the current opioid is stopped abruptly and immediately replaced with an equianalgesic dose of an alternative opioid.

30.4.2.4.3 Opioids to Use with Special Caution.

Methadone [Dolophine, Methadose] and *levorphanol* [Levo-Dromoran] must be used with caution. Both drugs have prolonged half-lives, which makes dosage titration difficult. If dosing is not done skillfully, these drugs can accumulate to dangerous levels, causing excessive sedation and respiratory depression.

TABLE 29-4 Equianalgesic Doses of Pure Opioid Agonists and Tramadol

Equianalgesic Dose ^a			
Drug	Parenteral	Oral	Duration (hr) ^b
Agents for Mild to Moderate Pain			
Codeine ^c	130 mg	200 mg	3–4
Hydrocodone ^d	NA	30–200 mg	3–5
Oxycodone ^e	NA	15 mg	3–5
Tramadol ^{f,g}	NA	50–100 mg	3–7
Agents for Moderate to Severe Pain			
Morphine ^h	10 mg	30 mg	3–4
Fentanyl ⁱ	100 mcg	NA	1–3
Hydromorphone	1.5 mg	7.5 mg	2–3
Levorphanol ^j	2 mg	4 mg	3–6
Methadone ^j	10 mg	3–20 mg ^k	4–8
Oxymorphone ^e	1 mg	10 mg	3–6
Modified from NCCN Clinical Practice Guidelines in Oncology: Adult Cancer Pain, Vol. 1. Atlanta: National Comprehensive Cancer Network, Inc., 2008.			
NA = not available.			

a Equianalgesic dose = dose that will produce the same degree of analgesia as 10 mg of parenteral morphine.

b Duration values apply to parenteral administration and to immediate-release oral formulations. Four opioids—morphine, oxycodone, oxymorphone, and tramadol—are available in immediate-release and sustained-release oral formulations.

c Codeine is not generally recommended for chronic therapy because the doses required to produce significant analgesia also produce significant side effects.

d Equivalence data not substantiated. Usually combined with aspirin or acetaminophen.

e Available in a sustained-release formulation administered every 12 hours.

- f Tramadol is a weak opioid agonist with some antidepressant activity. Reserve for mild to moderate pain. The recommended dosage is 100 mg 4 times a day. At the maximum dosage of 400 mg/day, tramadol is less effective than morphine and other strong pure opioid agonists.
- g Available in a sustained-release formulation administered every 24 hours.
- h Available in sustained-release formulations administered every 12 or 24 hours.
- i Available in a long-acting transdermal system (applied every 48 to 72 hours), and in short-acting transmucosal and buccal systems for control of breakthrough pain.
- j Has a long half-life. May need to be dosed every 4 hours initially, and then every 6 to 8 hours after steady state is achieved (in 1 to 2 weeks).
- k For patients converting from morphine to methadone, choosing the proper methadone dosage is complex, and should be done with the advice of a pain specialist familiar with methadone prescribing.

Codeine deserves special comment. Although codeine is capable of producing significant analgesia, side effects limit the dose that can be given. As a result, the degree of pain relief that can be achieved safely is quite low.

30.4.2.4.4

Opioids to Avoid.

Meperidine [Demerol], a pure opioid agonist, may be used for a few days, but no longer. When the drug is taken chronically, a toxic metabolite—normeperidine—can accumulate, thereby posing a risk of adverse CNS effects (dysphoria, agitation, seizures).

The *agonist-antagonists*—buprenorphine, butorphanol, nalbuphine, and pentazocine—should be avoided. Why? First, they are much less effective than pure opioid agonists, and hence, there is little reason to choose them. Second, if given to a patient who is physically dependent on a pure opioid agonist, these drugs can prevent the pure agonist from working, and can thereby block analgesia and precipitate withdrawal. Third, the agonist-antagonists can cause adverse psychologic reactions (nightmares, hallucinations, dysphoria).

294

295

30.4.2.5

Dosage

Dosage must be individualized. The objective is to find a dosage that can relieve pain without causing intolerable side effects. For patients with moderate pain and low opioid tolerance, very low doses (eg, 2 mg of parenteral morphine every 4 hours) can be sufficient. In contrast, when pain is severe or tolerance is high, much larger doses (eg, 600 mg of parenteral morphine every

few hours) may be required. The upper limit to dosage is determined only by the intensity of side effects. Accordingly, as pain and/or tolerance increase, dosage should be increased until pain is relieved—unless intolerable side effects (eg, excessive respiratory depression) occur first.

The dosing schedule is determined by the temporal pattern of the pain. If pain is intermittent and infrequent, PRN dosing can suffice. However, since most patients have persistent pain, PRN dosing is inappropriate. Instead, dosing should be done *on a fixed schedule* ATC. Why?

Because a fixed schedule can prevent opioid levels from becoming subtherapeutic, and can thereby prevent pain recurrence. As a result, the patient is spared needless suffering, both from the pain itself and from anxiety about its return.

What dose should be used when switching from one opioid to another, or from one route of administration to another? To help make this decision, an *equianalgesia table* (see [Table 29-4](#)) should be consulted. Equianalgesia tables indicate equivalent analgesic doses for different opioids, and for the same opioid administered by different routes. Let's assume, for example, that our patient has been getting 10 mg of IV morphine every 4 hours, and we want to switch to oral hydromorphone. By consulting [Table 29-4](#), we can see that 7.5 mg of oral hydromorphone is about equivalent to 10 mg of parenteral morphine, with both drugs being given every 4 hours. Hence, we might begin oral hydromorphone at 7.5 mg. However, there is a caveat: Because cross-tolerance among opioids is incomplete, the listed equianalgesic dose may actually produce a *stronger* effect than advertised. Accordingly, when switching drugs, it is safer to use a dose that is somewhat *lower* than the equianalgesic dose, and then titrate up.

30.4.2.6 Routes of Administration

Because most patients with cancer pain must take analgesics continuously, the route should be as convenient, affordable, and noninvasive as possible. Oral administration meets these criteria best, and hence is preferred for most patients. If oral medication cannot be used, the preferred alternative routes are rectal and transdermal: Both are relatively convenient, affordable, and noninvasive. If these routes are ineffective or inappropriate, then parenteral administration (IV or subQ) is indicated (IM injections should be avoided). For patients who cannot be managed with IV or subQ therapy, more invasive routes—intraspinal or intraventricular—can be tried.

30.4.2.6.1 Oral.

Oral administration is the preferred route for chronic therapy. Why? Because oral dosing is cheap, convenient, and noninvasive. Accordingly, in the absence of contraindications (eg,

vomiting, inability to swallow), oral therapy should be considered for all patients. Opioids are available in several formulations (eg, tablets, capsules, solution) for oral use. To reduce the number of daily doses, a long-acting formulation (eg, controlled-release morphine) can be used. Because oral opioids undergo substantial first-pass metabolism, oral doses must be larger than parenteral doses to achieve equivalent analgesic effects.

30.4.2.6.2 Rectal.

Rectal administration is a preferred alternative for patients who cannot take drugs by mouth. Three opioids—morphine, hydromorphone, and oxymorphone—are available in rectal formulations (suppositories). When switching from oral to rectal administration, dosing is begun with the same dose that was used orally, and then adjusted as needed. Rectal administration is inappropriate for patients with diarrhea or lesions of the rectum or anus. Also, children frequently object to this route.

30.4.2.6.3 Transdermal.

Transdermal administration is a preferred alternative to oral therapy. Only one opioid—fentanyl [Duragesic]—is available for chronic transdermal use. Fentanyl patches provide steady analgesia for 72 hours, and hence are appropriate for patients with pain that is continuous and does not fluctuate much in intensity. Absorption from the patch is very slow. As a result, when the first patch is applied, effective analgesia may take 12 to 24 hours to develop. During this time, PRN therapy with a short-acting opioid may be required. Fentanyl patches are available in five strengths, allowing dosage to be matched with pain intensity. As with other long-acting opioids, rescue doses with a short-acting opioid are needed when breakthrough pain occurs.

30.4.2.6.4 Intravenous and Subcutaneous.

Intravenous and subQ administration are acceptable alternatives when less invasive routes (oral, transdermal, rectal) cannot be used. The IV and subQ routes have two advantages: (1) onset of analgesia is quick and (2) these routes permit rapid escalation of dosage. Obvious disadvantages are inconvenience and increased cost. In addition, frequent subQ dosing is uncomfortable. Conditions that might justify IV or subQ administration include

- Persistent nausea and vomiting (which preclude oral dosing)
- Inability to swallow (which precludes oral dosing)
- Delirium or stupor (which precludes oral dosing)

- Pain that requires a large number of pills (which makes oral dosing inconvenient)
- Unstable pain that requires rapid dosage escalation (which precludes oral, rectal, and transdermal administration)

Dosages for IV and subQ administration are the same.

30.4.2.6.5

Intramuscular.

Intramuscular administration should be avoided. IM injections are painful, and hence unacceptable for repeated dosing. In addition, absorption from IM sites is inconsistent, hence pain relief is unpredictable.

30.4.2.6.6

Intraspinal.

Intraspinal administration is reserved for patients with intractable pain that cannot be controlled with less invasive routes (eg, IV, subQ). In this technique, opioids are delivered to the epidural or subarachnoid space via a percutaneous catheter connected to an infusion pump or injection port. By using this route, we can achieve high opioid concentrations at receptors on pain pathways in the spinal cord. It is important to note, however, that effects will not be limited to the spinal cord: Intraspinal opioids undergo absorption into the blood in amounts sufficient to cause systemic effects. In fact, blood levels may be equivalent to those achieved with conventional routes (eg, subQ). Intraspinal administration is especially use-ful for patients with severe pain in the lower body: Pain is relieved in up to 90% of appropriate candidates. Patients who are tolerant to opioids delivered by other routes will also be tolerant to opioids given intraspinally; dosage should be adjusted accordingly. Patients should have access to rescue medication in case breakthrough pain occurs, owing either to delivery system malfunction or inadequate dosing. Side effects with intraspinal administration are the same as with other routes. In addition, there is a risk of *delayed* respiratory depression as well as infection associated with the catheter.

295

296

30.4.2.6.7

Intraventricular.

Like intraspinal administration, intraventricular administration is reserved for patients whose pain cannot be controlled with less invasive routes. In this procedure, morphine is delivered to the cerebral ventricles via a catheter connected to an external infusion pump (for continuous administration) or a subcutaneous reservoir (for intermittent administration). Because morphine is delivered directly to the brain, bypassing the blood-brain barrier, analgesia can be achieved with extremely low doses (eg, 5 mg daily). Pain is relieved in 90% of patients.

Intraventricular administration is especially helpful for patients with intractable pain caused by head and neck malignancies or tumors that affect the brachial plexus.

30.4.2.6.8 Patient-Controlled Analgesia.

Patient-controlled analgesia (PCA) is a method of drug delivery that permits patients to control the amount of opioid they receive. PCA is accomplished using a PCA device to deliver opioids through an indwelling IV or subQ catheter. The PCA device is an electronically controlled infusion pump that (1) delivers a continuous basal infusion of opioid and (2) can be activated manually by the patient to deliver additional bolus doses for breakthrough pain. To prevent an overdose, the device (1) limits the total dose of opioid that can be delivered per hour and (2) sets a minimum interval (eg, 10 minutes) between bolus doses, thereby preventing the patient from giving a second dose before the first one can take full effect. PCA devices are safe for use in the hospital and at home, but should not be used by patients who are sedated or confused. PCA administration is discussed at length in [Chapter 28](#).

30.4.2.7 Managing Breakthrough Pain

Many patients whose pain is well controlled most of the day experience transient episodes of moderate to severe pain, known as breakthrough pain. Breakthrough pain develops quickly, reaches peak intensity in minutes, and may persist from minutes to hours (the median duration is 30 minutes). At least 50% of cancer patients experience these episodes, typically 1 to 4 times a day. Breakthrough pain may occur spontaneously, or it may be precipitated by coughing or other movements. In contrast to end-of-dose pain, which occurs because analgesic levels are lowest at that time, breakthrough pain can occur at any time during the dosing interval.

All patients receiving ATC opioids for persistent pain should have access to a rescue medication to manage breakthrough pain. Because breakthrough pain is both severe and self-limited, the best medication is a strong opioid with a rapid onset and short duration. The rapid onset permits speedy relief, and the short duration facilitates dosage titration. For ease of administration, oral and transmucosal formulations are preferred; examples include immediate-release oral morphine and transmucosal fentanyl [Actiq, Fentora]. The dosage, as recommended by the American Pain Society, should be equivalent to one-sixth of the total daily opioid dose, repeated in 2 hours if needed.

30.4.2.8 Managing Side Effects

Side effects of the opioids include respiratory depression, constipation, sedation, orthostatic hypotension, nausea, and vomiting. All can be effectively managed. In many patients, side effects can be reduced simply by decreasing the dosage (typically by 25%). If dosage reduction causes pain to return, adding a nonopioid analgesic may take care of the problem. Over time, tolerance develops to sedation, respiratory depression, nausea, and vomiting—but not to constipation.

30.4.2.8.1 Respiratory Depression.

Respiratory depression is the most serious side effect of the opioids; death can result. Fortunately, when dosage and monitoring are appropriate, significant respiratory depression is rare. Pain counteracts the depressant actions of opioids. Hence, as pain decreases, respiratory depression may deepen.

Respiratory depression is greatest at the outset of treatment and then decreases as tolerance develops. As a result, small initial doses of opioids (eg, 5 mg of IV morphine every hour) can pose a greater risk than much larger doses (eg, 1000 mg of IV morphine every hour) later on.

Significant respiratory depression is most likely when dosage is being titrated up. The best way to assess the risk of impending respiratory depression is to monitor opioid-induced sedation. Why? Because an increase in sedation generally precedes an increase in respiratory depression. Hence, if excessive sedation is observed, further dosing should be delayed.

Respiratory depression is increased by other drugs with CNS-depressant actions (eg, alcohol, barbiturates, benzodiazepines). Accordingly, these agents should be avoided.

Severe respiratory depression can be reversed with *naloxone* [Narcan], a pure opioid antagonist. However, caution is required: Excessive dosing will reverse analgesia, thereby putting the patient in great pain. Accordingly, naloxone dosage must be titrated carefully.

When death is near, should opioids be withheld out of fear that respiratory depression may bring death sooner? For several reasons, the answer is “No.” First, significant respiratory depression is rare in the tolerant patient. Hence, concerns about hastening death are largely unfounded. Second, unrelieved pain can itself hasten death. Third, when death is imminent, it is more important to provide comfort than prolong life. Accordingly, adequate opioids should be provided, even if doing so means life ends a bit sooner.

30.4.2.8.2 Constipation.

Constipation occurs in most patients. Opioids promote constipation by decreasing propulsive intestinal contractions, increasing nonpropulsive contractions, increasing the tone of the anal sphincter, and reducing fluid secretion into the intestinal lumen. No tolerance to these effects develops. To reduce constipation, all patients should increase dietary fiber and fluid.

However, most patients also need pharmacologic help. Options include stool softeners (eg, docusate), stimulant laxatives (eg, senna), osmotic laxatives (eg, sodium phosphate), and methyl-naltrexone [Relistor], which blocks opioid receptors in the intestine. For prophylaxis of constipation, current guidelines recommend daily therapy with a combination product, such as Senokot-S, which contains both senna and docusate. Osmotic laxatives are reserved for severe

296

297

constipation. Methyl-naltrexone [Relistor] is indicated only for constipation in patients with end-stage disease. Drugs with anticholinergic properties (eg, tricyclic antidepressants, antihistamines) can exacerbate opioid-induced constipation (by further depressing bowel function), and hence should be avoided.

30.4.2.8.3 Sedation.

Sedation is common early in therapy, but tolerance develops quickly. If sedation persists, it can be reduced by giving smaller doses of the opioid more frequently, while keeping the total daily dose the same. This dosing schedule decreases peak opioid levels, and thereby reduces excessive CNS depression. If necessary, sedation can be opposed with a CNS stimulant (eg, caffeine, methylphenidate, dextroamphetamine, modafinil).

30.4.2.8.4 Nausea and Vomiting.

Initial doses of opioids may cause nausea and vomiting. Fortunately, tolerance develops rapidly. Nausea and vomiting can be minimized by pretreatment with an antiemetic (eg, prochlorperazine, metoclopramide). A serotonin antagonist (eg, granisetron, ondansetron) may also be tried, but these drugs may increase constipation.

30.4.2.8.5 Other Side Effects.

Opioids promote histamine release, and can thereby cause *itching*, which can be relieved with an antihistamine (eg, diphenhydramine).

Opioids increase the tone in the urinary bladder sphincter, and can thereby cause *urinary retention*. Prostatic hypertrophy and use of anticholinergic drugs will exacerbate the problem. Patients should be monitored for urinary retention and encouraged to void every 4 hours.

Opioids can cause *orthostatic hypotension*. Patients should be informed about symptoms of hypotension (lightheadedness, dizziness) and instructed to sit or lie down if they occur. Orthostatic hypotension can be minimized by moving slowly when changing from a supine or seated position to an upright posture.

Opioid-induced *neurotoxicity* is a recently recognized syndrome. Symptoms include delirium, agitation, myoclonus, and hyperalgesia. Primary risk factors are renal impairment, pre-existing cognitive impairment, and prolonged, high-dose opioid use. Management consists of hydration, dose reduction, and opioid rotation.

TABLE 29-5 Adjuvant Drugs for Cancer Pain

Drug	Usual Adult Dosage	Beneficial Actions
Tricyclic Antidepressants		
Amitriptyline [Elavil]	25–150 mg/day PO	Reduce neuropathic pain
Desipramine [Norpramin]	10–150 mg/day PO	
Doxepin [Sinequan]	25–150 mg/day PO	
Imipramine [Tofranil]	20–100 mg/day PO	
Nortriptyline [Aventyl, Pamelor]	10–150 mg/day PO	
Other Antidepressants		
Bupropion [Wellbutrin]	100–450 mg/day PO	Reduce neuropathic pain
Duloxetine [Cymbalta]	30–60 mg/day PO	
Venlafaxine [Effexor]	37.5–225 mg/day PO	
Antiseizure Drugs		
Carbamazepine [Tegretol]	200–1600 mg/day PO	Reduce neuropathic pain
Gabapentin [Neurontin]	300–3600 mg/day PO	
Lamotrigine [Lamictal]	25–400 mg/day PO	
Phenytoin [Dilantin]	300–500 mg/day PO	
Pregabalin [Lyrica]	100–600 mg/day PO	
Local Anesthetics/Antidysrhythmics		
Lidocaine	5 mg/kg/day IV or subQ	Reduce neuropathic pain
Mexiletine [Mexitil]	450–600 mg/day PO	
CNS Stimulants		
Dextroamphetamine [Dexedrine]	5–10 mg/day PO	Enhance analgesia and reduce sedation from opioids
Methylphenidate [Ritalin]	10–15 mg/day PO	
Antihistamine		
Hydroxyzine [Vistaril]	300–450 mg/day IM or 200–400 mg PO	Reduces anxiety, insomnia, and nausea. Said to enhance analgesia, but proof is lacking.
Glucocorticoids		

Dexamethasone [Decadron, others]	16–96 mg/day PO or IV	Reduce pain associated with brain metastases and epidural spinal cord compression
Prednisone [Deltasone, Orasone]	40–100 mg/day PO	
Bisphosphonates		
Etidronate [Didronel]	7.5 mg/kg IV for 3 days	Reduce hypercalcemia and possibly bone pain
Pamidronate [Aredia]	60–90 mg IV once	

297

298

30.4.3 Adjuvant Analgesics

Adjuvant analgesics are used to *complement* the effects of opioids. Accordingly, these drugs are employed in *combination* with opioids—not as substitutes. Adjuvant analgesics can (1) enhance analgesia from opioids, (2) help manage concurrent symptoms that exacerbate pain, and (3) treat side effects caused by opioids. Several of the adjuvants are especially useful for *neuropathic pain*. The adjuvant analgesics differ from opioids in that pain relief is limited and less predictable, and often develops slowly.

Adjuvant agents may be employed at any step on the analgesic ladder. The adjuvants are interesting in that, although they can relieve pain, all of them were developed to treat other conditions (eg, depression, seizures, dysrhythmias). Accordingly, it is important to reassure patients that the adjuvant is being used to alleviate pain, and not for its original purpose. Dosages for the adjuvant analgesics are summarized in [Table 29-5](#).

30.4.3.1 Antidepressants

30.4.3.1.1 Tricyclic Antidepressants.

Amitriptyline [Elavil] and other tricyclic antidepressants (TCAs) can reduce pain of *neuropathic* origin. TCAs have analgesic effects of their own and they enhance the effects of opioids, and may thereby allow a reduction in opioid dosage. As a side benefit, TCAs can elevate mood. Important adverse effects are orthostatic hypotension, sedation, anticholinergic effects (dry mouth, urinary retention, constipation), and weight gain (secondary to improved appetite). Dosing at bedtime takes advantage of sedative effects, and minimizes hypotension during the day. Effects begin in 1 to 2 weeks and reach their maximum in 4 to 6 weeks. The TCAs are discussed at length in [Chapter 32](#).

30.4.3.1.2 Other Antidepressants.

In addition to the tricyclic agents, certain other antidepressants (eg, bupropion, duloxetine, venlafaxine) can help with neuropathic pain.

30.4.3.2 Antiseizure Drugs

Certain antiseizure drugs can help relieve *neuropathic pain*. Lancing pain (sharp, darting pain) is especially responsive, although other forms of neuropathic pain (cramping pain, aching pain, burning pain) also respond. Analgesia is thought to result from suppressing spontaneous neuronal firing. Of the available anticonvulsants, *carbamazepine* [Tegretol] has been used most widely. Because carbamazepine is myelosuppressive, it must be used with caution in patients receiving anticancer drugs that suppress bone marrow function. As discussed in [Chapter 24](#), caution is also needed in patients of Asian descent, owing to an increased risk of severe dermatologic reactions. Recent experience indicates that *gabapentin* [Neurontin] can be very effective, while causing fewer side effects than carbamazepine. Dosage should be low initially (100 mg once a day) and then gradually increased; dosages as high as 1200 mg 3 times a day have been employed. The anticonvulsants are discussed at length in [Chapter 24](#).

30.4.3.3 Local Anesthetics/Antidysrhythmics

Lidocaine (a local anesthetic and antidysrhythmic) and *mexiletine* (an antidysrhythmic related to lidocaine) are considered second-line agents for *neuropathic pain*. Intravenous infusion of lidocaine produces analgesia in 10 to 15 minutes. The drug may be most appropriate for rapidly escalating neuropathic pain. Both lidocaine and mexiletine are discussed in [Chapter 48](#) (Antidysrhythmic Drugs). Lidocaine is also discussed in [Chapter 26](#) (Local Anesthetics).

30.4.3.4 CNS Stimulants

The CNS stimulants, such as *dextroamphetamine* [Dexedrine] and *methylphenidate* [Ritalin], have two beneficial effects: they can enhance opioid-induced analgesia and they can counteract opioid-induced sedation. In addition, they can be used for rapid elevation of mood. Principal adverse effects are weight loss (because of appetite suppression) and insomnia (because of CNS stimulation). To minimize interference with sleep, dosing late in the day should be avoided. The CNS stimulants are discussed in [Chapter 36](#).

30.4.3.5 Antihistamines

Hydroxyzine [Vistaril], an antihistamine, promotes drowsiness and reduces anxiety. Although widely believed to enhance analgesia, proof is lacking. Drawbacks include worsening of constipation, urinary retention, and cognitive impairment. The antihistamines are discussed in [Chapter 69](#).

30.4.3.6 Glucocorticoids

Although glucocorticoids lack direct analgesic actions, they can help manage painful cancer-related conditions. Because glucocorticoids can reduce cerebral and spinal edema, they are essential for the emergency management of elevated intracranial pressure and epidural spinal cord compression. Similarly, glucocorticoids are part of the standard therapy for tumor-induced spinal cord compression. In addition to these benefits, glucocorticoids can improve appetite and impart a general sense of well-being; both actions help in managing anorexia (loss of appetite) and cachexia (weakness and emaciation) associated with terminal illness.

Glucocorticoids are very safe when used short term (even in high doses) and very dangerous when used long term (even in low doses). In particular, long-term therapy can cause adrenal insufficiency, osteoporosis, glucose intolerance (hyperglycemia), increased vulnerability to infection, thinning of the skin, and, possibly, peptic ulcer disease (PUD). Therapy with NSAIDs augments the risk of PUD. The risk of osteoporosis can be reduced by giving calcium supplements and vitamin D along with calcitonin or a bisphosphonate (eg, etidronate). The glucocorticoids are discussed in [Chapter 71](#).

30.4.3.7 Bisphosphonates

Bisphosphonates, such as *etidronate* [Didronel] and *pamidronate* [Aredia], can reduce cancer-related *bone pain* in some patients. Bone pain is common when cancers metastasize to bone. The cause of pain may be tumor-induced bone resorption, which can also cause hypercalcemia, osteoporosis, and related fractures. Bisphosphonates inhibit bone resorption and are approved for treating hypercalcemia of malignancy—but not bone pain. However, when these drugs were given to treat hypercalcemia, many patients reported a reduction in bone pain, although others did not. Hence, although these drugs appear promising, their use for management of bone pain is still considered investigational. The bisphosphonates are discussed in [Chapter 74](#).

298

30.5 NONDRUG THERAPY**30.5.1 Invasive Procedures**

Invasive therapies are the last resort for relieving intractable pain. Hence, for most patients, all other options should be exhausted first.

30.5.1.1 Neurolytic Nerve Block

The goal of this procedure is to destroy neurons that transmit pain from a limited area, thereby providing permanent pain relief. Nerve destruction is accomplished through local injection of a neurolytic (neurotoxic) substance, typically alcohol or phenol. To ensure that the right nerves are destroyed, reversible nerve block is done first, using a local anesthetic. If the local anesthetic relieves the pain, a neurolytic agent is then applied to the same site. Neurolytic nerve block can eliminate pain in up to 80% of patients. However, even if pain relief is only partial, the procedure can still permit some reduction in opioid dosage, and can thereby decrease side effects, such as sedation and constipation. When nerve block is successful and opioids are discontinued, opioid dosage should be tapered gradually to avoid withdrawal. Nerve block is not without risk. Potential complications include hypotension, paresis (slight paralysis), paralysis, and disruption of bowel and bladder function (eg, diarrhea, incontinence). The incidence of complications ranges between 0.5% and 2%.

30.5.1.2 Neurosurgery

Neurosurgeons can relieve cancer pain in several ways. They can destroy neurons that transmit pain signals; they can implant opioid infusion systems; and, in a procedure known as neuroaugmentation, they can implant electrodes to stimulate neurons that release endogenous opioid peptides (eg, endorphins). Nerve damage incurred during these surgeries can result in neurologic deficits and new pain. Less than 10% of cancer patients undergo neurosurgery for pain relief.

30.5.1.3 Tumor Surgery

When curative excision of a tumor is not feasible, it may still be appropriate to surgically debulk the tumor with the goal of relieving pain. Unfortunately, palliative debulking only provides temporary relief: Growth of residual cancer cells eventually causes pain to return. Radiation therapy following the surgery may extend pain relief.

30.5.1.4 Radiation Therapy

Radiation therapy relieves pain by causing tumor regression. Palliative treatment can be directed at primary tumors and at metastases anywhere in the body.

Radiation can be delivered in three forms: *brachytherapy* (implanted radioactive pellets), *teletherapy* (external beam radiation), and *intravenous radiopharmaceuticals*. With brachytherapy, cell kill is limited to the immediate area of the implanted pellets; hence, the technique is suited only for localized tumors. With teletherapy, cell kill can be localized or widespread, depending on the size of the beam employed; hence, the technique can be used for both local tumors and metastases. Intravenous radiopharmaceuticals travel throughout the body, and hence are best suited for widespread metastases.

With radiation therapy, as with chemotherapy, damage to normal tissue is dose limiting. Therefore, the challenge is to deliver a dose of radiation that is large enough to kill cancer cells, but not so large that it causes intolerable damage to healthy tissue.

Some side effects of radiation occur early and some are late. Early effects develop during or immediately after radiation exposure. Late reactions develop months or years later. The most common early effects are skin inflammation and lesions of the GI mucosa. Fortunately, in the regimens employed for palliation, these acute effects are generally mild. The most common late reaction is fibrosis, which occurs mainly in tissues that have a limited ability to regenerate (eg, brain, peripheral neurons, lung). Late reactions are of limited concern, however, because most patients die from their cancer before late reactions can develop.

30.5.2 Physical and Psychosocial Interventions

Physical and psychosocial interventions can help reduce pain, but the degree of relief is limited. Accordingly, these interventions should be used only in conjunction with drug therapy—not as substitutes.

30.5.2.1 Physical Interventions

Physical interventions (eg, heat, massage, vibration) can help relieve aches and pains associated with cancer.

30.5.2.1.1 Heat.

Application of heat can benefit the patient in at least two ways: (1) heat promotes vasodilation, and can thereby increase delivery of oxygen and nutrients to damaged tissue; and (2) heat increases elasticity in muscle, and can thereby reduce stiffness. Heat may be applied in several ways, including use of hot compresses, hot water bottles, and electric heating pads. Heat may be harmful to tissues exposed to radiation, and hence these should be avoided. There is some concern that heat may actually stimulate tumor growth and metastatic spread, although convincing data are lacking.

30.5.2.1.2 Cold.

Application of cold can reduce inflammation and muscle spasm. Cold can be applied using ice packs, chemical gel packs, and towels soaked in ice water. Application should last no longer than 15 minutes. Cold should not be applied to areas damaged by radiation. In addition, because cold promotes vasoconstriction, it should be avoided in patients with peripheral vascular disease, Raynaud's phenomenon, and all other disorders that can be exacerbated by vasoconstriction.

30.5.2.1.3 Massage.

Massage is primarily a comfort measure that provides relief through distraction and relaxation. In addition, massage may help ease discomfort at specific sites by increasing local circulation.

30.5.2.1.4 Exercise.

Exercise can reduce subacute and chronic pain by increasing muscle strength and joint mobility. Additional benefits include improved cardiovascular conditioning and restoration of coordination and balance. Range-of-motion exercises can preserve strength and joint function. When patients cannot perform these exercises on their own, family members should be taught to assist. Although weight-bearing exercise is desirable, it should be avoided in patients who are at risk of fractures because of tumor invasion or osteoporosis.

30.5.2.1.5 Acupuncture and Transcutaneous Electrical Nerve Stimulation.

In theory, these techniques reduce pain by stimulating peripheral nerves, which in turn activate central pain-modulating pathways. However, the efficacy of both techniques in cancer patients is uncertain. Acupuncture is performed by inserting solid needles through the

299

300

skin into the underlying muscle. Transcutaneous electrical nerve stimulation (TENS) is performed using low-voltage cutaneous electrodes. Because the efficacy of these techniques is questionable, pain status must be closely monitored.

30.5.2.2 Psychosocial Interventions

Psychosocial interventions can help patients cope by (1) increasing the sense of control over pain, (2) reversing negative thoughts and feelings, and (3) offering social support. Interventions that require learning and practice should be introduced early, so that they can be perfected while the patient still has sufficient energy and strength to learn them.

30.5.2.2.1 Relaxation and Imagery.

The aim of these techniques is to reduce pain by inducing both mental relaxation (alleviation of anxiety) and physical relaxation (release of tension in skeletal muscles). These techniques are easy to learn and require little or no special equipment. Examples include (1) meditation, (2) slow rhythmic breathing, (3) imagining a peaceful scene (eg, gentle waves breaking on a secluded, sunny beach), and (4) active listening to recorded music (eg, tapping a finger in time to an enjoyable tune).

30.5.2.2.2 Cognitive Distraction.

The goal of cognitive distraction is to divert attention away from pain and associated negative emotions. Distractions may be internal or external. Examples of internal distractions include praying, counting or singing in one's head, and repeating positive thoughts, such as "I can cope." External distractions include watching TV, listening to music, and conversing with friends.

30.5.2.2.3 Peer Support Groups.

Support groups composed of other cancer patients can help members cope with pain and all other sequelae of their disease. These groups can provide emotional support, cancer-related information, and a sense of social belonging. Talking with other cancer survivors can be especially helpful for the newly diagnosed. Some support groups welcome patients who have any form of cancer; others are dedicated to just one form of the disease (eg, breast cancer). Resources for locating a support group in your community include (1) the National Coalition for Cancer Survivorship, at 1-877-622-7937; (2) the National Cancer Information Service, at 1-800-4-CANCER; and (3) your local chapter of the American Cancer Society, whose number should be in your phone book.

30.6 PAIN MANAGEMENT IN SPECIAL POPULATIONS

30.6.1 The Elderly

In elderly patients, two issues are of special concern: (1) undertreatment of pain and (2) increased risk of adverse effects. Paradoxically, a third issue—heightedened drug sensitivity—contributes to both problems.

30.6.1.1 Heightened Drug Sensitivity.

The elderly are more sensitive to drugs than are younger adults, owing largely to a decline in organ function. In particular, rates of hepatic metabolism and renal excretion decline with age. As a result, drugs tend to accumulate in the body, causing responses to be more intense and prolonged.

30.6.1.2 Undertreatment of Pain.

Undertreatment is common in the elderly. In addition to the usual reasons (fears about tolerance, addiction, adverse effects, and regulatory actions), the elderly are denied adequate medication for two more: difficulties with assessment and erroneous ideas about old age.

Assessment is made difficult by cognitive impairment (eg, delirium, dementia) and by impairment of vision and hearing. As a result, self-reporting of pain may be inaccurate or even impossible. Because of these obstacles, special effort must be made to help ensure that assessment is accurate. However, because accuracy cannot be guaranteed, frequent reassessment is recommended.

Misconceptions about the elderly contribute to undertreatment. Specifically, providers may believe (incorrectly) that dosage should be low because (1) the elderly are relatively insensitive to pain; (2) if pain occurs, the elderly can tolerate it well; and (3) the elderly are highly sensitive to opioid side effects. The first two concepts have no basis in fact, and therefore must not be allowed to influence treatment. Although there is some truth to the third concept, concern about side effects is no excuse for inadequate dosing.

30.6.1.3 Increased Risk of Side Effects and Adverse Interactions.

For several reasons, elderly patients may experience more side effects than younger adults. As noted, drug elimination in the elderly is impaired, posing a risk that drug levels may rise dangerously high. However, with careful dosing, drug levels can be kept within a range that is

both safe and effective. Drugs with prolonged half-lives (eg, methadone) pose an increased risk of excessive accumulation, and should be avoided.

The risk of gastric ulceration and renal toxicity from NSAIDs is increased in older patients. Gastric erosion can be reduced by concurrent therapy with misoprostol. There is no specific way to prevent renal toxicity. Hence, the best we can do is monitor closely for evolving kidney damage.

Older patients are at increased risk of adverse drug-drug interactions. Why? Because, in addition to the disorder that's causing pain, the elderly are likely to have other disorders, and hence require more drugs than younger adults. The risk of serious injury from drug interactions can be reduced by careful drug selection and by monitoring for potential reactions.

30.6.2 Young Children

Management of cancer pain in children is much like management in adults. The principal difference is that assessment in children is more difficult. In addition, children frequently experience more pain from chemotherapy and other interventions than from the cancer itself.

30.6.2.1 Assessment

Assessment must be tailored to the child's developmental level and personality. Selecting an appropriate assessment method is especially important for children with developmental delays, learning disabilities, and emotional disturbances. Assessment can be greatly facilitated by open communication about pain between the child, family, and healthcare team.

Assessment methods include self-reporting, behavioral observation, and measurement of physiologic parameters (eg, heart rate, blood pressure, respiratory rate, sweating). As stressed earlier, self-reporting is preferred and should be employed whenever appropriate. Behavioral observation is a distant second choice. Because many factors other than pain can alter physiologic parameters, measuring these is the least reliable way to assess pain.

300

301

30.6.2.1.1 Verbal Children.

For children who can verbalize and are over the age of 4 years, self-reporting is the most reliable way to assess pain. Since children rarely claim to have pain that isn't there, there is little risk of error from over-reporting. However, there *is* a significant risk of error from under-reporting. Children may report less pain than they have for several reasons. These include (1) fear that revealing their pain will lead to additional injections and other painful procedures, (2) lack of awareness that we can help their pain go away, (3) a desire to protect

their parents from the knowledge that their cancer is getting worse, and (4) a desire to please. Because the self-report may conceal pain, it can be helpful to supplement the self-report with behavioral observation (see below).

30.6.2.1.2 Preverbal and Nonverbal Children.

Since preverbal and nonverbal children cannot self-report pain, a less reliable method must be used for assessment. The principal alternative is *behavioral observation*. Behavioral cues suggesting pain include vocalization (crying, whining, groaning), facial expression (grimacing, frowning, reduced affect), muscle tension, inability to be consoled, protection of body areas, and reduced activity. The biggest drawback to behavioral observation is the risk of a false-negative conclusion. That is, a child may be in pain although his or her behavior may lead the observer to conclude otherwise. For example, sleeping, watching TV, or laughing may suggest that a child is comfortable. However, these behaviors can actually represent an attempt to control pain. Similarly, although sitting quietly might indicate comfort, it could also mean that moving and talking are painful. When behavioral observation leaves doubt about whether the child is in pain, a trial with an analgesic can help confirm the assessment.

30.6.2.2 Treatment

Therapy of cancer pain in children is essentially the same as in adults. As in adults, drugs are the cornerstone of treatment; nondrug therapies are used only as supplements. Drug selection is guided by the WHO analgesic ladder. Because of the risk of Reye's syndrome, children with influenza or chickenpox should not receive NSAIDs; acetaminophen is a safe alternative. As in adults, oral administration is preferred; more invasive routes should be reserved for patients who cannot take drugs by mouth. Children generally object to rectal administration, and may refuse treatment by this route. Administration with a PCA device is an option for children over the age of 7 years.

Neonates and infants are highly sensitive to drugs, and hence must be treated with special caution. Drug sensitivity occurs for two reasons: (1) the blood-brain barrier is incompletely formed, giving drugs ready access to the CNS; and (2) the kidneys and liver are poorly developed, causing drug elimination to be slow. Because of heightened drug sensitivity, neonates and infants are at increased risk of respiratory depression from opioids. Accordingly, when opioids are given to nonventilated infants, the initial dosage should be very low (about one-third the dosage employed for older children). Furthermore, use of opioids should be accompanied by intensive monitoring of respiration.

30.6.3 Opioid Abusers

When treating cancer pain in opioid abusers, we have two primary obligations: we must try to (1) relieve the pain and (2) avoid giving opioids simply because the patient wants to get high. Both obligations are difficult to meet. Because of the challenge, treatment should be directed by a clinician trained in substance abuse as well as pain management.

Concerns about abuse can result in undertreatment of pain. This must be avoided. Remember, abusers feel pain like everyone else, and therefore need opioids like everyone else. Clinicians must take special care not to withhold opioids because they have confused relief-seeking behavior with drug-seeking behavior. In the end, we have little choice but to base treatment on the patient's self-report of pain. Hence, if the patient tells us that pain is persisting, adequate doses of opioids should be provided.

Because of opioid tolerance, initial doses in abusers must be higher than in nonabusers. To estimate how high the initial dosage should be, we must try to estimate the existing degree of tolerance by interviewing the patient about the extent of opioid use.

As with other adults, drug selection can be guided by the WHO analgesic ladder and the NCCN guidelines. If pain is sufficient to justify opioids, then opioids should be used; nonopioids (NSAIDs and acetaminophen) should not be substituted for opioids out of concern for addiction. If the patient is on methadone maintenance, methadone can be used for the pain. However, because regulations limit the dosage of methadone that drug-abuse clinics can dispense, the increased dosage required to manage pain will have to come from another source. One group of opioids—the agonist-antagonists—will precipitate withdrawal in opioid abusers, and hence must never be prescribed for these patients.

Drug delivery with a PCA device can be helpful. By using a PCA device, we can avoid potential conflicts between the patient and the clinician, who would otherwise have to administer each dose. Excessive dosing can be prevented by setting the PCA device to limit how much opioid the patient can self-administer.

30.7 PATIENT EDUCATION

Patient education is an integral part of cancer pain management. When education is successful, it can help reduce anxiety, dispel hopelessness, facilitate assessment, enhance compliance, decrease complications, provide a sense of control, and enable patients to take an active role in their care. All of these will promote pain relief.

30.7.1 General Issues

Common sense tells us that patient education should be accurate, comprehensive, and understandable. To reinforce communication, information should be presented at least twice and in more than one way. Major topics to discuss are (1) the nature and causes of pain, (2) assessment and the importance of honest self-reporting, and (3) plans for drug and nondrug therapy. Patients should be encouraged to express their fears and concerns about cancer, cancer pain, and pain treatment—and they should be reassured that pain can be effectively controlled in most cases. All patients should receive a written pain management plan. To facilitate ongoing education, patients should be invited to contact care providers whenever they feel the need—be it to discuss specific concerns with treatment or simply to acquire new information. Finally, patients should know when and how to contact the prescriber to report treatment failure, serious side effects, or new pain.

301

302

30.7.2 Drug Therapy

The goal in teaching patients about analgesic drugs is to maximize pain relief and minimize harm. To help achieve this goal, patients should know the following about each drug they take:

- Drug name and therapeutic category
- Dosage size and dosing schedule
- Route and technique of administration
- Expected therapeutic response and when it should develop
- Duration of treatment
- Method of drug storage
- Symptoms of major adverse effects and measures to minimize discomfort and harm
- Major adverse drug-drug and drug-food interactions
- Whom to contact in the event of therapeutic failure, severe adverse effects, or severe adverse interactions

The dosing schedule should be discussed. Patients should understand that PRN dosing is appropriate only if pain is intermittent. When pain is persistent, as it is for most patients, the objective is to *prevent* pain from returning. Hence, dosing should be done on a fixed schedule

ATC, not PRN. However, even with ATC dosing, breakthrough pain can occur. Hence, patients should be taught what dosage to use for rescue treatment.

Fears based on misconceptions about opioids can impair compliance, and can thereby impair pain control. The misconceptions that influence compliance most relate to tolerance, physical dependence, addiction, and side effects. To correct these misconceptions, and thereby dispel fears and improve compliance, the following topics should be discussed:

- *Tolerance*—Some patients fear that, because of tolerance, taking opioids now will decrease their effectiveness later. Hence, to help ensure pain relief in the future, they limit opioid use now, and thus suffer needless pain. These patients should be reassured that, if tolerance does develop, efficacy can be restored by increasing the dosage; tolerance does not mean that efficacy is lost.
- *Physical Dependence and Addiction*—Many patients fear opioid addiction, and hence are reluctant to take these drugs. This fear is based largely on the misconception that physical dependence (which eventually develops in all patients) equals addiction. Patients should be taught that physical dependence is not the same as addiction, and that physical dependence itself is nothing to fear. In addition, they should be taught that the behavior pattern that constitutes addiction rarely develops in people who take opioids in a therapeutic setting.
- *Fear of Severe Side Effects*—Some patients fear that opioids cannot relieve pain without causing severe side effects. These patients should be reassured that, when used correctly, opioids are both safe and effective. The most dangerous side effect—respiratory depression—is uncommon.

The rationale for using an adjuvant analgesic should be discussed. With all of the adjuvants, the objective is to *complement* the effects of opioid and nonopioid analgesics. Adjuvants are not intended to substitute for these drugs. Furthermore, because the drugs we use as adjuvants were originally developed to treat disorders other than pain, the rationale for prescribing specific adjuvants should be explained. For example, when imipramine is prescribed, the patient should understand that the objective is to relieve neuropathic pain and not depression, the disorder for which this drug was originally developed.

Basic issues related to patient education in drug therapy are discussed at length in [Chapter 2](#).

30.7.3 Nondrug Therapy

Education regarding nondrug therapy focuses on psychosocial interventions. Patients should understand that these interventions are intended as complements to analgesics—not as alternatives. Techniques for imagery, relaxation, and distraction should be introduced early in treatment. Family caregivers should be taught how to apply heat and cold and how to give a therapeutic massage. Patients should be informed about the benefits of peer support groups and given assistance in locating one.

30.8 THE JOINT COMMISSION PAIN MANAGEMENT STANDARDS

Thanks to *The Joint Commission* (TJC)—formerly known as the *Joint Commission on Accreditation of Healthcare Organizations* (JCAHO)—undertreatment of pain will no longer be tolerated. For readers who may not know, TJC is the authority that accredits hospitals and other healthcare institutions in the United States. On January 1, 2001, TJC established a set of standards designed to make assessment and management of pain a priority in the nation's healthcare system. Under the standards, *accountability for pain management is shifted from individual practitioners to the institution as a whole*. Compliance is mandatory: Healthcare organizations that fail to meet the standards will lose accreditation. This is serious. Why? Because loss of accreditation would mean loss of insurance reimbursement, and would disqualify teaching hospitals from offering training programs. Hence, thanks to the enforcement power wielded by TJC, healthcare institutions in the United States now have a very real incentive to correct the persistent problem of pain undertreatment. It should be noted that the standards are *not* a guideline on how to treat specific kinds of pain. Rather, they focus on (1) the rights of patients to receive appropriate assessment and management of pain and (2) ways for institutions to establish a formalized, systematic approach to pain management that involves interdisciplinary teams whose members have clearly identified responsibilities. Specific provisions include the following:

- Institutions must recognize assessment and management of pain as a right of all patients.
- Institutions must assess all patients for pain and, if pain is present, identify its nature and intensity.
- Pain must be regarded as a “fifth vital sign,” and pain intensity must be quantified and recorded along with blood pressure, heart rate, respiration, and temperature.
- Institutions must educate patients and their families about pain management, and must provide ready access to educational materials.

302

303

- Institutions must educate clinical staff about assessment and management of pain and must document the education provided.
- Institutions must establish a system to monitor pain management, including a system of checks and balances in which individuals who assess and manage pain are monitored for compliance with standards set by the institution.
- Institutions must monitor patient satisfaction with pain management.
- Discharge planning must provide for continuing reassessment and management of pain.

Where can you find the new standards? Unfortunately, they don't exist as a separate document. Rather, TJC has inserted content related to pain management throughout existing manuals, including the *Comprehensive Accreditation Manual for Hospitals: The Official Handbook*. If you don't want to search through the manuals, a summary is available: *Pain Assessment and Management: An Organizational Approach*, published by Joint Commission Resources, Inc.

30.8.1

KEY POINTS

- Cancer pain can be relieved in 90% of patients.
- Despite the availability of effective treatments, cancer pain goes unrelieved in a large number of patients.
- Barriers to pain relief include inadequate prescriber training, fears of addiction, and a healthcare system that, until recently, has put a low priority on pain management.
- Pain is a personal, subjective experience that encompasses not only the sensory perception of pain but also the patient's emotional and cognitive responses to both the painful sensation and the underlying disease.
- Pain has two major forms: nociceptive pain, which results from injury to tissues, and neuropathic pain, which results from injury to peripheral nerves.
- Management of cancer pain is an ongoing process that involves repeated cycles of assessment, intervention, and reassessment. The goal is to create an individualized treatment plan that can meet the changing needs of the patient.
- The patient self-report is the cornerstone of assessment.

- Behavioral observation is a poor substitute for the patient self-report as a method of assessment.
- Analgesic drugs are the principal modality for treating cancer pain.
- Three groups of analgesics are employed: nonopioid analgesics (NSAIDs and acetaminophen), opioid analgesics, and adjuvant analgesics.
- Drug selection is guided by the WHO analgesic ladder: As pain intensity increases, treatment progresses from nonopioid analgesics to opioids of moderate strength (eg, oxycodone), and then to powerful opioids (eg, morphine). Adjuvant analgesics can be used at any time. If pain is already intense, treatment can start with an opioid, rather than trying a nonopioid first.
- Because nonopioids and opioids relieve pain by different mechanisms, combining an opioid with a nonopioid can be more effective than either drug alone.
- NSAIDs produce their effects by inhibiting cyclooxygenase (COX), an enzyme with two basic forms: COX-1 and COX-2.
- Most NSAIDs inhibit both COX-1 and COX-2. A few NSAIDs are COX-2 selective.
- Principal adverse effects of the NSAIDs are GI injury, acute renal failure, and bleeding. In addition, all NSAIDs except aspirin pose a risk of thrombotic events.
- The COX-2 inhibitors cause less GI injury than the nonselective NSAIDs, but they pose a greater risk of thrombotic events. Accordingly, long-term use of COX-2 inhibitors is no longer recommended.
- By inhibiting platelet aggregation, NSAIDs increase the risk of bruising and bleeding in patients with thrombocytopenia, a common side effect of cancer chemotherapy.
- In contrast to opioids, NSAIDs do not cause tolerance, physical dependence, or psychologic dependence.
- Acetaminophen relieves pain but, unlike the NSAIDs, does not suppress inflammation, inhibit platelet aggregation, or promote gastric ulceration or renal failure.
- Because acetaminophen does not affect platelets, the drug is safe for patients with thrombocytopenia.

- Combining acetaminophen with alcohol, even in moderate amounts, can result in potentially fatal liver damage.
- Opioids are the most effective analgesics available, and hence are the primary drugs for treating moderate to severe cancer pain.
- Opioids are especially effective against nociceptive pain; efficacy against neuropathic pain is limited.
- Opioid analgesics relieve pain by mimicking the actions of endogenous opioid peptides (enkephalins, dynorphins, endorphins), primarily at mu receptors in the CNS.
- The opioids fall into two major groups: pure (full) agonists (eg, morphine) and agonist-antagonists (eg, butorphanol).
- There is a ceiling to pain relief with the agonist-antagonists, but not with the pure agonists. Hence, for patients with cancer, pure agonists are generally preferred.
- For most patients, opioids should be given on a fixed schedule ATC, with additional doses provided for breakthrough pain. PRN dosing should be limited to patients with intermittent pain.
- Oral administration is preferred for most patients; transdermal administration is a good alternative.
- Intramuscular opioids are painful and should be avoided.
- PCA is a desirable method of opioid delivery because it gives patients more control over their treatment.
- An equianalgesia table can facilitate dosage selection when switching from one opioid to another or from one route to another.
- Over time, opioids cause tolerance, a state in which a specific dose produces a smaller effect than it could when treatment began.
- Tolerance develops to analgesia, euphoria, respiratory depression, and sedation, but not to constipation.

- Over time, opioids produce physical dependence, a state in which an abstinence syndrome will occur if the drug is abruptly withdrawn. *Note:* Physical dependence is NOT the same as addiction!
- Addiction is a behavior pattern characterized by continued use of a psychoactive substance despite physical, psychologic, or social harm. *Note:* Addiction is NOT the same as physical dependence!
- Addiction to opioids is very rare in people taking these drugs to relieve pain.
- Misconceptions about opioid addiction are a major cause for undertreatment of cancer pain. Accordingly, we must correct these misconceptions by teaching physicians, nurses, patients, and family members that (1) addiction is not the same as physical dependence and (2) addiction is very rare in therapeutic settings.
- Respiratory depression is the most dangerous side effect of the opioids. Fortunately, significant respiratory depression is rare.
- Respiratory depression is increased by other drugs with CNS-depressant actions (eg, alcohol, barbiturates, benzodiazepines). Accordingly, combining these agents with opioids should be avoided.
- Severe respiratory depression can be reversed with naloxone [Narcan], an opioid antagonist. However, because excessive naloxone will reverse opioid analgesia and precipitate withdrawal, dosage must be titrated carefully.
- Opioids cause constipation in most patients. No tolerance develops. Constipation can be minimized by increasing dietary fiber and fluids, and by taking one or more appropriate drugs (stool softener, stimulant laxative, osmotic laxative, peripherally acting opioid antagonist).
- Use of meperidine (a pure opioid agonist) should be limited to a few days because, with longer use, a toxic metabolite can accumulate.
- Agonist-antagonist opioids must not be given to patients taking pure opioid agonists because doing so could reduce analgesia and precipitate withdrawal.
- Adjuvant analgesics can enhance analgesia from opioids, help manage concurrent symptoms that exacerbate pain, and treat side effects caused by opioids. In addition, several adjuvants are effective against neuropathic pain.

- Adjuvant analgesics are given to complement the effects of opioids. Accordingly, these drugs are employed in combination with opioids—not as substitutes.
- Invasive therapies (nerve blocks, neurosurgical procedures, radiation) are the last resort for relieving intractable pain. All other options should be exhausted before these are tried.
- Physical interventions (eg, heat, cold, massage, acupuncture, TENS) and psychosocial interventions (eg, relaxation, imagery, cognitive distraction, peer support groups) can help reduce pain, but the degree of relief is limited. Accordingly, these interventions should be used only in conjunction with drug therapy—not as substitutes.
- Elderly patients are more sensitive to drugs than are younger adults. The principal reason is drug accumulation secondary to a decline in hepatic metabolism and renal excretion.
- Undertreatment of pain is especially common in the elderly. Undertreatment is inexcusable and must not be allowed.
- The elderly are at risk of increased side effects and adverse drug interactions. Careful drug selection and monitoring can minimize risk.
- Management of cancer pain in children is much like management in adults, except that assessment is more difficult.
- For children who can verbalize and are older than 4 years, self-reporting is the most reliable way to assess pain. The self-report can be supplemented with behavioral observation to enhance accuracy.
- Preverbal and nonverbal children cannot self-report pain, and hence a less reliable assessment method must be used. The principal option is behavioral observation, a method that carries a significant risk of underassessment.
- When opioid abusers get cancer, they feel pain and need relief like everyone else. If pain is sufficient to justify opioids, then opioids should be used; nonopioids should not be substituted for opioids out of concern for addiction.
- Pain management standards from TJC are designed to make pain relief an institutional priority, and hence should greatly reduce the incidence of pain undertreatment.

³¹CHAPTER 30 Drugs for Headache

Headache is a common symptom that can be triggered by a variety of stimuli, including stress, fatigue, acute illness, and sensitivity to alcohol. Many people experience mild, episodic headaches that can be relieved with over-the-counter medications, such as aspirin, acetaminophen [Tylenol], and ibuprofen [Motrin, Advil]. For these individuals, medical intervention is unnecessary. In contrast, some people experience severe, recurrent, debilitating headaches that are frequently unresponsive to aspirin-like drugs. For these individuals, medical attention is merited. In this chapter, we focus on severe forms of headache—specifically, migraine, cluster, and tension-type headaches. Defining characteristics of these headaches are summarized in [Table 30-1](#).

When attempting to treat headache, we must differentiate between headaches that have an identifiable underlying cause (eg, severe hypertension; hyperthyroidism; tumors; infection; disorders of the eye, ear, nose, sinuses, and throat) and headaches that have no identifiable cause (eg, migraine and cluster headaches). Obviously, if there is a clear cause, it should be treated directly.

As we consider drugs for headache, keep three basic principles in mind. First, antiheadache drugs may be used in two ways: to abort an ongoing attack or to prevent an attack from occurring. Second, not all patients with a particular type of headache respond to the same drugs; hence, therapy must be individualized. Third, several of the drugs employed to treat severe headaches (eg, ergotamine, opioids) can cause physical dependence. Accordingly, every effort should be made to keep dependence from developing. If dependence does develop, a withdrawal procedure is needed.

TABLE 30-1 Characteristics of Major Headache Syndromes

	Migraine	Cluster Headache	Tension-type Headache
Pain Location	Unilateral (60%) Bilateral (40%)	Unilateral, behind the right or left eye	Bilateral, in “headband” configuration
Pain Quality	Throbbing	Throbbing, sometimes piercing	Nonthrobbing
Pain Severity	Moderate to severe	Severe	Mild to moderate
Duration	4 hr to 3 days	15 min to 2 hr [*]	30 min to 7 days [†]
Impact of Activity	Makes pain worse	None	None
Associated Symptoms	Nausea, vomiting, photophobia, phonophobia	Conjunctival redness, lacrimation, nasal congestion, rhinorrhea, ptosis, miosis—all on the same side as the headache	Uncommon
Usual Time of Onset	Early morning	Nighttime	Daytime
Preceded by Aura	Yes, in 30% of cases	No	No
Triggers	Many (see Table 30-2)	Usually unidentified	Tension, anxiety
Gender Prevalence	More common in females (3:1)	More common in males (5:1)	Slightly (10%) more common in females
Family History	Likely	Unlikely	Unlikely
Impact on Daily Life	Often substantial	Usually substantial	Minimal

* Headaches occur in clusters that typically consist of one or more headaches (lasting 15 minutes to 2 hours) every day for 2 to 3 months, with a headache-free interval (months to years) between each cluster.

† *Chronic* tension headaches occur at least 15 days per month for 6 months or longer.

305

306

31.1 MIGRAINE HEADACHE I: CHARACTERISTICS AND OVERVIEW OF TREATMENT

31.1.1 Characteristics

Migraine headache is characterized by throbbing head pain of moderate to severe intensity that may be unilateral (60%) or bilateral (40%). Most patients also experience nausea and vomiting, along with sensitivity to light and sound. Physical activity intensifies the pain. Migraines usually

develop in the morning after arising. Pain increases gradually and lasts 4 to 72 hours (median duration 24 hours). On average, attacks occur 1.5 times a month. Precipitating factors include anxiety, fatigue, stress, menstruation, alcohol, weather changes, and tyramine-containing foods ([Table 30-2](#)).

Migraine has two primary forms: migraine *with aura* (formerly called classic migraine) and migraine *without aura* (formerly called common migraine). In migraine with aura, the headache is preceded by visual symptoms (flashes of light, a blank area in the field of vision, zigzag patterns). Of the two forms, migraine without aura is more common, affecting about 70% of migraineurs.

In the United States, 29.5 million people suffer from migraine. The disorder affects nearly 1 in 5 women and 1 in 20 men. About 65% of migraineurs are women in their late teens, 20s, or 30s. With some women, migraine attacks are worse during menstruation but subside during pregnancy and cease after menopause, indicating a hormonal component to the attacks. A family history of the disease is typical.

TABLE 30-2 Factors That Can Precipitate Migraine Headache

Emotions
Stress
Anticipation
Anxiety
Depression
Excitement
Frustration
Foods That Contain:
Tyramine (eg, aged cheeses, Chianti wine)
Nitrates (eg, cured meat products)
Phenylethylamine (eg, chocolate)
Monosodium glutamate (eg, Chinese food, canned soups)
Aspartame (eg, diet sodas, artificial sweeteners)
Yellow food coloring
Drugs
Alcohol
Analgesics (excessive use or withdrawal)
Caffeine (excessive use or withdrawal)
Cimetidine
Cocaine
Estrogens (eg, oral contraceptives)
Nitroglycerin
Weather
Low temperature and low humidity
High temperature and high humidity
Major weather change over 1–2 days
High or low barometric pressure

Others

Carbon monoxide

Hormonal changes in women

Flickering lights/glare

Loud noises

Hypoglycemia

Change in altitude

Migraine is highly debilitating. An attack can prevent participation in social and leisure activities, and can result in lost productivity at home, school, and work. According to the World Health Organization, disability caused by a severe migraine attack equals that caused by quadriplegia, psychosis, or dementia.

31.1.2 Pathophysiology

Migraine headache is a *neurovascular* disorder that involves *dilation* and *inflammation* of intracranial blood vessels. Headache generation begins with neural events that trigger vasodilation. Vasodilation then leads to pain, which leads to further neural activation, thereby amplifying pain-generating signals. Neurons of the trigeminal vascular system, which innervate intracranial blood vessels, are key components.

The exact cause of migraine pain is not completely understood—although vasodilation and inflammation are clearly involved. Available data suggest that two compounds—*calcitonin gene-related peptide* (CGRP) and *serotonin* (5-hydroxytryptamine [5-HT])—play important roles. The role of CGRP is to *promote migraine*, and the role of 5-HT is to *suppress* migraine. Data that implicate CGRP as a cause of migraine include the following:

- Plasma levels of CGRP rise during a migraine attack.
- Stimulation of neurons of the trigeminal vascular system promotes release of CGRP, which in turn promotes vasodilation and release of inflammatory neuropeptides.
- Administration of sumatriptan, a drug that relieves migraine, lowers elevated levels of CGRP.
- Sumatriptan can suppress release of CGRP from cultured trigeminal neurons.

Data that support a suppressive role for 5-HT include the following:

- Plasma levels of 5-HT drop by 50% during a migraine attack.
- Depletion of 5-HT with reserpine can precipitate an attack in migraine-prone individuals.
- Administration of 5-HT or sumatriptan, both of which activate 5-HT receptors, can abort an ongoing attack.

31.1.3 Overview of Treatment

Drugs for migraine are employed in two ways: to abort an ongoing attack and to prevent attacks from occurring. Drugs used to abort an attack fall into two groups: nonspecific analgesics (aspirin-like drugs and opioid analgesics) and migrainespecific drugs (ergot alkaloids and serotonin_{1B/1D} receptor agonists [triptans]). Drugs employed for prophylaxis include beta blockers (eg, propranolol), tricyclic antidepressants (eg, amitriptyline), and antiepileptic drugs (eg, divalproex).

Non drug measures can help. Patients should try to control or eliminate triggers (see [Table 30-2](#)) and should maintain a regular pattern of eating, sleeping, and exercise. Why? Because, in people with migraine, the brain seems to have a low tolerance for the ups and downs of life. Once an attack has begun, the migraineur should retire to a dark, quiet room. Placing an ice pack on the neck and scalp can help.

306

31.2 MIGRAINE HEADACHE II: ABORTIVE THERAPY

307

The objective of abortive therapy is to eliminate headache pain and suppress associated nausea and vomiting. Treatment should commence at the earliest sign of an attack. Because migraine causes GI disturbances (nausea, vomiting, and gastric stasis), oral therapy may be ineffective once an attack has begun. Hence, for treatment of an established attack, a drug that can be administered by injection, inhalation, or rectal suppository may be best. As noted, two types of drugs are used: nonspecific analgesics and migraine-specific agents. Representative drugs are listed in [Table 30-3](#).

Drug selection depends on the intensity of the attack. For mild to moderate symptoms, an *aspirin-like drug* (eg, aspirin, naproxen, acetaminophen) may be sufficient. For moderate to severe symptoms, patients should take a migraine-specific drug—either an *ergot alkaloid* (ergotamine or dihydroergotamine) or a *serotonin_{1B/1D} agonist*. If these agents fail to relieve pain, an *opioid analgesic* (eg, butorphanol, meperidine) may be needed.

Use of abortive medications (both nonspecific and migraine specific) should be limited to 1 or 2 days a week. Why? Because more frequent use can lead to *medication overuse headache* (MOH), also known as drug-induced headache or drug-rebound headache ([Box 30-1](#)).

Antiemetics are important adjuncts to migraine therapy. By reducing nausea and vomiting, these drugs can (1) make the patient more comfortable, and (2) permit therapy with oral antimigraine drugs. Two antiemetics—*metoclopramide* [Reglan] and *prochlorperazine* [Compazine]—are used most often. Of the two, metoclopramide is preferred. Why? Because, in addition to suppressing nausea and vomiting, metoclopramide can reverse gastric stasis caused by the attack, and can thereby facilitate absorption of oral antimigraine drugs. Like metoclopramide, prochlorperazine suppresses nausea and vomiting. However, because of its anticholinergic actions, prochlorperazine can make gastric stasis even worse.

31.2.1 Analgesics

31.2.1.1 Aspirin-like Drugs

Aspirin, acetaminophen, naproxen, and other aspirin-like analgesics can provide adequate relief of mild to moderate migraine attacks. In fact, when combined with metoclopramide (to enhance absorption), aspirin may work as well as sumatriptan, a highly effective antimigraine drug. Moreover, the combination of aspirin plus metoclopramide costs less than sumatriptan and causes fewer adverse effects.

Acetaminophen should be used only in combination with other drugs. It should not be used alone. One effective combination, marketed as *Excedrin Migraine*, consists of acetaminophen, aspirin, and caffeine. An older and less effective product, marketed as *Midrin*, consists of acetaminophen, isometheptene (a sympathomimetic drug), and dichloralphenazone (a sedative).

31.2.1.2 Opioid Analgesics

Opioid analgesics are reserved for severe migraine that has not responded to first-line medications. The agents used most often are *meperidine* [Demerol] and *butorphanol nasal spray* [Stadol NS]. Of the two, butorphanol is preferred. Why? Because meperidine can cause all of the adverse effects associated with other pure opioid agonists (eg, respiratory depression, sedation, constipation) and also has significant abuse potential. These drawbacks are less of a problem with butorphanol.

TABLE 30-3 Migraine Headache: Drugs for Abortive Therapy

Nonspecific Analgesics
Aspirin-like Drugs
Nonsteroidal anti-inflammatory drugs (eg, aspirin, naproxen)
Acetaminophen + Aspirin + Caffeine [Excedrin Migraine]
Opioid Analgesics
Butorphanol [Stadol NS]
Meperidine [Demerol]
Migraine-Specific Drugs
Ergot Alkaloids
Dihydroergotamine [D.H.E. 45, Migranal]
Ergotamine [Ergomar]
Ergotamine + Caffeine [Cafergot, Ercaf]
Selective Serotonin_{1B/1D} Receptor Agonists (Triptans)
Almotriptan [Axert]
Eletriptan [Relpax]
Frovatriptan [Frova]
Naratriptan [Amerge]
Rizatriptan [Maxalt]
Sumatriptan [Imitrex]
Zolmitriptan [Zomig]

31.2.2 Ergot Alkaloids

31.2.2.1 Ergotamine

31.2.2.1.1 Mechanism of Antimigraine Action.

The actions of ergotamine are complex, and the precise mechanism by which the drug aborts migraine attacks is unknown. Ergotamine can alter transmission at serotonergic, dopaminergic, and alpha-adrenergic junctions. Current evidence suggests that antimigraine

effects are related to agonist activity at subtypes of serotonin receptors, specifically 5-HT_{1B} and 5-HT_{1D} receptors. Additional evidence indicates that ergotamine can block inflammation associated with the trigeminal vascular system, perhaps by suppressing release of CGRP. Relief may also be related to vascular effects. In cranial arteries, ergotamine acts directly to promote constriction and reduce the amplitude of pulsations. In addition, the drug can affect blood flow by depressing the vasomotor center.

31.2.2.1.2 Therapeutic Uses.

Ergotamine is a drug of choice for stopping an ongoing migraine attack. It is also used to treat cluster headaches. Because of the risk of dependence (see below), ergotamine should not be taken daily on a long-term basis.

31.2.2.1.3 Pharmacokinetics.

Administration may be oral, sublingual, rectal, or by inhalation. Bioavailability with oral and sublingual administration is low. Bioavailability with rectal and inhalation administration is higher. Although the half-life of ergotamine is only 2 hours, pharmacologic effects can still be observed 24 hours after dosing. Ergotamine undergoes metabolism by CYP3A4 (the 3A4 isozyme of cytochrome P450) followed by excretion in the bile.

31.2.2.1.4 Adverse Effects.

Ergotamine is well tolerated at usual therapeutic doses. The drug can stimulate the chemoreceptor trigger zone, causing *nausea and vomiting* in about 10% of patients, thereby augmenting nausea and vomiting caused by the migraine itself. Concurrent treatment with metoclopramide or a phenothiazine antiemetic (eg, prochlorperazine) can help reduce these responses. Other common side effects include *weakness in the legs, myalgia, numbness and tingling in fingers and toes, angina-like pain, and tachycardia or bradycardia*.

307

308

31.2.2.1.4.1 BOX 30-1 Special Interest Topic

31.2.2.1.4.1.1 MEDICATION OVERUSE HEADACHE: TOO MUCH OF A GOOD THING

People who take headache medicine every day often develop medication overuse headaches (MOHs), also known as drug-rebound headaches or drug-induced headaches. What's a MOH? A chronic headache that develops in response to frequent use of headache medicines, and that resolves days to weeks after the overused drug is withdrawn. The stage for MOH is set when headache drugs are taken too often—

especially if the dosage is high. Once the stage has been set, discontinuing the medication brings on the MOH, which causes the patient to resume taking medicine—thereby setting up a repeating cycle of MOH, followed by medication use and discontinuation, followed by another MOH, and so on. One reason the cycle gets established is that patients don't realize that the drugs they're taking to *treat* headache can, if taken too often, become the *cause* of headache. Failing to recognize MOH for what it is, patients take more and more medicine to make their headaches go away—but only succeed in making MOH worse.

Which drugs can cause MOH? Almost all of the medicines used for abortive headache therapy. Hence, MOH can be caused by overuse of analgesics (aspirin-like drugs, opioids), ergotamine (but not dihydroergotamine), triptans, and caffeine.

How can MOH be treated? The only hope is to stop taking headache medicine. Unfortunately, when medication is withdrawn, headaches will increase for a while. Their duration and intensity depend on the drug that was overused. With triptans, withdrawal headaches are relatively mild and often resolve in a few days. In contrast, with analgesics or ergots, withdrawal headaches are more intense and may persist for 2 weeks or more.

Several measures can decrease the risk of MOH. The most important is limiting the use of abortive medicines. If possible, patients should take these drugs no more than 2 or 3 times a week—and doses should be no higher than actually needed. Alternating headache medicines may help too, since this would limit exposure to any one drug. If headaches begin to occur more than 2 or 3 times a month, prophylactic therapy should be tried. Implementing nondrug measures—stress reduction, avoidance of triggers, getting sufficient sleep, relaxation techniques, and biofeedback—can reduce the need for headache medicines, and can thereby decrease exposure to the drugs that cause MOH.

31.2.2.1.5 Overdose.

Acute or chronic overdose can cause serious toxicity referred to as *ergotism*. In addition to the adverse effects seen at therapeutic doses, overdose can cause ischemia secondary to constriction of peripheral arteries and arterioles: the extremities become cold, pale, and numb; muscle pain develops; and gangrene may eventually result. Patients should be informed about these responses and instructed to seek immediate medical attention if they develop. The risk of ergotism is highest in patients with sepsis, peripheral vascular disease, and renal or hepatic impairment. Management consists of discontinuing ergotamine, followed by measures to

maintain circulation (treatment with anticoagulants, low-molecular-weight dextran, and/or intravenous nitroprusside as appropriate).

31.2.2.1.6 Drug Interactions.

31.2.2.1.6.1 Triptans.

Ergotamine should not be combined with triptans (eg, sumatriptan, zolmitriptan) because a prolonged vasospastic reaction could occur. To avoid this problem, dosing with ergotamine and serotonin agonists should be separated by at least 24 hours.

31.2.2.1.6.2 CYP3A4 Inhibitors.

Potent inhibitors of CYP3A4 can raise ergotamine to dangerous levels, posing a risk of intense vasospasm. Cerebral and/or peripheral ischemia can result. Accordingly, concurrent use with CYP3A4 inhibitors is contraindicated. Drugs to avoid include certain HIV protease inhibitors (eg, ritonavir, nelfinavir), azole antifungal drugs (eg, ketoconazole, itraconazole), and macrolide antibiotics (eg, erythromycin, clarithromycin). Less potent inhibitors (eg, saquinavir, nefazodone, fluconazole, grapefruit juice) should be used with caution.

31.2.2.1.7 Physical Dependence.

Regular daily use of ergotamine, even in moderate doses, can cause physical dependence. The withdrawal syndrome is characterized by headache, nausea, vomiting, and restlessness. That is, withdrawal resembles a migraine attack. Patients who experience these symptoms are likely to resume taking the drug, thereby perpetuating the cycle of dependence. Hospitalization may be required to break the cycle. To avoid dependence, dosage and duration of treatment must be restricted (see dosing guidelines below).

31.2.2.1.8 Contraindications.

Ergotamine is contraindicated for patients with hepatic or renal impairment, sepsis (gangrene has resulted), coronary artery disease (CAD), and peripheral vascular disease, and for those taking potent inhibitors of CYP3A4. In addition, the drug should not be taken during pregnancy. Why? Because its ability to promote uterine contractions can cause fetal harm or abortion. In fact, because of its effects on the uterus, ergotamine is classified in Food and Drug Administration (FDA) Pregnancy Risk Category X: The risk of use by pregnant women clearly outweighs any possible benefits. Warn women of child-bearing age to avoid pregnancy while using this drug.

31.2.2.1.9 Preparations, Dosage, and Administration.

Ergotamine by itself is available in tablets for sublingual use. In addition, ergotamine is available in combination with other drugs for oral and rectal administration.

31.2.2.1.9.1 Sublingual.

Ergotamine tartrate [Ergomar] is supplied in 2-mg tablets for sublingual use. One tablet should be placed under the tongue immediately after onset of aura or headache. If needed, additional tablets can be administered at 30-minute intervals—up to a maximum of 3 tablets/24 hr or 5 tablets/wk.

31.2.2.1.9.2 Oral.

Two oral formulations—Cafergot Tablets and Ercaf Tablets—contain 1 mg ergotamine tartrate and 100 mg caffeine; a third—Cafatine-PB Tablets—contains 30 mg pentobarbital and 0.125 mg belladonna alkaloids in addition to the ergotamine and caffeine. Caffeine is present to enhance vasoconstriction and ergotamine absorption. Pentobarbital provides sedation. Belladonna alkaloids suppress emesis. With all three oral formulations, 2 tablets are taken immediately after onset of aura or headache. One additional tablet can be administered every 30 minutes—up to a maximum of 6 per attack or 10 per week.

308

31.2.2.1.9.3 Rectal.

Suppositories for rectal administration—Cafergot Supps—contain 2 mg ergotamine tartrate and 100 mg caffeine. No more than 2 suppositories should be administered per attack.

309

31.2.2.2 Dihydroergotamine

31.2.2.2.1 Therapeutic Uses.

Parenteral dihydroergotamine [D.H.E. 45, Migranal] is a drug of choice for terminating migraine and cluster headaches. Administration is by nasal spray or injection (IM, IV, subQ). Intranasal dihydroergotamine is less effective than intranasal sumatriptan (see below), but is associated with a lower rate of migraine recurrence.

31.2.2.2.2 Pharmacologic Effects.

The actions of dihydroergotamine are similar to those of ergotamine. Like ergotamine, dihydroergotamine alters transmission at serotonergic, dopaminergic, and alpha-adrenergic junctions. In contrast to ergotamine, dihydroergotamine causes little nausea and vomiting, no

physical dependence, and minimal peripheral vasoconstriction (when used alone). Diarrhea, however, is prominent.

31.2.2.2.3 Pharmacokinetics.

Dihydroergotamine may be administered parenterally or by nasal spray—but not by mouth (owing to extensive first-pass metabolism). In the liver, the drug is metabolized by CYP3A4. An active metabolite (8'-hydroxydihydroergotamine) contributes to therapeutic effects. The half-life of dihydroergotamine plus the active metabolite is about 21 hours.

31.2.2.2.4 Drug Interactions.

As with ergotamine, dihydroergotamine should not be combined with potent inhibitors of CYP3A4, and should not be administered within 24 hours of a serotonin agonist (eg, sumatriptan).

31.2.2.2.5 Contraindications.

Like ergotamine, dihydroergotamine is contraindicated for patients with CAD, peripheral vascular disease, sepsis, pregnancy, and hepatic or renal impairment, and for patients taking triptans or potent inhibitors of CYP3A4.

31.2.2.2.6 Parenteral Administration.

Dihydroergotamine mesylate [D.H.E. 45] is available in solution (1 mg/mL) for IM, IV, and subQ administration.

31.2.2.2.6.1 Intramuscular and Subcutaneous.

The initial dose is 1 mg immediately after onset of symptoms. Additional 1-mg doses may be given hourly—but the total dose should not exceed 3 mg/24 hr for IM or subQ administration, or 2 mg/24 hr for IV administration. With all routes, the total dose should not exceed 6 mg/wk.

31.2.2.2.6.2 Intravenous.

One milligram is given initially, followed by 1 mg an hour later if needed. Dosage should not exceed 2 mg/24 hr or 6 mg/wk.

31.2.2.2.7 Intranasal Administration.

The nasal spray device [Migranal] delivers 0.5 mg of dihydroergotamine per actuation. The dosage is 1 spray in each nostril, repeated in 15 minutes, for a total of 2 mg. Pain is relieved in 60% of patients within 2 hours. The 24-hour recurrence rate is 15%.

31.2.3 Serotonin_{1B/1D} Receptor Agonists (Triptans)

The serotonin_{1B/1D} receptor agonists, also known as *triptans*, are first-line drugs for terminating a migraine attack. These agents relieve pain by constricting intracranial blood vessels and suppressing release of inflammatory neuropeptides. All are well tolerated. Rarely, they cause symptomatic coronary vasospasm.

31.2.3.1 Sumatriptan

Sumatriptan [Imitrex] was the first triptan available and will serve as our prototype for the group. The drug can be administered by mouth, nasal inhalation, or subQ injection.

31.2.3.1.1 Mechanism of Action.

Sumatriptan, an analog of 5-HT, causes selective activation of 5-HT_{1B} and 5-HT_{1D} receptors (5-HT_{1B/1D} receptors). The drug has no affinity for 5-HT₂ or 5-HT₃ receptors, nor does it bind to adrenergic, dopaminergic, muscarinic, or histaminergic receptors. Binding to 5-HT_{1B/1D} receptors on intracranial blood vessels causes vasoconstriction. Binding to 5-HT_{1B/1D} receptors on sensory nerves of the trigeminal vascular system suppresses release of CGRT, a compound that promotes release of inflammatory neuropeptides. As a result, sumatriptan reduces release of inflammatory neuropeptides, and thereby diminishes perivascular inflammation. Both actions—vasoconstriction and decreased perivascular inflammation—help relieve migraine pain.

31.2.3.1.2 Therapeutic Use.

Sumatriptan is taken to abort an ongoing migraine attack. The drug relieves headache and associated symptoms (nausea, photophobia, phonophobia). In clinical trials, sumatriptan gave complete relief to the majority of patients. Beneficial effects begin about 15 minutes after subQ or intranasal dosing, and 30 to 60 minutes after oral dosing. Complete relief occurs in 70% to 80% of patients 2 hours after subQ dosing, in 60% of patients 2 hours after intranasal dosing, and in 50% to 60% of patients 4 hours after oral dosing. Unfortunately, headache returns in about 40% of patients within 24 hours. In comparison, the 24-hour recurrence rate

with dihydroergotamine is only 18%. In patients who respond to subQ sumatriptan, subsequent administration of oral sumatriptan can delay recurrence but does not prevent it. In addition to use in migraine, sumatriptan is approved for cluster headaches.

31.2.3.1.3 Pharmacokinetics.

With oral or intranasal administration, bioavailability is low (about 15%), whereas subQ bioavailability is high (97%). As a result, oral and intranasal doses are considerably higher than subQ doses. Once in the blood, sumatriptan undergoes hepatic metabolism followed by excretion in the urine. The half-life is short—about 2.5 hours.

31.2.3.1.4 Adverse Effects.

Sumatriptan is generally well tolerated. Most side effects are transient and mild. Coronary vasospasm is the biggest concern.

31.2.3.1.4.1 Chest Symptoms.

About 50% of patients experience unpleasant chest symptoms, usually described as “heavy arms” or “chest pressure” rather than pain. These symptoms are transient and *not* related to ischemic heart disease. Possible causes are pulmonary vasoconstriction, esophageal spasm, intercostal muscle spasm, and bronchoconstriction. Patients should be forewarned of these symptoms and reassured they are not dangerous.

31.2.3.1.4.2 Coronary Vasospasm.

Rarely, sumatriptan causes angina secondary to coronary vasospasm. Electrocardiographic changes have been observed in patients with CAD or Prinzmetal's (vasospastic) angina. To reduce the risk of angina, avoid sumatriptan in patients with risk factors for CAD until CAD has been ruled out. These patients include postmenopausal women, men over 40, smokers, and patients with hypertension, hypercholesterolemia, obesity, diabetes, or a family history of CAD. Because of the risk of coronary vasospasm, sumatriptan is contraindicated for patients with a history of ischemic heart disease, myocardial infarction (MI), uncontrolled hypertension, or other heart disease.

31.2.3.1.4.3 Teratogenesis.

Sumatriptan should be avoided during pregnancy. When given daily to pregnant rabbits, the drug was embryolethal at blood levels only 3 times higher than those achieved with a 6-mg subQ injection in humans (a typical dose). Accordingly, unless the prescriber directs otherwise, women should be instructed to avoid the drug if they are pregnant or think they

might be, if they are trying to become pregnant, or if they are not using an adequate form of contraception. Sumatriptan is classified in FDA Pregnancy Risk Category C.

309

31.2.3.1.4.4 Other Adverse Effects.

310

Mild reactions include *vertigo*, *malaise*, *fatigue*, and *tingling sensations*. Transient pain and redness may occur at sites of subQ injection. The intranasal formulation tastes bad and may irritate the nose and throat.

31.2.3.1.5 Drug Interactions.

31.2.3.1.5.1 Ergot Alkaloids and Other Triptans.

Sumatriptan, other triptans, and ergot alkaloids (eg, ergotamine, dihydroergotamine) all cause vasoconstriction. Accordingly, if one triptan is combined with another or with an ergot alkaloid, excessive and prolonged vasospasm could result. Accordingly, sumatriptan should not be used within 24 hours of an ergot derivative or another triptan.

31.2.3.1.5.2 Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) can suppress degradation of sumatriptan, causing its plasma level to rise. Toxicity can result. Accordingly, sumatriptan and MAOIs should not be used together. Furthermore, sumatriptan should not be administered within 2 weeks of stopping an MAOI.

31.2.3.1.6 Preparations, Dosage, and Administration.

31.2.3.1.6.1 Subcutaneous.

Sumatriptan succinate [Imitrex] for subQ injection is available in two strengths: 4 mg and 6 mg. The 4-mg strength is supplied in a STATdose Pen for self-injection. The 6-mg strength is supplied in single-dose vials as well as in a STATdose Pen. The maximum single dose is 6 mg. The maximum that may be given in 24 hours is two 6-mg doses, separated by at least 1 hour.

31.2.3.1.6.2 Oral.

Sumatriptan [Imitrex], by itself, is available in 25-, 50-, and 100-mg tablets for oral use. The usual dose is 25 mg, but doses as high as 100 mg may be tried. If, after 2 hours, the response to the first dose is unsatisfactory, a second dose may be given.

Oral sumatriptan is also available with naproxen in fixed-dose combination tablets marketed as *Treximet* (see below).

31.2.3.1.6.3 Nasal Spray.

Sumatriptan [Imitrex] is available in 5- and 20-mg unit-dose spray devices. The initial dose is 5 or 20 mg, which can be repeated in 2 hours if needed. The maximum 24-hour dose is 40 mg.

31.2.3.2 Other Serotonin $1B/1D$ Receptor Agonists

In addition to sumatriptan, the triptan family includes six other drugs: naratriptan [Amerge], rizatriptan [Maxalt], zolmitriptan [Zomig], almotriptan [Axert], frovatriptan [Frova], and eletriptan [Relpax]. All six are administered orally, and one—zolmitriptan—is also given by nasal spray. All six are essentially equal to sumatriptan with respect to efficacy and safety, and all have the same mechanism of action: activation of 5-HT $_{1B/1D}$ receptors with subsequent intracranial vasoconstriction and decreased perivascular inflammation. All are in FDA Pregnancy Risk Category C. Because the triptans are very similar, selection among them is based on differences in kinetics, side effects, and drug interactions. Dosage and time course are summarized in [Table 30-4](#).

31.2.3.2.1 Zolmitriptan.

Zolmitriptan [Zomig, Zomig ZMT] is indicated for terminating an ongoing migraine attack. The drug is similar to sumatriptan with regard to mechanism, efficacy, time course, side effects, and interactions. Zolmitriptan is formulated for oral and intranasal use. Two oral preparations are available: standard tablets (2.5 and 5 mg), sold as *Zomig*, and melt-in-the-mouth tablets (2.5 mg), sold as *Zomig ZMT*. *Zomig ZMT* dissolves in saliva on the tongue; no water is needed, and hence the drug can be taken conveniently as soon as an aura is perceived. Be aware, however, that onset of effects is no faster than with standard *Zomig* tablets. With either formulation, a 2.5-mg dose produces the most favorable response/tolerability ratio. Intranasal zolmitriptan, sold as *Zomig*, is available in a 5-mg single-dose spray device. Effects begin in 15 minutes, compared with 30 to 45 minutes for the oral products. However, although the nasal spray is faster, it does have two drawbacks: it tastes bad (albeit not as bad as sumatriptan nasal spray) and only one strength (5 mg/spray) is available. If a smaller dose is needed, an oral formulation must be used. Regardless of the formulation used, about 65% of patients respond within 2 hours. If headache persists, dosing can be repeated 2 hours after the initial dose. The maximum dose per 24 hours is 10 mg. Headache recurs in 8% to 32% of patients. Adverse effects are generally mild and transient. Like sumatriptan, zolmitriptan

causes harmless, transient chest discomfort. Of much greater concern, the drug can cause coronary vasospasm, and hence is contraindicated for patients with ischemic heart disease, prior MI, or uncontrolled hypertension. To avoid excessive vasospasm, zolmitriptan should not be administered within 24 hours of an ergot alkaloid or another triptan, or within 2 weeks of stopping an MAOI.

31.2.3.2.2 **Naratriptan.**

Naratriptan [Amerge] is indicated for oral therapy of an ongoing migraine attack. The drug differs from most other triptans in two respects: (1) it has a relatively long half-life (6 hours versus 2 to 3 hours for most other triptans), and (2) it can be safely combined with an MAOI. Onset of effects is slower than with other triptans, but the duration is longer. Because effects persist, the 24-hour migraine recurrence rate may be reduced. Naratriptan is available in 1- and 2.5-mg tablets. The 2.5-mg strength is more effective but causes more side effects. The initial dose is 1 or 2.5 mg. Dosing may be repeated in 4 hours if needed. The maximum daily dose is 5 mg. Like other triptans, naratriptan causes transient chest discomfort. Also like other triptans, the drug can cause coronary vasospasm, and hence is contraindicated for patients with ischemic heart disease, prior MI, or uncontrolled hypertension. To avoid excessive vasospasm, naratriptan should not be administered within 24 hours of an ergot alkaloid or another triptan.

31.2.3.2.3 **Rizatriptan.**

Rizatriptan [Maxalt, Maxalt MLT] is used to terminate an ongoing migraine attack. The drug is similar to sumatriptan with regard to mechanism, efficacy, time course, side effects, and interactions. Rizatriptan is available in two oral formulations: standard tablets [Maxalt] and melt-in-the-mouth tablets [Maxalt MLT] that can be taken without water. Both formulations come in 5- and 10-mg strengths. The initial dose is 5 or 10 mg. Dosing may be repeated in 2 hours if needed. No more than 30 mg should be taken per day. Adverse effects are generally mild and transient. Like other triptans, rizatriptan causes harmless, transient chest discomfort. Also like other triptans, the drug can cause coronary vasospasm, and hence is contraindicated for patients with ischemic heart disease, prior MI, or uncontrolled hypertension. To avoid excessive vasospasm, rizatriptan should not be administered within 24 hours of an ergot alkaloid or another triptan, or within 2 weeks of stopping an MAOI. Propranolol can raise levels of rizatriptan; a dosage reduction may be needed. Rizatriptan may harm the developing fetus: In rats, the drug increased perinatal mortality, reduced learning capacity, and decreased pre and post-weaning weight. However, postmarketing surveillance data suggest that, in humans, rizatriptan may not increase the risk of congenital anomalies or spontaneous abortion. Until more is known, the drug should be used with caution in pregnant women.

31.2.3.2.4 Almotriptan.

Almotriptan [Axert] is indicated for oral therapy of an ongoing migraine attack. The drug is similar to sumatriptan with regard to mechanism, efficacy, and time course—and is better tolerated. Almotriptan is available in 6.25- and 12.5-mg tablets for oral use. The initial dose is 6.25 or 12.5 mg. Dosing can be repeated in 2 hours if headache persists. The maximum dose per 24 hours is 25 mg. Adverse effects are minimal. Like other triptans, almotriptan can cause harmless, transient chest discomfort—but the incidence is very low (only 0.3%). Also like other triptans, the drug can cause coronary vasospasm, and hence is contraindicated for patients with ischemic heart disease, prior MI, or uncontrolled hypertension. To avoid excessive vasospasm, zolmitriptan should not be administered within 24 hours of an ergot alkaloid or another triptan. In contrast to some triptans, almotriptan can be combined safely with an MAOI.

31.2.3.2.5 Frovatriptan.

Frovatriptan [Frova] is indicated for oral therapy of an ongoing migraine attack. The drug is similar to other triptans with regard to mechanism and side effects—but is less effective and has very different kinetics. Effects begin slowly, but are sustained—thanks to the drug's long half-life (26 hours). Although the number of patients responding at 2 hours is low (37% to 46%), rates of headache recurrence are low too (7% to 23%)—lower than with any other triptan. Frovatriptan is available in 2.5-mg tablets. The initial dose is 2.5 mg. If headache recurs after initial relief, dosing can be repeated—but no sooner than 2 hours after the first dose. If there was no response to the first dose, repeat dosing is unlikely to help. The maximum dose per 24 hours is 7.5 mg. Adverse effects are mild and transient. Like sumatriptan, frovatriptan can cause harmless, transient chest discomfort. In addition, the drug can cause coronary vasospasm, and hence is contraindicated for patients with ischemic heart disease, prior MI, or uncontrolled hypertension. To avoid excessive vasospasm, frovatriptan should not be administered within 24 hours of an ergot alkaloid or another triptan. However, it can be used concurrently with an MAOI. Dosage should be reduced in patients receiving propranolol.

31.2.3.2.6 Eletriptan.

Eletriptan [Relpax] is indicated for oral therapy of an ongoing migraine attack. The drug is at least as effective as oral sumatriptan, and may have a faster onset. Eletriptan is available in 20- and 40-mg tablets. The initial dose is 20 or 40 mg, which can be repeated in 2 hours if needed. The total dose in 24 hours should not exceed 80 mg. Like other triptans, eletriptan can

cause transient chest discomfort. Also like other triptans, it can cause coronary vasospasm, and hence is contraindicated for patients with ischemic heart disease, prior MI, or uncontrolled hypertension. To avoid excessive vasospasm, eletriptan should not be administered within 24 hours of an ergot alkaloid or another triptan. However, the drug may be used concurrently with an MAOI. Eletriptan is metabolized in the liver by CYP3A4, and hence strong inhibitors of CYP3A4 (eg, ketoconazole, itraconazole, clarithromycin, ritonavir) 310 may cause toxicity by raising eletriptan levels. Accordingly, eletriptan 311 should not be used within 72 hours of these drugs. Eletriptan levels may also be raised by verapamil, a moderate CYP3A4 inhibitor used for migraine prophylaxis; caution is advised.

TABLE 30-4 Clinical Pharmacology of the Triptans

Drug	Route	Onset (min)	Duration	Half-Life (hr)	Dosage	Comments
Sumatriptan [Imitrex]	Oral	30–60	Short	2.5	25, 50, or 100 mg; may repeat in 2 hr (max. 200 mg/24 hr)	First triptan available. Most widely used and best understood. Available in nasal and subQ formulations, which act faster than oral triptans.
	Nasal	15–20			5 or 20 mg; may repeat in 2 hr (max. 40 mg/24 hr)	
	SubQ	10–15			4–6 mg; may repeat in 1 hr (max. 12 mg/24 hr)	
Almotriptan [Axert]	Oral	30–120	Short	3.1	6.25 or 12.5 mg; may repeat in 2 hr (max. 25 mg/24 hr)	Incidence of chest discomfort (pain, tightness, pressure) is lower than with other triptans. Safe for use with MAOIs.
Frovatriptan [Frova]	Oral	120–180	Long	26	2.5 mg; may repeat in 2 hr	Longest half-life; slowest onset—but also lowest rate of headache recurrence. Decrease dose if combined with propranolol. Safe for use with MAOIs.
Eletriptan [Relpax]	Oral	60	Short	4	20 or 40 mg; may repeat in 2 hr (max. 40 mg/24 hr)	Bioavailability increased by high-fat meal. Safe for use with MAOIs. Don't take within 72 hr of a CYP3A4 inhibitor.

Naratriptan [Amerge]	Oral	60–180	Long	6	1 or 2.5 mg; may repeat in 4 hr (max. 5 mg/24 hr)	Available in melt-in-the-mouth tablets that can be taken without water. Safe for use with MAOIs.
Rizatriptan [Maxalt]	Oral	30–120	Short	2–3	5 or 10 mg; may repeat in 2 hours (max. 30 mg/24 hr)	May be the most consistently effective triptan. Decrease dose if combined with propranolol. Available in melt-in-the-mouth tablets that can be taken without water. Don't combine with an MAOI.
Zolmitriptan [Zomig]	Oral	45	Short	3	2.5 or 5 mg; may repeat in 2 hr (max. 10 mg/24 hr)	Available in melt-in-the-mouth tablets that can be taken without water, and in a fast-acting nasal spray. Don't combine with an MAOI.
	Nasal	15			5 mg; may repeat in 2 hr (max. 10 mg/24 hr)	
MAOI = monoamine oxidase inhibitor.						

31.2.4 Other Abortive Agents

31.2.4.1 Sumatriptan/Naproxen.

Sumatriptan and naproxen (a nonsteroidal anti-inflammatory drug) are now available in a fixed-dose combination under the trade name *Treximet*. Each tablet contains 85 mg sumatriptan and 500 mg naproxen. In clinical trials, the combination was better than either agent alone at relieving the pain of a migraine attack. In addition, the combination effectively reduced nausea and sensitivity to both light and sound. Presumably, the superior benefits of the combination derive from attacking migraine by multiple mechanisms: naproxen reduces pain and inflammation, while sumatriptan causes vasoconstriction and inhibits release of inflammatory neuropeptides.

31.2.4.2 Haloperidol.

Haloperidol [Haldol], a neuroleptic drug developed for schizophrenia, can relieve pain of migraine. In a small, placebo-controlled trial, 5 mg of intravenous haloperidol decreased migraine pain dramatically. As measured on a visual analog scale, pain intensity dropped from 7.7 to 2.2 with haloperidol, versus only 7.2 to 6.3 with placebo. Furthermore, the relapse rate with haloperidol was low—only 3%. The effects of haloperidol are even more impressive considering that most of the patients in this trial had been unresponsive to conventional antimigraine drugs. The major adverse effects of haloperidol were sedation and akathisia (a sense of restlessness and a compelling need to be in motion). The basic pharmacology of haloperidol is discussed in [Chapter 31](#) (Antipsychotic Agents and Their Use in Schizophrenia).

31.2.4.3 Telcagepant.

Telcagepant, an experimental *CGRP receptor antagonist*, has the same efficacy as zolmitriptan—and is better tolerated. In a randomized, double-blind, placebo-controlled trial that enrolled 1388 patients with moderate to severe migraine, 300 mg of telcagepant produced the same reductions in pain, phonophobia, photophobia, and nausea as did 5 mg of zolmitriptan. Furthermore, side effects with telcagepant—which were limited to dry mouth, fatigue, and vomiting—occurred only slightly more often than with placebo.

31.3 MIGRAINE HEADACHE III: PREVENTIVE THERAPY

Prophylactic therapy can reduce the frequency and intensity of migraine attacks. Preventive treatment is indicated for patients who have frequent attacks (two or more a month), attacks that are especially severe, or attacks that do not respond adequately to abortive agents. Preferred drugs for prophylaxis include propranolol, divalproex, and amitriptyline. All three are effective and well tolerated. Major preventive agents are listed in [Table 30-5](#).

31.3.1 Beta Blockers

Beta blockers are preferred drugs for migraine prevention. Of the available beta blockers, *propranolol* [Inderal] is used most often. Treatment can reduce the number and intensity of attacks in 70% of patients. Benefits take a few weeks to develop. The most common side effects are extreme tiredness and fatigue, which occur in about 10% of patients. In addition, the drug can exacerbate symptoms of asthma, and might promote depression. The usual maintenance dosage is 80 to 240 mg/day, taken either as a single dose (using a long-acting formulation) or in two divided doses (using a short-acting formulation). In addition to propranolol, four other beta blockers—*timolol*, *atenolol*, *metoprolol*, and *nadolol*—can help prevent migraine attacks. In contrast, beta

311

312

blockers that possess intrinsic sympathomimetic activity (eg, acebutolol, pindolol) are *not* effective. The basic pharmacology of the beta blockers is discussed in [Chapter 18](#).

TABLE 30-5 Migraine Headache: Drugs for Preventive Therapy

Beta-Adrenergic Blocking Agents
Propranolol [Inderal]
Timolol [Blocadren]
Antiepileptic Drugs
Divalproex [Depakote ER]
Topiramate [Topamax]
Tricyclic Antidepressants
Amitriptyline [Elavil]
Calcium Channel Blockers
Verapamil [Calan]
Flunarizine*
Estrogens (for menstrual migraine)
Estrogen gel
Estrogen patch [Alora, Climara, Esclim, Estraderm, Vivelle]

* Not available in the United States.

31.3.2 Tricyclic Antidepressants

Tricyclic antidepressants can prevent migraine and tension-type headaches in some patients. The underlying mechanism has not been established, but may involve inhibiting reuptake of serotonin, making more of the transmitter available for action. The tricyclic agent used most often is *amitriptyline* [Elavil]. Benefits equal those of propranolol. The dosage range is 25 to 150 mg once daily at bedtime. Since amitriptyline is effective in patients who are not depressed, it would seem that benefits do not depend on elevation of mood. Like other tricyclic antidepressants, amitriptyline can cause hypotension and anticholinergic effects (dry mouth, constipation, urinary retention, blurred vision, tachycardia). Excessive doses can cause dysrhythmias. The basic pharmacology of amitriptyline is discussed in [Chapter 32](#).

31.3.3 Antiepileptic Drugs

Several drugs that were developed for epilepsy can reduce migraine attacks. Proof of efficacy is strongest for divalproex [Depakote ER] and topiramate [Topamax]. Gabapentin [Neurontin] and tiagabine [Gabitril] appear promising, although extensive proof of efficacy is lacking.

31.3.3.1 Divalproex.

Divalproex [Depakote ER], employed first for epilepsy and later for bipolar disorder (manic-depressive illness), is now approved for prophylaxis of migraine too. The drug is a form of valproic acid (see [Chapter 24](#)). Divalproex reduces the incidence of attacks by 50% or more in 30% to 50% of patients. However, when attacks do occur, their intensity and duration are not diminished. In migraineurs, the most common side effect is nausea. Other side effects include fatigue, weight gain, tremor, and reversible hair loss. Potentially fatal pancreatitis and hepatitis occur rarely. Divalproex can cause neural tube defects in the developing fetus, and hence is contraindicated during pregnancy. The drug is available in standard and extended-release (ER) tablets. Only the ER tablets are approved for preventing migraine. The dosage range is 800 to 1500 mg once a day.

31.3.3.2 Topiramate.

Topiramate [Topamax], originally developed for epilepsy, was approved for migraine prophylaxis in 2004. Benefits take several weeks to develop, and appear equal to those of beta blockers, tricyclic antidepressants, or divalproex. However, topiramate costs much more than these drugs. In clinical trials, topiramate reduced migraine frequency by at least 50% in 83% of adolescents and about 50% of adults. The drug also reduced the need for rescue medication. Unfortunately, side effects are common, especially paresthesias, fatigue, and cognitive dysfunction (psychomotor slowing, word-finding difficulty, impairment of concentration and memory). Other side effects include metabolic acidosis and moderate weight loss (owing to anorexia, nausea, and diarrhea). To minimize side effects, dosage should be low initially and then gradually increased. The recommended titration schedule is 25 mg in the evening the first week, 25 mg in the morning and evening the second week, 25 mg in the morning and 50 mg in the evening the third week, and 50 mg in the morning and evening thereafter. The basic pharmacology of topiramate is discussed in [Chapter 24](#).

31.3.4 Estrogens (for Menstrual Migraine)

Menstrual migraine is defined as migraine that routinely occurs within 2 days of the onset of menses. An important trigger is the decline in estrogen levels that precedes menstruation. For

many women, menstrual migraine can be prevented by taking estrogen supplements, which compensate for the premenstrual estrogen drop. Topical preparations—estrogen gel and estrogen patches [eg, Climara, Estraderm]—work well. Effective dosages are 1.5 mg/day for the gel and 100 mg/day for the patches. Dosing is done for 7 days each month, beginning 2 days before the expected attack.

There is evidence that frovatriptan [Frova] can significantly reduce the frequency, intensity, and duration of menstrual migraine. The dosage is 2.5 mg taken once or twice daily for 6 days, beginning 2 days before the expected attack.

31.3.5 Other Drugs for Prophylaxis

31.3.5.1 Calcium Channel Blockers

Of the calcium channel blockers (CCBs) evaluated for migraine prevention, two appear especially useful: *verapamil* and *flunarizine* (a drug not yet available in the United States). Both agents are less effective than propranolol or divalproex, and their effects develop slowly, reaching a maximum in 1 to 2 months. Although CCBs can relieve vasospasm, it is not clear that vasodilation explains antimigraine effects. Another possible mechanism is modulation of neurotransmitter release, a calcium-dependent process that CCBs are known to affect. It is noteworthy that benefits take several weeks to develop, suggesting benefits may result from central nervous system *adaptation* to CCBs, and not directly from blockade of calcium channels on blood vessels or neurons. When used for prophylaxis, CCBs cause side effects in 20% to 60% of patients. Constipation and orthostatic hypotension are most common. The basic pharmacology of CCBs is discussed in [Chapter 44](#).

312

31.3.5.2 Candesartan, an Angiotensin II Receptor Blocker (ARB)

313

For prophylaxis of migraine, candesartan [Atacand] appears about as effective as more established therapies (beta blockers, divalproex, amitriptyline) and is much better tolerated. In a double-blind, placebo-controlled trial, about half of the patients receiving candesartan (16 mg/day) experienced 47% fewer migraine days and 46% fewer migraine hours. Treatment also reduced the need for rescue therapy with triptans and analgesics. Adverse effects were equivalent to those of placebo. How candesartan reduces migraine attacks is unknown. The basic pharmacology of the ARBs is discussed in [Chapter 43](#).

31.3.5.3 Supplements

31.3.5.3.1 Riboflavin.

Riboflavin (vitamin B₂) can reduce the number and severity of migraine attacks, but benefits are modest and develop slowly. In one study, migraineurs with frequent attacks took 400 mg of riboflavin a day. After 3 months, the number of attacks was decreased by 37%. In addition, the average duration of each attack also declined. Side effects were minimal.

31.3.5.3.2 Coenzyme Q-10.

In a preliminary study, daily therapy with coenzyme Q-10 (CoQ-10) produced a significant reduction in the occurrence of migraine attacks. Subjects took 150 mg of CoQ-10 each morning. After 3 months, the number of days on which headaches occurred declined by at least 50% in 61% of study participants. However, although headache frequency declined, headache intensity was not affected. CoQ-10 was well tolerated.

31.3.5.3.3 Butterbur.

Extracts made from the root of *Petasites hybridus*, a plant whose common name is butterbur, can reduce the frequency of migraine attacks. In a double-blind, placebo-controlled trial, about 1 in 5 patients taking 75 mg of extract twice daily experienced a 50% or greater reduction in migraine frequency. The only side effects were mild GI symptoms (eg, nausea, burping, stomach pain). However, butterbur root contains pyrrolizidine alkaloids, which, if not removed during processing, can cause liver damage and cancer. In the study noted, the preparation employed, sold as Petadolex, is pyrrolizidine free.

31.4 CLUSTER HEADACHES

31.4.1 Characteristics

Cluster headaches occur in a series or “cluster” of attacks. Each attack lasts 15 minutes to 2 hours and is characterized by severe, throbbing, unilateral pain in the orbital-temporal area (ie, near the eye). A typical cluster consists of one or two such attacks every day for 2 to 3 months. An attack-free interval of months to years separates each cluster. Along with headache, patients usually experience lacrimation, conjunctival redness, nasal congestion, rhinorrhea, ptosis (drooping eyelid), and miosis (constriction of the pupil)—all on the same side as the headache. Although related to migraine, cluster headaches differ in several ways: (1) they are not preceded by an aura, (2) they do not cause nausea and vomiting, (3) they can be more debilitating, (4) they are less

common and occur mostly in males (5:1), (5) they are not associated with a family history of attacks, and (6) management is different.

31.4.2 Drug Therapy

31.4.2.1 Prophylaxis.

Primary therapy is directed at prophylaxis. Effective agents include *prednisone*, *lithium*, and *verapamil*. High-dose prednisone (40 to 80 mg/day) acts rapidly, producing results in 48 hours. However, because long-term use of glucocorticoids carries serious risks (see [Chapter 71](#)), treatment should stop in 1 to 2 months. Lithium is a drug of choice for preventing chronic cluster headache. Benefits begin in 1 to 2 weeks. To ensure therapeutic effects and minimize toxicity, blood levels of lithium must be monitored. The target range is 0.6 to 1.2 mEq/L. Verapamil (160 to 480 mg/day) is less effective than lithium but safer and easier to use. Prophylactic therapy should be limited to the cluster cycle, and then discontinued when the current cycle is over. Drugs for prophylaxis are listed in [Table 30-6](#).

TABLE 30-6 Drugs Used for Prophylaxis of Cluster Headache

Drug*	Usual Daily Dosage (mg)
Calcium Channel Blockers	
Verapamil [Calan, others]	160–480
Neurostabilizers	
Divalproex [Depakote]	500–1500
Topiramate [Topamax]	50–200
Lithium [Lithobid]	600–1200†
Nonsteroidal Anti-inflammatory Drugs	
Indomethacin	100–150
Naproxen	1000–1500
Glucocorticoids	
Prednisone	40–80
Ergot Alkaloids	
Ergotamine	1.2

* None of the drugs listed is approved by the FDA for cluster headache prophylaxis.

† Dosage is adjusted on the basis of serum lithium levels.

31.4.2.2 Treatment.

If an attack occurs despite preventive therapy, it can be aborted with *oxygen*, *sumatriptan*, or an *ergot preparation*. Inhaling 100% oxygen for 10 minutes or less brings rapid relief to most patients. The mechanism is unknown. Speedy relief can also be achieved with *sublingual* ergotamine tartrate, *intranasal* dihydroergotamine, or *subcutaneous* sumatriptan. Slower relief can be achieved with an ergotamine-caffeine *suppository*. *Oral* ergotamine acts too slowly to be of much help.

31.5 TENSION-TYPE HEADACHE

31.5.1 Characteristics

Tension-type headaches (formerly called muscle-contraction headaches) are the most common headache type. These headaches are characterized by moderate, nonthrobbing pain, usually located in a “headband” distribution. Headache is often associated with scalp formication and a sense of tightness or pressure in the head and neck. Precipitating factors include eye strain, aggravation, frustration, and life's daily stresses. Depressive symptoms (sleep disturbances, including early and frequent awakening) are often present. Tension headaches may be episodic or chronic. By definition, chronic tension-type headaches occur 15 or more days per month for at least 6 months.

31.5.2 Treatment

An acute attack of mild to moderate intensity can be relieved with a nonopioid analgesic: acetaminophen or a nonsteroidal anti-inflammatory drug (eg, aspirin, ibuprofen, naproxen). An analgesic-sedative combination (eg, aspirin-butalbital) may also be used. However, because of their potential for dependence and abuse, these combinations should be reserved for acute therapy of episodic attacks; they are inappropriate for patients with chronic headache syndrome.

For prophylaxis, *amitriptyline* [Elavil], a tricyclic antidepressant, is the drug of choice. Dosing at bedtime will help relieve any depression-related sleep disturbances in addition to protecting against headache. Amitriptyline can cause anticholinergic side effects (eg, dry mouth, constipation) and poses a risk of cardiotoxicity at high doses (see [Chapter 32](#)).

In addition to receiving drugs, patients should be taught how to manage stress. Instruction should include cognitive coping skills and information on relaxation techniques (eg, massage, hot baths, biofeedback, deep muscle relaxation).

31.5.2.1

KEY POINTS

- Migraine is a neurovascular disorder involving dilation and inflammation of intracranial arteries.
- Antimigraine drugs are used in two ways: abortive and prophylactic.
- The goal of abortive therapy is to eliminate headache pain and associated nausea and vomiting.
- The goal of prophylactic therapy is to reduce the incidence and intensity of migraine attacks.
- There are two kinds of drugs for abortive therapy: nonspecific analgesics (aspirin-like drugs and opioids) and migraine-specific drugs (ergot alkaloids and triptans).
- Aspirin-like analgesics (eg, acetaminophen, aspirin, naproxen) are effective for abortive therapy of mild to moderate migraine.

313

- Opioid analgesics (eg, butorphanol) are reserved for severe migraine that has not responded to other drugs.
- Ergotamine is a first-line drug for abortive therapy of severe migraine.
- Overdose with ergotamine can cause ergotism, a serious condition characterized by severe tissue ischemia secondary to generalized constriction of peripheral arteries.
- Ergotamine must not be taken routinely because physical dependence will occur.
- Ergotamine can cause uterine contractions and must not be taken during pregnancy.
- Ergotamine must not be combined with potent inhibitors of CYP3A4, owing to a risk of intense vasoconstriction and associated ischemia.
- Triptans (eg, sumatriptan) are first-line drugs for abortive therapy of moderate to severe migraine.
- Triptans activate 5-HT_{1B/1D} receptors and thereby constrict intracranial blood vessels and suppress release of inflammatory neuropeptides.
- All triptans are available in oral formulations, which have a relatively slow onset. Two triptans—sumatriptan and zolmitriptan—are available in fast-acting formulations (either nasal spray, subQ injection, or both).

314

- Triptans can cause coronary vasospasm, and hence are contraindicated for patients with ischemic heart disease, prior MI, or uncontrolled hypertension.
- Triptans should not be combined with one another or with ergot derivatives because excessive vasoconstriction could occur.
- Prophylactic therapy is indicated for migraineurs who have frequent attacks (two or more a month), especially severe attacks, or attacks that do not respond adequately to abortive agents.
- Propranolol, divalproex, and amitriptyline are preferred drugs for migraine prophylaxis.
- Estrogen supplements can help prevent menstrual-associated migraine.

31.5.2.2

Summary of Major Nursing Implications*

31.5.2.2.1

ERGOTAMINE AND DIHYDROERGOTAMINE

31.5.2.2...

Preadministration Assessment

31.5.2.2...

Therapeutic Goal

Termination of migraine or cluster headache.

31.5.2.2...

Baseline Data.

Determine the age of onset, frequency, location, intensity, and quality (throbbing or nonthrobbing) of headaches as well as the presence or absence of a prodromal aura. Assess for trigger factors (eg, stress, anxiety, fatigue) and for a family history of severe headache.

Assess for possible underlying causes of headache (eg, severe hypertension; hyperthyroidism; infection; tumors; disorders of the eye, ear, nose, sinuses, or throat), which should be treated if present.

31.5.2.2...

Identifying High-Risk Patients

Ergot alkaloids are *contraindicated* in patients with hepatic or renal impairment, sepsis, CAD, or peripheral vascular disease, and for patients who are pregnant, taking triptans, or taking potent inhibitors of CYP3A4.

31.5.2.2... Implementation: Administration

31.5.2.2... Routes

31.5.2.2... Ergotamine Alone.

Sublingual.

31.5.2.2... Ergotamine Plus Caffeine.

Oral, rectal.

31.5.2.2... Dihydroergotamine.

Nasal spray, IM, IV, and subQ.

31.5.2.2... Dosage and Administration

Instruct patients to commence dosing immediately after onset of symptoms.

Nausea and vomiting from the headache and from ergotamine itself may prevent complete absorption of oral ergotamine. Concurrent treatment with metoclopramide or another antiemetic can minimize these effects. (Nausea and vomiting are minimal with dihydroergotamine.)

Ergotamine (but not dihydroergotamine) can cause physical dependence and serious toxicity if dosage is excessive. **Inform patients about the risks of dependence and toxicity and the importance of not exceeding the prescribed dosage.**

31.5.2.2... Implementation: Measures to Enhance Therapeutic Effects

Educate patients in ways to control, avoid, or eliminate trigger factors (eg, stress, fatigue, anxiety, alcohol, tyramine-containing foods).

Teach patients about relaxation techniques (eg, biofeedback, deep muscle relaxation). Advise patients to rest in a quiet, dark room for 2 to 3 hours after drug administration and to apply an ice pack to the neck and scalp.

31.5.2.2...	Ongoing Evaluation and Interventions	
31.5.2.2...	Evaluating Therapeutic Effects	
	Determine the size and frequency of doses used and the extent to which therapy has reduced the intensity and duration of attacks.	
31.5.2.2...	Minimizing Adverse Effects	
31.5.2.2...	Nausea and Vomiting.	
	<i>Ergotamine</i> promotes nausea and vomiting. Minimize these by concurrent therapy with metoclopramide or a phenothiazine-type antiemetic.	314
31.5.2.2...	Ergotism.	315
	Toxicity (ergotism) can result from acute or chronic overdose. Teach patients the early manifestations of ergotism (muscle pain; paresthesias in fingers and toes; extremities become cold, pale, and numb) and instruct them to seek immediate medical attention if they develop. Treat by withdrawing ergotamine and administering drugs (anticoagulants, low-molecular-weight dextran, intravenous nitroprusside) as appropriate to maintain circulation.	
31.5.2.2...	Physical Dependence.	
	<i>Ergotamine</i> can cause physical dependence. Warn patients not to overuse the drug, since physical dependence can result. Teach patients the signs and symptoms of withdrawal (headache, nausea, vomiting, restlessness) and instruct them to inform the prescriber if these develop during a drug-free interval. Patients who become dependent may require hospitalization to bring about withdrawal.	
31.5.2.2...	Abortion.	
	Ergot alkaloids are uterine stimulants that can cause abortion in high doses. Warn women of child-bearing age to avoid pregnancy while using these drugs.	

31.5.2.2... Minimizing Adverse Interactions

31.5.2.2... Inhibitors of CYP3A4.

Ergotamine and *dihydroergotamine* must not be combined with potent inhibitors of CYP3A4, which can raise these drugs to toxic levels, thereby posing a risk of intense vasoconstriction and associated ischemia. Drugs to avoid include certain HIV protease inhibitors (eg, ritonavir, nelfinavir), azole antifungal drugs (eg, ketoconazole, itraconazole), and macrolide antibiotics (eg, erythromycin, clarithromycin).

31.5.2.2.2 SEROTONIN_{1B/1D} RECEPTOR AGONISTS (TRIPTANS)

Almotriptan

Eletriptan

Frovatriptan

Naratriptan

Rizatriptan

Sumatriptan

Zolmitriptan

31.5.2.2... Preadministration Assessment

31.5.2.2... Therapeutic Goal

Termination of migraine headache.

31.5.2.2... Baseline Data

See *Ergotamine and Dihydroergotamine*.

31.5.2.2...

Identifying High-Risk Patients

All triptans are *contraindicated* for patients with ischemic heart disease, prior MI, or uncontrolled hypertension, and for patients taking ergot alkaloids or other triptans. *Sumatriptan*, *rizatriptan*, and *zolmitriptan* are *contraindicated* for patients taking MAOIs.

31.5.2.2...

Implementation: Administration

31.5.2.2...

Routes

31.5.2.2...

Oral.

All triptans.

31.5.2.2...

Subcutaneous.

Sumatriptan.

31.5.2.2...

Intranasal.

Sumatriptan and zolmitriptan.

31.5.2.2...

Dosage and Administration

Instruct patients to administer triptans immediately after onset of symptoms.

Teach patients how to use the sumatriptan auto-injector.

31.5.2.2...

Implementation: Measures to Enhance Therapeutic Effects

Educate patients in ways to control, avoid, or eliminate trigger factors (eg, stress, fatigue, anxiety, alcohol, tyramine-containing foods).

Teach patients biofeedback or another relaxation technique. Advise patients to rest in a quiet, dark room for 2 to 3 hours after drug administration and to apply an ice pack to the neck and scalp.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Determine the size and frequency of doses used and the extent to which therapy has reduced the intensity and duration of attacks.

Minimizing Adverse Effects

Coronary Vasospasm.

All triptans can cause coronary vasospasm with resultant anginal pain. Avoid these drugs in patients with ischemic heart disease, prior MI, or uncontrolled hypertension. In patients with risk factors for CAD, rule out CAD before giving triptans.

Teratogenesis.

Sumatriptan can cause birth defects in laboratory animals, and hence must not be used during pregnancy. *Rizatriptan* may also pose fetal risk.

Minimizing Adverse Interactions

Ergot Alkaloids and Other Triptans.

Combining a triptan with an ergot alkaloid (eg, ergotamine, dihydroergotamine) or another triptan can cause prolonged vasospasm. Do not administer a triptan within 24 hours of an ergot alkaloid or another triptan.

MAOIs.

MAOIs can intensify the effects of *sumatriptan*, *rizatriptan*, and *zolmitriptan*. Do not give these triptans to patients who are taking MAOIs or who stopped taking MAOIs within the last 14 days.

Propranolol.

Propranolol can raise levels of *frovatriptan* and *rizatriptan*. Dosage of the triptan should be reduced.

* Patient education information is highlighted as **blue text**

³²CHAPTER 31 Antipsychotic Agents and Their Use in Schizophrenia

The antipsychotic agents are a chemically diverse group of compounds used for a broad spectrum of psychotic disorders. Specific indications include schizophrenia, delusional disorders, bipolar disorder, depressive psychoses, and drug-induced psychoses. In addition to their psychiatric applications, the antipsychotics are used to suppress emesis and to treat Tourette's syndrome and Huntington's chorea. As a rule, antipsychotics should not be used to treat dementia in the elderly, owing to a risk of increased mortality.

Since their introduction in the early 1950s, the antipsychotic agents have catalyzed revolutionary change in the management of psychotic illnesses. Before these drugs were available, psychoses were largely untreatable and patients were fated to a life of institutionalization. With the advent of antipsychotic medications, many patients with schizophrenia and other severe psychotic disorders have been able to leave psychiatric hospitals and return to the community. Others have been spared hospitalization entirely. For those who must be institutionalized, antipsychotic drugs have at least reduced suffering.

The antipsychotic drugs fall into two major groups: (1) *first-generation antipsychotics* (FGAs), also known as *conventional antipsychotics*, and (2) *second-generation antipsychotics* (SGAs), also known as *atypical antipsychotics*. All of the FGAs block receptors for dopamine in the central nervous system (CNS). As a result, they all can cause serious movement disorders, known as *extrapyramidal symptoms* (EPS). The SGAs produce only moderate blockade of receptors for dopamine and much stronger blockade of receptors for serotonin. Because dopamine receptor blockade is low, the risk of EPS is low as well. However, although the SGAs carry little risk of EPS, they do pose a risk of *metabolic effects*—weight gain, diabetes, and dyslipidemia—that can cause cardiovascular events and early death. Nonetheless, owing to aggressive marketing and a *perception* of clinical superiority, SGAs have become our most widely prescribed antipsychotic drugs, outselling the FGAs by 10 to 1.

^{32.1}SCHIZOPHRENIA: CLINICAL PRESENTATION AND ETIOLOGY

^{32.1.1} Clinical Presentation

Schizophrenia is a chronic psychotic illness characterized by disordered thinking and a reduced ability to comprehend reality. Symptoms usually emerge during adolescence or early adulthood. In the United States, about 3.2 million people are affected. Diagnostic criteria for schizophrenia are presented in [Table 31-1](#).

32.1.1.1 Three Types of Symptoms

Symptoms of schizophrenia can be divided into three groups: positive symptoms, negative symptoms, and cognitive symptoms. Positive and negative symptoms are summarized in [Table 31-2](#).

32.1.1.1.1 Positive Symptoms and Negative Symptoms.

Positive symptoms can be viewed as an exaggeration or distortion of normal function, whereas negative symptoms can be viewed as a loss or diminution of normal function. Positive symptoms include hallucinations, delusions, agitation, tension, and paranoia. Negative symptoms include lack of motivation, poverty of speech, blunted affect, poor self-care, and social withdrawal. Positive symptoms respond equally to FGAs and SGAs. Negative symptoms may respond better to SGAs.

32.1.1.1.2 Cognitive Symptoms.

Cognitive symptoms include disordered thinking, reduced ability to focus attention, and prominent learning and memory difficulties. Subtle changes may appear years before symptoms become florid, when thinking and speech may be completely incomprehensible to others. Cognitive symptoms may respond better to SGAs than to FGAs.

316

317

TABLE 31-1 DSM-IV-TR Diagnostic Criteria for Schizophrenia

A. Characteristic Symptoms

At least two of the following are present for a significant time during a 1-month period (or less if successfully treated):

- Delusions
- Hallucinations
- Disorganized speech (eg, frequent derailment or incoherence)
- Grossly disorganized or catatonic behavior
- Negative symptoms (affective flattening, alogia, or avolition)

Note: Only one symptom is required if delusions are bizarre or if hallucinations consist of either (1) a voice making running comments on the person's behavior or thoughts or (2) voices conversing with each other.

B. Social/Occupational Dysfunction

For a significant time since the onset of the disturbance, at least one major area of functioning (eg, work, interpersonal relations, self-care) is markedly below the preonset level *or*, if the onset occurred in childhood or adolescence, the individual failed to achieve the expected level of inter-personal, academic, or occupational functioning.

C. Duration

Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (ie, active-phase symptoms). It may also include periods of prodromal or residual symptoms; during these times the disturbance is manifested only by negative symptoms or by at least two symptoms from Criterion A that are present in attenuated form (eg, odd beliefs, unusual perceptual experience).

D. Schizoaffective and Mood Disorder Exclusion

Schizoaffective Disorder and Mood Disorder with Psychotic Features have been ruled out because either (1) no Major Depressive, Manic, or Mixed Episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.

E. Substance/General Medical Condition Exclusion

The disturbance is not due to the direct physiologic effects of a substance (eg, drug of abuse, medication) or a general medical condition.

F. Relationship to a Pervasive Developmental Disorder

If there is a history of Autistic Disorder or another Pervasive Developmental Disorder, the additional diagnosis of Schizophrenia is made only if prominent delusions or hallucinations are present for at least 1 month (or less if successfully treated).

Adapted from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Press, 2000, with permission. Copyright © 2000 American Psychiatric Association.

TABLE 31-2 Positive and Negative Symptoms of Schizophrenia

Positive Symptoms	Negative Symptoms
Hallucinations	Social withdrawal
Delusions	Emotional withdrawal
Disordered thinking	Lack of motivation
Disorganized speech	Poverty of speech
Combateness	Blunted affect
Agitation	Poor insight
Paranoia	Poor judgment
	Poor self-care

32.1.1.2 Acute Episodes

During an acute schizophrenic episode, delusions (fixed false beliefs) and hallucinations are frequently prominent. Delusions are typically religious, grandiose, or persecutory. Auditory hallucinations, which are more common than visual hallucinations, may consist of voices arguing or commenting on one's behavior. The patient may feel controlled by external influences. Disordered thinking and loose association may render rational conversation impossible. Affect may be blunted or labile. Misperception of reality may result in hostility and lack of cooperation. Impaired self-care skills may leave the patient disheveled and dirty. Patterns of sleeping and eating are usually disrupted.

32.1.1.3 Residual Symptoms

After florid symptoms (eg, hallucinations, delusions) of an acute episode remit, less vivid symptoms may remain. These include suspiciousness, poor anxiety management, and diminished judgment, insight, motivation, and capacity for self-care. As a result, patients frequently find it difficult to establish close relationships, maintain employment, and function independently in society. Suspiciousness and poor anxiety management contribute to social

withdrawal. An inability to appreciate the need for continued drug therapy may cause nonadherence, resulting in relapse and perhaps hospital readmission.

317

32.1.1.4 Long-Term Course

318

The long-term course of schizophrenia is characterized by episodic acute exacerbations separated by intervals of partial remission. As the years pass, some patients experience progressive decline in mental status and social functioning. However, many others stabilize, or even improve. Maintenance therapy with antipsychotic drugs reduces the risk of acute relapse, but may fail to prevent long-term deterioration.

32.1.2 Etiology

Although there is strong evidence that schizophrenia has a biologic basis, the exact etiology is unknown. Genetic, perinatal, neurodevelopmental, and neuroanatomic factors may all be involved. Possible primary defects include excessive activation of CNS receptors for dopamine, and insufficient activation of CNS receptors for glutamate. Although psychosocial stressors can precipitate acute exacerbations in susceptible patients, they are not considered causative.

32.2 FIRST-GENERATION (CONVENTIONAL) ANTIPSYCHOTICS: GROUP PROPERTIES

In this section we discuss pharmacologic properties shared by all of the FGAs. Much of our attention focuses on adverse effects. Of these, extrapyramidal side effects are of particular concern. Because of these neurologic side effects, the FGAs are also known as *neuroleptics*.

32.2.1 Classification

The FGAs can be classified by potency or chemical structure. From a clinical viewpoint, classification by potency is more helpful.

32.2.1.1 Classification by Potency

First-generation antipsychotics can be classified as *low potency*, *medium potency*, or *high potency* ([Table 31-3](#)). The low-potency drugs, represented by chlorpromazine [Thorazine], and the high-potency drugs, represented by haloperidol [Haldol], are of particular interest.

It is important to note that, although the FGAs differ from one another in potency, they all have the same ability to relieve symptoms of psychosis. Recall that the term *potency* refers only to the size of the dose needed to elicit a given response; potency implies nothing about the

maximal effect a drug can produce. Hence, when we say that haloperidol is more potent than chlorpromazine, we mean only that the dose of haloperidol required to relieve psychotic symptoms is smaller than the required dose of chlorpromazine; we do not mean that haloperidol can produce greater effects. When administered in therapeutically equivalent doses, both drugs elicit an equivalent antipsychotic response.

If low-potency and high-potency neuroleptics are equally effective, why distinguish between them? The answer is that, although these agents produce identical *antipsychotic* effects, they differ significantly in *side effects*. Hence, by knowing the potency category to which a particular neuroleptic belongs, we can better predict its undesired responses. This knowledge is useful in drug selection and providing patient care and education.

32.2.1.2 Chemical Classification

The FGAs fall into six major chemical categories ([Table 31-4](#)). One of these categories, the phenothiazines, has three subgroups. Drugs in all groups are equivalent with respect to antipsychotic actions. Because of this equivalence, chemical classification is not emphasized in this chapter.

Two chemical categories—*phenothiazines* and *butyrophenones*—deserve special attention. The phenothiazines were the first of the modern antipsychotic agents. Chlorpromazine, our prototype of the low-potency neuroleptics, belongs to this family. The butyrophenones stand out because they are the family to which haloperidol belongs. Haloperidol is the prototype of the high-potency FGAs.

32.2.2 Mechanism of Action

The FGAs block a variety of receptors within and outside the CNS. To varying degrees, they block receptors for dopamine, acetylcholine, histamine, and norepinephrine. There is little question that blockade at these receptors is responsible for the major *adverse effects* of the antipsychotics. However, since the etiology of psychotic illness is unclear, the relationship of receptor blockade to *therapeutic effects* can only be guessed. The current dominant theory suggests that FGA drugs suppress symptoms of psychosis by blocking dopamine₂ (D₂) receptors in the mesolimbic area of the brain. In support of this theory is the observation that all of the FGAs produce D₂ receptor blockade. Furthermore, there is a close correlation between the clinical potency of these drugs and their potency as D₂ receptor antagonists.

32.2.3 Therapeutic Uses

32.2.3.1 Schizophrenia.

Schizophrenia is the primary indication for antipsychotic drugs. These agents effectively suppress symptoms during acute psychotic episodes and, when taken chronically, can greatly decrease the risk of relapse. Initial effects may be seen in 1 to 2 days, but substantial improvement usually takes 2 to 4 weeks, and full effects may not develop for several months. Positive symptoms (eg, delusions, hallucinations) respond better than either negative symptoms (eg, social and emotional withdrawal, blunted affect, poverty of speech) or cognitive dysfunction (eg, disordered thinking, learning and memory difficulties). All of the FGA agents are equally effective, although individual patients may respond better to one FGA than to another. Consequently, selection among these drugs is based primarily on their side effect profiles, rather than on therapeutic effects. It must be noted that antipsychotic drugs do not alter the underlying pathology of schizophrenia. Hence, treatment is not curative—it offers only symptomatic relief. Management of schizophrenia is discussed in depth later in the chapter.

32.2.3.2 Bipolar Disorder (Manic-Depressive Illness).

Most patients with bipolar disorder are managed with a mood-stabilizing agent (eg, lithium, valproic acid). Neuroleptics may be employed acutely, usually in combination with lithium or valproic acid, to help manage patients going through a severe manic phase. Bipolar disorder and its treatment are the subject of [Chapter 33](#).

32.2.3.3 Tourette's Syndrome.

This rare inherited disorder is characterized by severe motor tics, barking cries, grunts, and outbursts of obscene language, all of which are spontaneous and beyond control of the patient. 318

In addition to these core symptoms, patients frequently have symptoms resembling those of obsessive-compulsive disorder (OCD) or attention-deficit/hyperactivity disorder (ADHD). 319
Neuroleptic drugs (eg, pimozide, fluphenazine, haloperidol) are the most effective agents for managing core symptoms. When core symptoms are mild, clonidine is the drug of choice. Symptoms of OCD can be managed with a selective serotonin reuptake inhibitor (eg, fluoxetine [Prozac]). Symptoms of ADHD can be controlled with a CNS stimulant (eg, methylphenidate [Ritalin]).

TABLE 31-3 Antipsychotic Drugs: Relative Potency and Incidence of Side Effects

Incidence of Side Effects								
Drug	Trade Name	Equivalent Oral Dose (mg)*	Extrapyramidal Effects†	Sedation	Ortho-static Hypo-tension	Anticho-linergic Effects	Weight Gain, Diabetes, Dyslipidemia	Significant QT Prolongation
First-Generation (Conventional) Antipsychotics								
Low Potency								
Chlorpromazine	Thorazine	100	Moderate	High	High	Moderate	Moderate	Yes
Thioridazine	Mellaril	100	Low	High	High	High	Moderate	Yes
Medium Potency								
Loxapine	Loxitane	10	Moderate	Moderate	Low	Low	Low	—
Molindone	Moban	10	Moderate	Moderate	Low	Low	Low	—
Perphenazine	generic only	10	Moderate	Moderate	Low	Low	—	—

* Doses listed are the therapeutic equivalent of 100 mg of oral chlorpromazine.

† Incidence refers to *early* extrapyramidal reactions (acute dystonia, parkinsonism, akathisia). The incidence of *late* reactions (tardive dyskinesia) is the same for all traditional antipsychotics; tardive dyskinesia has not been reported with second-generation antipsychotics.

32.2.3.4 Prevention of Emesis.

Neuroleptics suppress emesis by blocking dopamine receptors in the chemoreceptor trigger zone of the medulla. These drugs can be employed to suppress vomiting associated with cancer chemotherapy, gastroenteritis, uremia, and other conditions.

32.2.3.5 Other Applications.

Neuroleptics can be used for *delusional disorders*, *schizoaffective disorder*, and *dementia and other organic mental syndromes* (ie, psychiatric syndromes resulting from organic causes, such as infection, metabolic disorders, poisoning, and structural injury to the brain). In addition, neuroleptics can relieve symptoms of *Huntington's chorea*.

32.2.4 Adverse Effects

The antipsychotic drugs block several kinds of receptors, and hence produce an array of side effects. Side effects associated with blockade of specific receptors are summarized in [Table 31-5](#).

Although antipsychotic agents produce a variety of undesired effects, these drugs are, on the whole, very safe; death from overdose is practically unheard of. Among the many side effects FGAs can produce, the most troubling are the extrapyramidal reactions—especially tardive dyskinesia (TD).

32.2.4.1 Extrapyramidal Symptoms

Extrapyramidal symptoms (EPS) are movement disorders resulting from effects of antipsychotic drugs on the extrapyramidal motor system. The extrapyramidal system is the same neuronal network whose malfunction is responsible for the movement disorders of Parkinson's disease (PD). Although the exact cause of EPS is unclear, blockade of D₂ receptors is strongly suspected.

Four types of EPS occur. They differ with respect to time of onset and management. Three of these reactions—acute dystonia, parkinsonism, and akathisia—occur early in therapy and can be managed with a variety of drugs. The fourth reaction—tardive dyskinesia—occurs late in therapy and has no satisfactory treatment. Characteristics of EPS are summarized in [Table 31-6](#).

The *early* reactions occur *less frequently* with *lowpotency* agents (eg, chlorpromazine) than with high-potency agents (eg, haloperidol). In contrast, the risk of TD is equal with all FGAs.

319

TABLE 31-4 Antipsychotic Drugs: Routes and Dosages

			Usual Total Daily Dose (mg)	
Chemical Group and Generic Name	Trade Name	Route	Short Term	Maintenance
First-Generation (Conventional) Antipsychotics				
Phenothiazine: Aliphatic				
Chlorpromazine	Thorazine	PO, IM, IV, R ⁺ *	200–1000	50–400
Phenothiazine: Piperidine				
Thioridazine	Mellaril	PO	200–800	50–400
Phenothiazine: Piperazine				
Fluphenazine	Prolixin	PO, IM	5–30	1–15
Perphenazine	generic only	PO	12–64	8–24
Trifluoperazine	generic only	PO, IM	10–60	4–30
Thioxanthene				
Thiothixene	Navane	PO	10–60	6–30
Butyrophenone				
Haloperidol	Haldol	PO, IM	5–50	1–5
Dihydroindolone				
Molindone	Moban	PO	40–225	15–100
Dibenzoxazepine				
Loxapine	Loxitane	PO	20–160	20–60
Diphenylbutylpiperadine				
Pimozide	Orap	PO	1–2 [†]	10 [†]
Second-Generation (Atypical) Antipsychotics				
Dibenzodiazepine				
Clozapine	Clozaril, FazaClo	PO	300–900	300–600
Benzisoxazole				
Risperidone	Risperdal	PO, IM	2–4	4–6
Paliperidone	Invega	PO	6	6
Thiobenzodiazepine				

Pharmacology for Nursing Care, 7th Edition

Olanzapine	Zyprexa	PO, IM	5–10	10–20
Dibenzothiozepine				
Quetiapine	Seroquel	PO	50	400–800
Benzisothiazolyl Piperazine				
Ziprasidone	Geodon	PO, IM	40	80–120
Quinolinone				
Aripiprazole	Abilify	PO	10–15	10–15

* R = rectal (suppository).

† Dosage for Tourette's syndrome.

32.2.4.1.1

Acute Dystonia.

Acute dystonia can be both disturbing and dangerous. The reaction develops within the first few days of therapy, and frequently within hours of the first dose. Typically, the patient develops severe spasm of the muscles of the tongue, face, neck, or back. Oculogyric crisis (involuntary upward deviation of the eyes) and opisthotonus (tetanic spasm of the back muscles causing the trunk to arch forward, while the head and lower limbs are thrust backward) may also occur. Severe cramping can cause joint dislocation. Laryngeal dystonia can impair respiration.

Intense dystonia is a crisis that requires rapid intervention. Initial treatment consists of anticholinergic medication (eg, benztropine, diphenhydramine) administered IM or IV. As a rule, symptoms resolve within 5 minutes of IV dosing and within 15 to 20 minutes of IM dosing.

It is important to differentiate between acute dystonia and psychotic hysteria. Why? Because misdiagnosis of acute dystonia as hysteria could result in escalation of antipsychotic dosage, thereby causing the acute dystonia to become even worse.

32.2.4.1.2

Parkinsonism.

Antipsychotic-induced parkinsonism is characterized by bradykinesia, mask-like facies, drooling, tremor, rigidity, shuffling gait, cogwheeling, and stooped posture. Symptoms develop within the first month of therapy and are indistinguishable from those of idiopathic PD.

Neuroleptics cause parkinsonism by blocking dopamine receptors in the striatum. Since idiopathic PD is also due to reduced activation of striatal dopamine receptors (see [Chapter 21](#)), it is no wonder that PD and neuroleptic-induced parkinsonism share the same symptoms.

320

321

TABLE 31-5 Receptor Blockade and Side Effects of Antipsychotic Drugs

Receptor Type	Consequence of Blockade
D ₂ dopaminergic	EPS*; prolactin release
H ₁ histaminergic	Weight gain, sedation
Muscarinic cholinergic	Dry mouth, blurred vision, urinary retention, constipation, tachycardia
Alpha ₁ -adrenergic	Orthostatic hypotension, reflex tachycardia
EPS = extrapyramidal symptoms.	

Neuroleptic-induced parkinsonism is treated with some of the drugs used for idiopathic PD. Specifically, centrally acting *anticholinergic drugs* (eg, benztropine, diphenhydramine) and *amantadine* [Symmetrel] may be employed. Levodopa and direct dopamine agonists (eg, bromocriptine) should be avoided. Why? Because these drugs activate dopamine receptors, and might thereby counteract the beneficial effects of antipsychotic treatment.

Use of antiparkinsonism drugs should not continue indefinitely. Antipsychotic-induced parkinsonism tends to resolve spontaneously, usually within months of its appearance. Accordingly, antiparkinsonism drugs should be withdrawn after a few months to determine if they are still needed.

If parkinsonism is severe, switching to an SGA is likely to help. As discussed below, the risk of parkinsonism with the SGAs is much lower than with FGAs.

32.2.4.1.3 Akathisia.

Akathisia is characterized by pacing and squirming brought on by an uncontrollable need to be in motion. This profound sense of restlessness can be very disturbing. The syndrome usually develops within the first 2 months of treatment. Like other early EPS, akathisia occurs most frequently with high-potency FGAs.

Three types of drugs have been used to suppress symptoms: *beta blockers*, *benzodiazepines*, and *anticholinergic drugs*. Although these drugs can help, reducing antipsychotic dosage or switching to a low-potency FGA may be more effective.

It is important to differentiate between akathisia and exacerbation of psychosis. If akathisia were to be confused with anxiety or psychotic agitation, it is likely that antipsychotic dosage would be increased, thereby making akathisia more intense.

32.2.4.1.4 Tardive Dyskinesia.

Tardive dyskinesia, the most troubling EPS, develops in 15% to 20% of patients during long-term therapy. The risk is related to duration of treatment and dosage size. For many patients, symptoms are irreversible.

Tardive dyskinesia is characterized by involuntary choreoathetoid (twisting, writhing, worm-like) movements of the tongue and face. Patients may also present with lip-smacking movements, and their tongues may flick out in a “fly-catching” motion. One of the earliest manifestations of TD is slow, worm-like movement of the tongue. Involuntary movements that involve the tongue and mouth can interfere with chewing, swallowing, and speaking. Eating difficulties can result in malnutrition and weight loss. Over time, TD produces involuntary movements of the limbs, toes, fingers, and trunk. For some patients, symptoms decline following a dosage reduction or drug withdrawal. For others, TD is irreversible.

The cause of TD is complex and incompletely understood. One theory suggests that symptoms result from excessive *activation* of dopamine receptors. It is postulated that, in response to chronic receptor blockade, dopamine receptors of the extrapyramidal system undergo a functional change such that their sensitivity to activation is increased. Stimulation of these “supersensitive” receptors produces an imbalance in favor of dopamine, and thereby produces abnormal movement. In support of this theory is the observation that symptoms of TD can be reduced (temporarily) by *increasing* antipsychotic dosage, which increases dopamine receptor blockade. (Since symptoms eventually return even though antipsychotic dosage is kept high, dosage elevation cannot be used to treat TD.)

There is no reliable management for TD. Measures that may be tried include gradual withdrawal of anticholinergic drugs, administration of benzodiazepines, and reducing the dosage of the offending FGA. For patients with severe TD, switching to an SGA agent may be beneficial. These drugs do not seem to cause TD, and may actually suppress symptoms in patients who have developed the disorder.

321

322

TABLE 31-6 Extrapyramidal Side Effects of Antipsychotic Drugs

Type of Reaction	Time of Onset	Features	Management
Early Reactions			
Acute dystonia	A few hours to 5 days	Spasm of muscles of tongue, face, neck, and back; opisthotonus	Anticholinergic drugs (eg, benztropine) IM or IV.
Parkinsonism	5–30 days	Bradykinesia, mask-like facies, tremor, rigidity, shuffling gait, drooling, cogwheeling, stooped posture	Anticholinergics (eg, benztropine, diphenhydramine), amantadine, or both. For severe symptoms, switch to a second-generation antipsychotic.
Akathisia	5–60 days	Compulsive, restless movement; symptoms of anxiety, agitation	Reduce dosage or switch to a low-potency antipsychotic. Treat with a benzodiazepine, beta blocker, or anticholinergic drug.
Late Reaction			
Tardive dyskinesia	Months to years	Oral-facial dyskinesias, choreoathetoid movements	Best approach is prevention; no reliable treatment. Discontinue all anticholinergic drugs. Give benzodiazepines. Reduce anti-psychotic dosage. For severe TD, switch to a second-generation antipsychotic.

Since TD has no reliable means of treatment, prevention is the best approach. Antipsychotic drugs should be used in the lowest effective dosage for the shortest time required. After 12 months, the need for continued therapy should be assessed. If drug use must continue, a neurologic evaluation should be done at least every 3 months to detect early signs of TD. For patients with chronic schizophrenia, dosage should be tapered periodically (at least annually) to determine the need for continued treatment.

32.2.4.2 Other Adverse Effects

32.2.4.2.1 Neuroleptic Malignant Syndrome.

Neuroleptic malignant syndrome (NMS) is a rare but serious reaction that carries a 4% risk of mortality—down from 30% in the past, thanks to early diagnosis and intervention. Primary symptoms are “lead pipe” rigidity, sudden high fever (temperature may exceed 41°C), sweating, and autonomic instability, manifested as dysrhythmias and fluctuations in blood pressure. Level of consciousness may rise and fall, the patient may appear confused or mute, and seizures or coma may develop. Death can result from respiratory failure, cardiovascular collapse, dysrhythmias, and other causes. NMS is more likely with high-potency agents than with low-potency agents.

Treatment consists of supportive measures, drug therapy, and immediate withdrawal of antipsychotic medication. Hyperthermia should be controlled with cooling blankets and antipyretics (eg, aspirin, acetaminophen). Hydration should be maintained with fluids. Benzodiazepines may relieve anxiety and help reduce blood pressure and tachycardia. Two drugs—*dantrolene* and *bromocriptine*—may be especially helpful. Dantrolene is a direct-acting muscle relaxant (see [Chapter 25](#)). In patients with NMS, this drug reduces rigidity and hyperthermia. Bromocriptine is a dopamine receptor agonist (see [Chapter 21](#)) that may relieve CNS toxicity.

Resumption of antipsychotic therapy carries a small risk of NMS recurrence. The risk can be minimized by (1) waiting at least 2 weeks before resuming antipsychotic treatment, (2) using the lowest effective dosage, and (3) avoiding high-potency agents. If a second episode occurs, switching to an SGA may be helpful.

32.2.4.2.2 Anticholinergic Effects.

First-generation agents produce varying degrees of muscarinic cholinergic blockade (see [Table 31-3](#)). By blocking muscarinic receptors, these drugs can elicit the full spectrum of anticholinergic responses (dry mouth, blurred vision, photophobia, urinary hesitancy, constipation, tachycardia). Patients should be informed about these responses and taught how to minimize danger and discomfort. As indicated in [Table 31-3](#), anticholinergic effects are more likely with low-potency FGAs than with high-potency FGAs. Anticholinergic effects and their management are discussed in detail in [Chapter 14](#).

32.2.4.2.3 Orthostatic Hypotension.

Antipsychotic drugs promote orthostatic hypotension by blocking α_1 -adrenergic receptors on blood vessels. Alpha-adrenergic blockade prevents compensatory vasoconstriction when the patient stands, thereby causing blood pressure to fall. Patients should be informed about signs of hypotension (lightheadedness, dizziness) and advised to sit or lie down if these occur. In addition, patients should be informed that hypotension can be minimized by moving slowly when assuming an erect posture. With hospitalized patients, blood pressure and pulses should be checked before drug administration and 1 hour after. Measurements should be made while the patient is lying down and again after the patient has been sitting or standing for 1 to 2 minutes. If blood pressure is low, or if pulse rate is high, the drug should be withheld and the prescriber consulted. Hypotension is more likely with low-potency FGAs than with the high-potency FGAs (see [Table 31-3](#)). Tolerance to hypotension develops in 2 to 3 months.

32.2.4.2.4 Sedation.

Sedation is common during the early days of treatment but subsides within a week or so. Neuroleptic-induced sedation is thought to result from blockade of histamine₁ receptors in the CNS. Daytime sedation can be minimized by giving the entire daily dose at bedtime. Patients should be warned against participating in hazardous activities (eg, driving) until sedative effects diminish.

32.2.4.2.5 Neuroendocrine Effects.

Antipsychotics increase levels of circulating prolactin by blocking the inhibitory action of dopamine on prolactin release. Elevation of prolactin levels promotes *gynecomastia* (breast growth) and *galactorrhea* in up to 57% of women. Up to 97% of women experience menstrual irregularities. Gynecomastia and galactorrhea can also occur in males. Since prolactin can promote growth of prolactin-dependent carcinoma of the breast, neuroleptics should be avoided in patients with this form of cancer. (It should be noted that, although FGAs can promote the growth of cancers that already exist, there is no evidence that FGAs actually *cause* cancer.)

32.2.4.2.6 Seizures.

First-generation agents can reduce seizure threshold, thereby increasing the risk of seizure activity. The risk of seizures is greatest in patients with epilepsy and other seizure disorders.

These patients should be monitored, and, if loss of seizure control occurs, the dosage of their antiseizure medication must be increased.

32.2.4.2.7 Sexual Dysfunction.

First-generation agents can cause sexual dysfunction in women and men. In women, these drugs can suppress libido and impair the ability to achieve orgasm. In men, FGAs can suppress libido and cause erectile and ejaculatory dysfunction; the incidence of these effects is 25% to 60%. Drug-induced sexual dysfunction can make treatment unacceptable to sexually active patients, thereby leading to poor compliance. A reduction in dosage or switching to a high-potency FGA may reduce effects on sexual function. Patients should be counseled about possible sexual dysfunction and encouraged to report problems.

32.2.4.2.8 Dermatologic Effects.

Drugs in the *phenothiazine* class can sensitize the skin to ultraviolet light, thereby increasing the risk of severe sunburn. Patients should be warned against excessive exposure to sunlight and advised to apply a sunscreen and wear protective clothing. Phenothiazines can also produce pigmentary deposits in the skin, cornea, and lens of the eye.

Handling antipsychotics can cause contact dermatitis in patients and healthcare workers. Dermatitis can be prevented by avoiding direct contact with these drugs.

32.2.4.2.9 Agranulocytosis.

Agranulocytosis is a rare but serious reaction. Among the FGAs, the risk is highest with chlorpromazine and certain other phenothiazines. Since agranulocytosis severely compromises the ability to fight infection, a white blood cell count (WBC) should be done whenever signs of infection (eg, fever, sore throat) appear. If agranulocytosis is diagnosed, the neuroleptic should be withdrawn. Agranulocytosis reverses upon cessation of treatment.

322

323

32.2.4.2.10 Severe Dysrhythmias.

Four FGAs—*chlorpromazine*, *thioridazine*, *haloperidol*, and *pimozide*—pose a risk of fatal cardiac dysrhythmias. The mechanism is prolongation of the QT interval, an index of cardiac function that can be measured with an electrocardiogram (ECG). As discussed in [Chapter 7](#) (Adverse Drug Reactions and Medication Errors), drugs that prolong the QT interval increase the risk of torsades de pointes, a dysrhythmia that can progress to fatal ventricular fibrillation. To reduce the risk of dysrhythmias, patients should undergo an ECG and serum potassium

determination prior to treatment and periodically thereafter. In addition, they should avoid other drugs that cause QT prolongation (see [Chapter 7](#), [Table 7-2](#)), as well as drugs that can increase levels of the drugs under consideration.

32.2.5 Physical and Psychologic Dependence

Development of physical and psychologic dependence is rare. Patients should be reassured that addiction and dependence are not likely.

Although physical dependence is minimal, abrupt withdrawal of FGAs *can* precipitate a mild abstinence syndrome. Symptoms, which are related to chronic cholinergic blockade, include restlessness, insomnia, headache, gastric distress, and sweating. The syndrome can be avoided by withdrawing FGAs gradually.

32.2.6 Drug Interactions

32.2.6.1 Anticholinergic Drugs.

Drugs with anticholinergic properties will intensify anticholinergic responses to neuroleptics. Patients should be advised to avoid all drugs with anticholinergic actions, including antihistamines and certain over-the-counter sleep aids.

32.2.6.2 CNS Depressants.

Neuroleptics can intensify CNS depression caused by other drugs. Patients should be warned against using alcohol and all other drugs with CNS-depressant actions (eg, antihistamines, benzodiazepines, barbiturates).

32.2.6.3 Levodopa and Direct Dopamine Receptor Agonists.

Levodopa (a drug for Parkinson's disease) may counteract the antipsychotic effects of neuroleptics. Conversely, neuroleptics may counteract the therapeutic effects of levodopa. These interactions occur because levodopa and neuroleptics have opposing effects on receptors for dopamine: Levodopa activates dopamine receptors, whereas neuroleptics cause receptor blockade. Like levodopa, the direct dopamine receptor agonists (eg, bromocriptine) activate dopamine receptors, and hence have interactions with neuroleptics identical to those of levodopa.

32.2.7 Toxicity

First-generation antipsychotics are very safe; death by overdose is extremely rare. With chlorpromazine, for example, the therapeutic index is about 200. That is, the lethal dose is 200 times the therapeutic dose.

Overdose produces hypotension, CNS depression, and extrapyramidal reactions. Extrapyramidal reactions can be treated with antiparkinsonism drugs. Hypotension can be treated with IV fluids plus an alpha-adrenergic agonist (eg, phenylephrine). There is no specific antidote to CNS depression. Excess drug should be removed from the stomach by gastric lavage. Emetics cannot be used because their effects would be blocked by the antiemetic action of the neuroleptic.

32.3 FIRST-GENERATION (CONVENTIONAL) ANTIPSYCHOTICS: INDIVIDUAL AGENTS

All of the FGAs are equally effective at alleviating symptoms of schizophrenia, although individual patients may respond better to one FGA than to another. Differences among these agents relate primarily to side effects (see [Table 31-3](#)). Because the high-potency agents produce fewer side effects than the low-potency agents, high-potency agents are generally preferred.

32.3.1 Low-Potency Agents

32.3.1.1 Chlorpromazine

Chlorpromazine [Thorazine] was the first modern antipsychotic medication and is the prototype for all that followed. None of the newer FGAs is superior at relieving symptoms of psychotic illnesses. Chlorpromazine is a low-potency FGA and belongs to the phenothiazine family of compounds.

32.3.1.1.1 Therapeutic Uses.

Principal indications are schizophrenia and other psychotic disorders. Additional psychiatric indications are schizoaffective disorder and the manic phase of bipolar disorder. Other uses include suppression of emesis and relief of intractable hiccups.

32.3.1.1.2 Pharmacokinetics.

Chlorpromazine may be administered PO, IM, IV, and by rectal suppository. Following oral administration, the drug is well absorbed but undergoes extensive first-pass metabolism. As a

result, oral bioavailability is only 30%. When chlorpromazine is given IM or IV, peak plasma levels are 10 times those achieved with an equal oral dose. Excretion is renal, almost entirely as metabolites.

32.3.1.1.3 Adverse Effects.

The most common adverse effects are sedation, orthostatic hypotension, and anticholinergic effects (dry mouth, blurred vision, urinary retention, photophobia, constipation, tachycardia). Neuroendocrine effects—galactorrhea, gynecomastia, menstrual irregularities—occur occasionally. Photosensitivity reactions are possible, and patients should be advised to minimize unprotected exposure to sunlight. Because chlorpromazine is a low-potency neuroleptic, the risk of early extrapyramidal reactions (dystonia, akathisia, parkinsonism) is relatively low. However, the risk of TD is the same as with all other FGAs. Chlorpromazine lowers seizure threshold. Accordingly, patients with seizure disorders should be especially diligent about taking antiseizure medication. Agranulocytosis and NMS occur rarely.

32.3.1.1.4 Drug Interactions.

Chlorpromazine can intensify responses to CNS depressants (eg, antihistamines, benzodiazepines, barbiturates) and anticholinergic drugs (eg, antihistamines, tricyclic antidepressants, atropine-like drugs).

323

32.3.1.1.5 Preparations, Dosage, and Administration.

324

Chlorpromazine [Thorazine] is available in four formulations: *tablets* (10, 25, 50, 100, and 200 mg), *oral concentrate* (30 and 100 mg/mL), *rectal suppositories* (25 and 100 mg), and *solution for injection* (25 mg/mL).

32.3.1.1.5.1 Oral Therapy.

The initial dosage for adults is 25 mg 3 times a day. Dosage should be gradually increased until symptoms are controlled. The usual maintenance dosage is 400 mg/day. Elderly patients require less drug than younger patients.

32.3.1.1.5.2 Parenteral Therapy.

Parenteral therapy is indicated for acutely psychotic, hospitalized patients. Intramuscular administration is preferred to IV administration. (Intravenous chlorpromazine is highly irritating and generally avoided.) The initial dose is 25 to 50 mg. Dosage may be increased

gradually to a maximum of 400 mg every 4 to 6 hours. Once symptoms are controlled, oral therapy should be substituted for parenteral therapy.

32.3.1.2 Thioridazine

Thioridazine [Mellaril] is a low-potency FGA that prolongs the QT interval, and hence can cause fatal cardiac dysrhythmias. Because of this danger, the drug should be reserved for treating schizophrenia in patients who have not responded to safer agents. The most common adverse effects are sedation, orthostatic hypotension, anticholinergic effects, weight gain, and inhibition of ejaculation. Effects seen occasionally include extrapyramidal reactions (dystonia, parkinsonism, akathisia, TD), galactorrhea, gynecomastia, menstrual irregularities, and photosensitivity reactions. NMS, convulsions, agranulocytosis, and pigmentary retinopathy occur rarely. Principal interactions are with anticholinergic drugs and CNS depressants.

Thioridazine is available in two oral formulations: tablets (10, 15, 25, 50, 100, 150, and 200 mg) and a liquid concentrate (30 and 100 mg/mL). The initial dosage is 50 to 100 mg 3 times a day. Dosage may be gradually increased until symptoms are controlled, but should not exceed 800 mg/day. The usual maintenance dosage is 200 to 800 mg/day in two to four divided doses.

32.3.2 Medium-Potency Agents

32.3.2.1 Loxapine.

Loxapine [Loxitane] is a medium-potency agent indicated only for schizophrenia. The side effect profile is similar to that of fluphenazine (see below). The drug is available in capsules (5, 10, 25, and 50 mg) for oral use. The initial dosage is 10 mg twice a day. Dosage is increased until symptoms are controlled, typically with 60 to 100 mg/day in divided doses. The dosage should be reduced for maintenance therapy; the usual range is 20 to 60 mg/day.

32.3.2.2 Molindone.

Molindone [Moban] is a medium-potency agent approved only for schizophrenia. The most common adverse effects are early extrapyramidal reactions (dystonia, parkinsonism, akathisia) and anticholinergic effects (dry mouth, blurred vision, photophobia, urinary retention, constipation, tachycardia). Effects seen occasionally include sedation, menstrual irregularities, weight loss, and TD. Orthostatic hypotension and NMS occur rarely. Molindone is available in tablets (5, 10, 25, 50, and 100 mg) for oral use. The initial dosage is 50 to 75 mg/day in divided doses. Dosage is then increased until symptoms are controlled. As much as 225 mg/day has been given. Dosage should be reduced to the lowest effective amount for maintenance.

32.3.2.3 Perphenazine.

Perphenazine, formerly available as *Trilafon*, is a medium-potency agent used for schizophrenia and other psychotic disorders. Its side effect profile is like that of fluphenazine (see below). The drug is available in tablets (2, 4, 8, and 16 mg) and an oral concentrate (16 mg/5 mL). The initial dosage is 4 to 8 mg 3 times daily. Once symptoms have been controlled, the dosage should be reduced to the lowest effective amount.

32.3.3 High-Potency Agents

High-potency agents differ from low-potency agents primarily in that high-potency agents cause more early EPS but less sedation, orthostatic hypotension, and anticholinergic effects. Because they cause fewer side effects, high-potency agents are generally preferred for initial therapy.

32.3.3.1 Haloperidol

32.3.3.1.1 Actions and Uses.

Haloperidol [Haldol], a member of the *butyrophenone* family, is the prototype of the highpotency FGAs. Antipsychotic actions are equivalent to those of chlorpromazine. Principal indications are schizophrenia and acute psychosis. In addition, haloperidol is a preferred agent for Tourette's syndrome. The drug is also effective in refractory migraine, although it is not approved for this use.

32.3.3.1.2 Pharmacokinetics.

Haloperidol may be administered PO or IM. Oral bioavailability is about 60%. Hepatic metabolism is extensive. Parent drug and metabolites are excreted in the urine.

32.3.3.1.3 Adverse Effects.

As indicated in [Table 31-3](#), early extrapyramidal reactions (acute dystonia, parkinsonism, akathisia) occur frequently, whereas sedation, hypotension, and anticholinergic effects are uncommon. Note that the incidence of these reactions is opposite to that seen with chlorpromazine and other low-potency agents. The incidence of TD with haloperidol is the same as with the low-potency drugs. Like chlorpromazine, haloperidol occasionally causes gynecomastia, galactorrhea, and menstrual irregularities. NMS, photosensitivity, convulsions, and impotence are rare.

Haloperidol can prolong the QT interval, and hence may pose a risk of *serious dysrhythmias*, especially when given IV and/or in high doses. The drug should be used with caution in patients with dysrhythmia risk factors, including long QT syndrome, hypokalemia or hyperkalemia, or a history of dysrhythmias, heart attack, or severe heart failure. Combined use with other QT-prolonging drugs (eg, amiodarone, erythromycin, quinidine) should be avoided.

32.3.3.1.4 Preparations, Dosage, and Administration.

32.3.3.1.4.1 Preparations.

Haloperidol [Haldol] is available in tablets (0.5, 1, 2, 5, 10, and 20 mg) and a liquid concentrate (2 mg/mL) for oral use. Two injectable forms—*haloperidol lactate* (5 mg/mL) and *haloperidol decanoate* (50 and 100 mg/mL)—are available for parenteral (IM) administration. Haloperidol lactate is employed for acute therapy. Haloperidol decanoate is a depot preparation used for long-term therapy.

32.3.3.1.4.2 Oral Therapy.

The initial dosage for adults is 0.5 to 2 mg taken 2 or 3 times a day. For severe illness, daily doses up to 100 mg have been employed. Once symptoms have been controlled, the dosage should be reduced to the lowest effective amount.

32.3.3.1.4.3 Intramuscular Therapy.

For *acute therapy* of severe psychosis, haloperidol lactate is administered IM in doses of 2 to 5 mg. Dosing may be repeated as often as every 60 minutes, although intervals of 4 to 8 hours may be satisfactory. Once symptoms are under control, the patient should be switched to oral therapy.

For *long-term therapy*, haloperidol decanoate is given once every 4 weeks by deep IM injection—but only to patients already stabilized on oral haloperidol. The initial dose is 10 to 20 times the current oral dose—but no greater than 100 mg. Maintenance doses are 10 to 15 times the previous oral dose.

32.3.3.2 Other High-Potency Agents

32.3.3.2.1 Fluphenazine.

Fluphenazine [Prolixin] is a high-potency agent indicated for schizophrenia and other psychotic disorders. The drug belongs to the piperazine subclass of phenothiazines. As with other high-potency agents, the most common adverse effects are early extrapyramidal reactions (acute dystonia, parkinsonism, akathisia). The risk of TD equals that of other FGAs. Effects seen occasionally include sedation, orthostatic hypotension, anticholinergic effects, gynecomastia, galactorrhea, and menstrual irregularities. NMS, convulsions, and agranulocytosis are rare.

Fluphenazine may be given PO or IM. For oral use, the drug is available in tablets (1, 2.5, 5, and 10 mg) and an elixir (2.5 mg/5 mL). The initial *oral* dosage is 2.5 to 10 mg/day, given in divided doses every 6 to 8 hours. Daily dosages greater than 3 mg are rarely needed, although some patients may require as much as 30 mg. Once symptoms have been controlled, the dosage should be reduced to the lowest effective amount, typically 1 to 5 mg/day taken as a single dose.

Two injectable preparations are available: *fluphenazine hydrochloride* (2.5 mg/mL) and *fluphenazine decanoate* (25 mg/mL). Both are given IM. Fluphenazine hydrochloride is a fast-acting preparation used for acute therapy. The usual dosage is 2.5 to 10 mg/day, given in divided doses every 6 to 8 hours. Fluphenazine decanoate [Prolixin Decanoate] is a depot preparation used for long-term therapy—but only in patients already stabilized on oral fluphenazine (or another phenothiazine antipsychotic). Intramuscular doses are based on the oral dosage. A reasonable conversion ratio is 12.5 mg of IM fluphenazine every 3 weeks for each 10 mg of oral fluphenazine taken daily.

324

325

32.3.3.2.2 Trifluoperazine.

Trifluoperazine (formerly available as *Stelazine*) is a high-potency agent used for schizophrenia and other psychotic disorders. The drug belongs to the piperazine subclass of phenothiazines. The most common adverse effects are early extrapyramidal reactions (acute dystonia, parkinsonism, akathisia). Effects seen occasionally include sedation, orthostatic hypotension, anticholinergic effects, gynecomastia, galactorrhea, menstrual irregularities, and TD. NMS, convulsions, and agranulocytosis are rare. Trifluoperazine is available in tablets (1, 2, 5, and 10 mg) for oral use. Dosing is begun at 2 to 5 mg twice daily, and then increased until an optimal response has been produced, usually with 15 to 20 mg/day.

32.3.3.2.3 Thiothixene.

Thiothixene [Navane] is a high-potency agent approved only for schizophrenia. The most common adverse effects are early extrapyramidal reactions (acute dystonia, parkinsonism, akathisia) and anticholinergic responses. Side effects seen occasionally include galactorrhea, gynecomastia, menstrual irregularities, sedation, orthostatic hypotension, and TD.

Agranulocytosis, NMS, and convulsions are rare. Thiothixene is available in capsules (1, 2, 5, 10, and 20 mg) for oral use. The initial dosage is 2 mg 3 times daily. Dosage is increased until an optimal response has been achieved, usually with 20 to 30 mg/day.

32.3.3.2.4 Pimozide.

Pimozide [Orap] is a high-potency FGA approved only for suppressing symptoms of *Tourette's syndrome*, a rare disorder characterized by severe motor tics and uncontrollable grunts, barking cries, and outbursts of obscene language. Like other neuroleptics, pimozide can cause sedation, postural hypotension, and extrapyramidal reactions (acute dystonia, parkinsonism, akathisia, TD). Pimozide can prolong the QT interval, and hence poses a risk of fatal cardiac dysrhythmias. Sertraline [Zoloft] increases this risk by raising pimozide levels, and hence the two drugs should not be combined. Pimozide is available in tablets (1 and 2 mg) for oral therapy. The initial dosage is 1 to 2 mg/day in divided doses. Dosage should be slowly increased to a maintenance level of 10 mg/day or 0.2 mg/kg/day (whichever is less).

32.4 SECOND-GENERATION (ATYPICAL) ANTIPSYCHOTICS

The second-generation antipsychotics (SGAs), also known as *atypical antipsychotics*, were introduced in the 1990s and quickly took over 90% of the market, owing to the *perception* of superior efficacy and greater safety. However, neither initial perception has held up. Thanks to two large, government-sponsored studies, one in the United States and the other in Great Britain, we now know that, in most cases, SGAs and FGAs are equally effective. As for major side effects, the SGAs *are* less likely to cause EPS, including TD. However, the SGAs carry an even greater risk of their own, namely, potentially fatal metabolic effects—weight gain, diabetes, and dyslipidemia—that can lead to cardiovascular events and premature death. Furthermore, like the FGAs, the SGAs can cause sedation and orthostatic hypotension, and can increase the risk of death when used to treat dementia in the elderly. Lastly, even though SGAs have no clear clinical advantage over FGAs, the SGAs cost *ten* times as much.

In addition to their use in schizophrenia, all of the SGAs are approved for bipolar disorder (see [Chapter 33](#)).

32.4.1 Clozapine

Clozapine [Clozaril, FazaClo] was the first SGA and will serve as our prototype for the group—even though other SGAs are now used more widely. Most authorities agree that clozapine is our most effective drug for schizophrenia, the only indication that clozapine has. However, because it can cause agranulocytosis, clozapine should be reserved for patients who have not responded to safer alternatives.

32.4.1.1 Mechanism of Action

Antipsychotic effects result from blockade of receptors for dopamine and serotonin (5-hydroxytryptamine [5-HT]). Like the FGAs, clozapine blocks D₂ dopamine receptors, but its affinity for these receptors is relatively low. In contrast, the drug produces strong blockade of 5-HT₂ serotonin receptors. Combined blockade of D₂ receptors and 5-HT₂ receptors is thought to underlie therapeutic effects. Low affinity for D₂ receptors may explain why EPS are uncommon. In addition to blocking receptors for dopamine and serotonin, clozapine blocks receptors for norepinephrine (α₁), histamine, and acetylcholine.

32.4.1.2 Therapeutic Use

32.4.1.2.1 Schizophrenia.

Clozapine is approved for relieving general symptoms of schizophrenia and for reducing suicidal behavior in patients with schizophrenia or schizoaffective disorder who are at chronic suicide risk. Because of the risk of fatal agranulocytosis (see below), clozapine should be reserved for patients with severe disease who have not responded to safer alternatives. Like the FGAs, clozapine improves positive symptoms of schizophrenia. However, in contrast to FGAs, clozapine also improves negative symptoms. Patients become more animated, behavior is more socially acceptable, and rates of rehospitalization are reduced. Because the incidence of EPS with clozapine is low, the drug is well suited for patients who have experienced severe EPS with an FGA.

32.4.1.2.2 Levodopa-Induced Psychosis.

Psychosis is a common side effect of levodopa, a drug used for Parkinson's disease (PD). Clozapine is preferred to FGAs for treatment. As discussed in [Chapter 21](#), the movement disorders of PD result from insufficient dopamine in the striatum, a component of the extrapyramidal system. Levodopa reduces symptoms of PD by increasing dopamine

availability. Since FGAs cause profound blockade of dopamine receptors in the striatum, they will intensify symptoms of PD. In contrast, clozapine causes little or no blockade of striatal dopamine receptors, and hence can alleviate levodopa-induced psychosis without making symptoms of PD worse. The dosage of clozapine required is only 25 mg a day—about 20 times less than the dosage for schizophrenia.

32.4.1.3 Pharmacokinetics

Clozapine is rapidly absorbed following oral administration. Plasma levels peak in 3.2 hours. About 95% of the drug is bound to plasma proteins. Clozapine undergoes extensive metabolism followed by fecal and urinary excretion. Its half-life is approximately 12 hours.

32.4.1.4 Adverse Effects and Interactions

Common adverse effects include sedation and weight gain (from blocking H₁ histamine receptors); orthostatic hypotension (from blocking alpha-adrenergic receptors); and dry mouth, blurred vision, urinary retention, constipation, and tachycardia (from blocking muscarinic cholinergic receptors). Neuroendocrine effects (galactorrhea, gynecomastia, amenorrhea) and interference with sexual function are minimal.

In contrast to FGAs, clozapine carries a low risk of extrapyramidal effects. TD has not been reported. In fact, TD may improve when patients switch to clozapine from an FGA.

32.4.1.4.1 Agranulocytosis.

Clozapine produces agranulocytosis in 1% to 2% of patients. The overall risk of death is about 1 in 5000. The usual cause is gram-negative septicemia. Agranulocytosis typically occurs during the first 6 months of treatment, and the onset is usually gradual. Why agranulocytosis occurs is unknown.

325

Because of the risk of fatal agranulocytosis, monitoring of the WBC *and* absolute neutrophil count (ANC) is mandatory. Prior to starting clozapine, both the total WBC and ANC must be in the normal range (ie, 3500/mm³ or greater and 2000/mm³ or greater, respectively). During treatment, the WBC and ANC must be monitored weekly for the first 6 months, every 2 weeks for the next 6 months, and monthly thereafter. If the total WBC count falls below 3000/mm³ or if the ANC falls below 1500/mm³, treatment should be interrupted. When subsequent *daily* monitoring indicates that counts have risen above these values, clozapine can be resumed. If the total WBC count falls below 2000/mm³ or if the ANC falls below 1000/mm³,

326

clozapine should be permanently discontinued. Blood counts should be monitored for 4 weeks after drug withdrawal.

Patients should be informed about the risk of agranulocytosis and told that clozapine will not be dispensed if the blood tests have not been done. Also, patients should be informed about early signs of infection (fever, sore throat, fatigue, mucous membrane ulceration) and instructed to report these immediately.

32.4.1.4.2

Metabolic Effects: Weight Gain, Diabetes, and Dyslipidemia.

Clozapine and the other SGAs can cause a group of closely linked metabolic effects—obesity, diabetes, and dyslipidemia—all of which increase the risk of cardiovascular events. As indicated in [Table 31-3](#), risk is highest with clozapine and olanzapine, lower with risperidone, paliperidone, and quetiapine, and lowest with ziprasidone and aripiprazole.

Weight gain is the metabolic effect of greatest concern. Why? Because it seems to underlie development of diabetes and dyslipidemia. Among patients taking clozapine, weight gain can be significant. Increases in excess of 30 pounds have been reported. Patients should be informed about the possibility of weight gain and encouraged to get regular exercise, monitor their weight, and control caloric intake. Weight should be measured at baseline; 4, 8, and 12 weeks later; and every 3 months thereafter. In addition, waist circumference should be measured at baseline and annually thereafter. If significant weight gain occurs, it can be managed with a combination of lifestyle measures (diet and exercise) and *metformin*, an oral hypoglycemic agent used for diabetes. In a recent study, metformin was more effective than lifestyle measures, and the combination of metformin plus lifestyle measures was more effective than either intervention alone. Why do antipsychotic drugs promote weight gain? Probably through blockade of histamine H₁ receptors in the brain.

Clozapine and all other SGAs can cause *new-onset diabetes*. Patients taking these drugs have developed typical diabetes symptoms, including hyperglycemia, polyuria, polydipsia, polyphagia, and dehydration. In extreme cases, hyperglycemia has led to ketoacidosis, hyperosmolar coma, and even death. Because of diabetes risk, fasting blood sugar should be measured before starting clozapine, 12 weeks later, and annually thereafter. Patients with documented diabetes at treatment onset should be monitored for worsening of glucose control. All patients should be informed about symptoms of diabetes and instructed to report them. If diabetes develops, it can be managed with insulin or an oral hypoglycemic drug, such as metformin. Discontinuing clozapine is also an option. However, if the drug has produced

control of psychotic symptoms, continuing clozapine and treating the diabetes would seem preferable.

Dyslipidemia associated with clozapine and other SGAs can manifest as increased total cholesterol, LDL cholesterol, and triglycerides, along with decreased HDL cholesterol. This lipid profile increases the risk of atherosclerosis and coronary heart disease. To monitor effects on lipids, a fasting lipid profile should be obtained at baseline, 12 weeks later, and every 5 years thereafter.

32.4.1.4.3 Seizures.

Generalized tonic-clonic convulsions occur in 3% of patients. The risk of seizures is dose related. Patients should be warned not to drive or to participate in other potentially hazardous activities if a seizure has occurred. Patients with a history of seizure disorders should use the drug with great caution.

32.4.1.4.4 Myocarditis.

Very rarely, clozapine has been associated with myocarditis (inflammation of the heart muscle), which can be fatal. If a patient develops signs and symptoms (eg, unexplained fatigue, dyspnea, tachypnea, chest pain, palpitations), clozapine should be withheld until myocarditis has been ruled out. If myocarditis is diagnosed, clozapine should not be used again.

32.4.1.4.5 Orthostatic Hypotension.

Clozapine can cause orthostatic hypotension, sometimes with fainting. Rarely, collapse is severe, and accompanied by respiratory and/or cardiac arrest. Hypotension is most likely during initial dosage titration, especially if dosage escalation is rapid.

32.4.1.4.6 Effects in Elderly Dementia Patients.

When used off-label to treat elderly patients with dementia, FGAs and SGAs about double the rate of mortality. Most deaths result from heart-related events (eg, heart failure, sudden death) or from infection (mainly pneumonia). Since FGAs and SGAs are not approved for treating dementia, and since doing so increases the risk of death, it would seem that such use is ill advised.

32.4.1.4.7 Drug Interactions.

Because of its ability to cause agranulocytosis, clozapine is contraindicated for patients taking other drugs that can suppress bone marrow function (eg, many anticancer drugs).

32.4.1.5 Preparations, Dosage, and Administration

Clozapine is available in standard tablets (12.5, 25, 50, 100, and 200 mg), sold as *Clozaril*, and in orally disintegrating tablets (25 and 100 mg), sold as *FazaClo*. To minimize side effects, treatment should begin with a 12.5-mg dose, followed by 25 mg once or twice daily. Dosage is then increased by 25 mg/day until it reaches 300 to 450 mg/day. Further increases can be made once or twice weekly in increments no larger than 100 mg. The usual maintenance dosage is 300 to 600 mg/day in three divided doses. The maximum dosage is 900 mg/day. If therapy is interrupted, it should resume with a 12.5-mg dose and then follow the original escalation guidelines. Because of the risk of agranulocytosis, dispensing is normally limited to a 1-week supply.

32.4.2 Other Atypical Antipsychotics

32.4.2.1 Risperidone

Risperidone [Risperdal] is a rapid-acting drug originally approved for schizophrenia and then later approved for acute bipolar mania. Most recently, the drug was approved for children with autistic disorder, with the goal of reducing irritability-associated symptoms, such as tantrums, aggression, mood swings, and self-injury. In patients with schizophrenia, the drug improves positive symptoms, negative symptoms, and cognitive function. Like other SGAs, it causes fewer EPS than FGAs. Risperidone is structurally unrelated to clozapine.

32.4.2.1.1 Mechanism of Action.

We know that risperidone binds to multiple receptors, but we don't know with certainty how clinical benefits are produced. Risperidone is a powerful antagonist at 5-HT₂ receptors and a less powerful antagonist at D₂ receptors. Antagonism at both sites probably underlies therapeutic effects. Risperidone does not block cholinergic receptors but does block H₁ receptors as well as alpha-adrenergic receptors.

32.4.2.1.2 Pharmacokinetics.

Absorption is rapid and not affected by food. Plasma levels peak about 1 hour after oral dosing. Much of each dose is metabolized to 9-hydroxyrisperidone, whose activity equals that of risperidone itself. Parent drug and metabolite are excreted primarily in the urine. The effective half-life is 24 hours. In patients with hepatic or renal dysfunction, the half-life is prolonged.

32.4.2.1.3 Therapeutic Effects.

Risperidone relieves positive and negative symptoms of schizophrenia and improves cognitive function. Significant improvement may be seen in 1 week. By contrast, benefits of haloperidol develop more slowly and are limited primarily to positive symptoms. In patients with severe TD, risperidone may have an antidyskinetic effect.

32.4.2.1.4 Adverse Effects.

Side effects are generally infrequent and mild, and only rarely require discontinuation of treatment. The incidence of EPS is very low at the recommended dosage. However, at dosages above 10 mg/day, there is a dose-related increase in EPS. With the long-acting IM formulation, the incidence of EPS is substantial (about 25%). TD has not been observed. Risperidone increases prolactin levels, but symptoms (gynecomastia, galactorrhea) are uncommon. Like other SGAs, risperidone can cause metabolic effects: weight gain, diabetes, and dyslipidemia. Adverse effects that have led to discontinuing the drug include agitation, dizziness, somnolence, and fatigue. Excessive doses have caused difficulty concentrating, sedation, and disruption of sleep. When used off-label to treat elderly dementia patients, risperidone doubles or triples the risk of stroke, and nearly doubles the risk of death (usually from cardiac events or pneumonia).

32.4.2.1.5 Preparations, Dosage, and Administration.

32.4.2.1.5.1 Schizophrenia, Oral Therapy.

For oral therapy, risperidone is available in standard tablets (0.25, 0.5, 1, 2, 3, and 4 mg) and solution (1 mg/mL), both sold as *Risperdal*, and in orally disintegrating tablets (0.5, 1, and 2 mg), sold as *Risperdal M-TAB*. The recommended dosage is 1 mg twice daily the first day, 2 mg twice daily the second day, and 3 mg twice daily thereafter. Dosages above 2 or 3

mg twice daily do not increase therapeutic effects, but do increase the risk of EPS and other side effects. Dosage should be reduced in patients with renal or hepatic impairment.

32.4.2.1.5.2 Schizophrenia, Intramuscular Therapy.

Intramuscular risperidone [Risperdal Consta] is a depot preparation used for *long-term* therapy, not for acute therapy. In this formulation, risperidone is bound to a matrix that has been encapsulated within microspheres. Following IM injection, the matrix gradually breaks down to release free drug. Importantly, main release doesn't begin until 2 to 3 weeks after the injection, producing therapeutic levels 4 to 6 weeks after the injection. Because effects are delayed, patients should take an oral antipsychotic during the first 3 weeks of Risperdal Consta use. The IM dosage range is 25 to 50 mg every 2 weeks.

32.4.2.1.5.3 Bipolar Disorder.

Dosage for bipolar disorder is presented in [Chapter 33 \(Table 33-5\)](#).

32.4.2.1.5.4 Irritability Associated with Autistic Disorder.

The initial dosage is 0.25 mg/day (for children under 20 kg) and 0.5 mg/day (for children 20 kg and over). After a minimum of 4 days, dosage may be increased to the recommended maintenance level of 0.5 mg/day (for children under 20 kg) or 1 mg/day (for children 20 kg and over). If needed, dosage may be slowly titrated higher. For all children, the total daily dose can be administered as a single dose or as two divided doses of equal size.

32.4.2.2 Paliperidone

Paliperidone [Invega] is the active metabolite of risperidone (9-hydroxyrisperidone), and hence has the same adverse and therapeutic effects as risperidone itself. The two drugs differ primarily in that paliperidone is not extensively metabolized, and has no significant kinetic interactions with other drugs. Also, in contrast to risperidone, paliperidone is dosed just once a day, and doesn't require initial dosage titration. Paliperidone can prolong the QT interval, and hence should not be combined with other QT-prolonging drugs. Paliperidone is approved for acute therapy and maintenance therapy of schizophrenia.

Paliperidone is available in extended-release tablets (3, 6, and 9 mg) that employ the osmotic-release oral system (OROS) for delivery. Dosing is done once daily in the morning, with or without food. Patients should be instructed to swallow the tablets whole, without crushing, chewing, or dividing. Also, they should be informed that Invega tablets have a nonabsorbable

shell that passes intact into the stool. For patients with normal renal function, the usual dosage is 6 mg/day. For patients with moderate renal impairment (creatinine clearance 50 to 80 mL/min), dosage must not exceed 6 mg/day. For patients with severe renal impairment (creatinine clearance 10 to 50 mL/min), dosage should not exceed 3 mg/day.

32.4.2.3 Olanzapine

Olanzapine [Zyprexa] is an SGA approved for (1) schizophrenia, (2) maintenance therapy of bipolar disorder, and (3) acute agitation associated with schizophrenia and bipolar mania. In addition, olanzapine is used off-label to suppress nausea and vomiting in cancer patients. The drug is similar to clozapine in structure and actions, but does not cause agranulocytosis. The risk of metabolic effects with this drug is higher than with most other SGAs.

32.4.2.3.1 Mechanism of Action.

Olanzapine blocks receptors for serotonin, dopamine, histamine, acetylcholine, and norepinephrine. Therapeutic effects are believed to result from blocking 5-HT₂ receptors and D₂ receptors. Adverse effects result in part from blocking receptors for histamine, acetylcholine, and norepinephrine.

32.4.2.3.2 Pharmacokinetics.

Olanzapine is well absorbed following oral administration. Food does not alter the rate or extent of absorption. Plasma levels peak 6 hours after dosing and decline with a half-life of 30 hours. Hepatic metabolism is extensive.

32.4.2.3.3 Therapeutic Uses.

32.4.2.3.3.1 Schizophrenia.

In patients with schizophrenia, olanzapine is at least as effective as haloperidol or risperidone and produces fewer EPS than either drug. Comparative trials with clozapine have not been done. Interestingly, olanzapine can relieve psychosis induced by drugs taken for Parkinson's disease without reversing antiparkinsonism effects.

32.4.2.3.3.2 Bipolar Disorder.

Olanzapine is approved for monotherapy of acute mania in patients with bipolar disorder. Benefits appear equal to those of lithium, a drug of choice for this condition (see [Chapter 33](#)).

32.4.2.3.4 Adverse Effects.

Regarding serious adverse effects, olanzapine is a mixed blessing: the drug carries a low risk of EPS and high risk of metabolic effects. Acute EPS are minimal when the drug is used at the recommended dosage. TD has not been reported. Among the SGAs, olanzapine (along with clozapine) poses the highest risk of serious metabolic effects: weight gain, diabetes, and dyslipidemia—all of which can lead to adverse cardiovascular events and premature death. Unlike clozapine, olanzapine does not cause agranulocytosis. But, like all other antipsychotic drugs, olanzapine can increase mortality in elderly patients with dementia.

Mild effects are relatively common. Olanzapine causes somnolence in 26% of patients, presumably by blocking H₁ receptors. Blockade of muscarinic receptors causes constipation and other anticholinergic effects. Alpha₁-adrenergic blockade causes orthostatic hypotension. In addition, case reports indicate that olanzapine can cause sleepwalking and writer's cramp. Following overdose, the only signs are slurred speech and drowsiness.

32.4.2.3.5 Preparations, Dosage, and Administration.

32.4.2.3.5.1 Preparations.

For oral therapy, olanzapine [Zyprexa, Zyprexa Zydis] is available in standard tablets (2.5, 5, 7.5, 10, and 25 mg), sold as *Zyprexa*, and in orally disintegrating tablets (5, 10, 15, and 20 mg), sold as *Zyprexa Zydis*. For IM therapy, olanzapine [Zyprexa IntraMuscular] is available as a powder (10 mg) to be reconstituted with 2.1 mL of sterile water.

32.4.2.3.5.2 Schizophrenia Dosage.

The recommended *oral* dosage is 5 to 10 mg once a day for the first few days, and 10 mg once a day thereafter. Dosages greater than 10 mg/day are no more effective, but do increase the risk of side effects. *Intramuscular* doses range from 2.5 to 10 mg.

32.4.2.3.5.3 Bipolar Disorder Dosage.

For treatment of bipolar disorder, olanzapine is available in two oral formulations: olanzapine alone [Zyprexa, Zyprexa Zydis] and olanzapine plus fluoxetine [Symbyax]. The dosage for olanzapine alone is presented in [Chapter 33 \(Table 33-5\)](#). The dosage range for olanzapine plus fluoxetine is 6 to 12 mg/day of olanzapine plus 25 to 50 mg/day of fluoxetine.

32.4.2.4 Quetiapine

32.4.2.4.1 Actions and Uses.

Quetiapine [Seroquel] is an SGA indicated for schizophrenia and acute bipolar mania. In patients with schizophrenia, the drug can improve both positive and negative symptoms, although negative symptoms respond less consistently. The drug also improves cognitive function. Like other SGAs, quetiapine produces strong blockade of 5-HT₂ receptors and weaker blockade of D₂ receptors. Blockade of both receptor types is believed responsible for beneficial effects. In addition to blocking receptors for serotonin and dopamine, quetiapine blocks H₁ receptors and alphaadrenergic receptors, but does not block receptors for acetylcholine.

32.4.2.4.2 Pharmacokinetics.

Quetiapine is well absorbed following oral administration. The drug undergoes hepatic metabolism followed by excretion in the urine and feces. The half-life is 6 hours.

32.4.2.4.3 Adverse Effects.

Quetiapine carries a moderate risk of serious metabolic effects: weight gain, diabetes, and dyslipidemia. As with other SGAs, the risk of EPS is low at therapeutic doses. Tardive dyskinesia has not been reported. Despite structural similarity to clozapine, quetiapine does not pose a risk of agranulocytosis. However, quetiapine does share the ability to increase mortality in elderly patients with dementia. Common side effects include sedation (from H₁ blockade) and orthostatic hypotension (from alpha blockade).

Cataracts are a concern. Cataracts developed in dogs fed 4 times the maximum human dose for 6 or 12 months. Lens changes have also developed in patients; quetiapine may have been the cause. Because quetiapine may pose a risk of cataracts, the manufacturer recommends examination of the lens for cataracts prior to treatment and every 6 months thereafter.

327

32.4.2.4.4 Drug Interactions.

Metabolism of quetiapine is accelerated by phenytoin, a drug that induces CYP3A4, an isozyme of hepatic cytochrome P450 (CYP) drug-metabolizing enzymes. As a result, a larger dose of quetiapine may be needed to maintain antipsychotic effects. Other inducers of CYP3A4 (eg, barbiturates, carbamazepine, rifampin) may have the same effect.

328

Although clinical data are not yet available, it seems likely that inhibitors of CYP3A4 (eg, ketoconazole, itraconazole, fluconazole, erythromycin) will increase levels of quetiapine, thereby posing a risk of toxicity. Caution is advised.

32.4.2.4.5 Preparations, Dosage, and Administration.

32.4.2.4.5.1 Preparations.

Quetiapine is available in immediate-release tablets (25, 50, 100, 200, 300, and 400 mg), marketed as *Seroquel*, and in extended-release tablets (200, 300, and 400 mg), marketed as *Seroquel XR*.

32.4.2.4.5.2 Schizophrenia Dosage.

With the *immediate-release* tablets, the initial dosage is low—25 mg twice a day—to minimize orthostatic hypotension. Dosage is gradually increased over the next 3 days to a maintenance level of 400-800 mg/day, given in two or three divided doses. For patients who may be especially sensitive to quetiapine (eg, the elderly, those with hepatic impairment, those predisposed to hypotension), a slower titration rate and lower maintenance dosage may be advisable.

With the *extended-release* tablets, dosing begins at 300 mg once daily, and is later increased to a maintenance level of 400 to 800 mg once daily. Patients currently using immediate-release quetiapine may be switched to extended-release quetiapine at the equivalent total daily dosage.

32.4.2.4.5.3 Bipolar Disorder Dosage.

Dosage for bipolar disorder is presented in [Chapter 33 \(Table 33-5\)](#).

32.4.2.5 Ziprasidone

Ziprasidone [Geodon] is an SGA indicated for schizophrenia and acute bipolar mania. In patients with schizophrenia, ziprasidone can improve positive symptoms, negative symptoms, and cognitive function, while causing fewer EPS than FGAs. Ziprasidone stands out from other SGAs in that it can cause significant prolongation of the QT interval, thereby posing a risk of potentially fatal dysrhythmias.

32.4.2.5.1 Mechanism of Action.

Ziprasidone blocks multiple receptor types, including D₂, 5-HT₂, H₁, and alpha-adrenergic receptors. In addition, it blocks reuptake of two transmitters: serotonin and norepinephrine. As with other SGAs, therapeutic effects are believed to result from blockade of D₂ and 5-HT₂ receptors. Blockade of serotonin and norepinephrine uptake may provide antidepressant effects.

32.4.2.5.2 Pharmacokinetics.

Oral ziprasidone is well absorbed, especially in the presence of food. Binding to plasma proteins is extensive. Ziprasidone undergoes hepatic metabolism (primarily by CYP3A4) followed by excretion in the urine and feces. The elimination half-life is about 7 hours.

32.4.2.5.3 Adverse Effects.

Ziprasidone is generally well tolerated. The most common side effects are somnolence (perhaps from H₁ blockade), orthostatic hypotension (perhaps from alpha-adrenergic blockade), and rash (the side effect most responsible for discontinuing the drug). EPS develop in about 5% of patients. Like other SGAs, ziprasidone can promote weight gain, diabetes, and dyslipidemia. However, the risk is low. In contrast to clozapine, ziprasidone does not cause agranulocytosis. Like other antipsychotic drugs, ziprasidone may increase mortality in elderly patients with dementia.

Ziprasidone *prolongs the QT interval*, and thereby poses a risk of torsades de pointes, a dysrhythmia that can progress to fatal ventricular fibrillation. QT prolongation is greater than with haloperidol but less than with thioridazine [Mellaril]. Because of QT prolongation, ziprasidone should not be given to patients with risk factors for torsades de pointes, the most important being hypokalemia, hypomagnesemia, bradycardia, congenital QT prolongation, or a history of dysrhythmias, myocardial infarction, or severe heart failure.

32.4.2.5.4 Drug Interactions.

Ziprasidone should not be combined with other drugs that prolong the QT interval. Among these are tricyclic antidepressants, thioridazine, several antidysrhythmic drugs (eg, amiodarone, dofetilide, quinidine), and certain antibiotics (eg, clarithromycin, erythromycin, moxifloxacin, gatifloxacin, sparfloxacin).

Drugs that induce CYP3A4 (eg, carbamazepine, phenytoin) can accelerate the metabolism of ziprasidone, and may thereby decrease its levels. Conversely, drugs that inhibit CYP3A4 (eg, ketoconazole) may increase ziprasidone levels.

32.4.2.5.5 Preparations, Dosage, and Administration.

32.4.2.5.5.1 Preparations.

Ziprasidone [Geodon] is available in capsules (20, 40, 60, and 80 mg) for oral dosing and 20-mg single-use vials for IM injection.

32.4.2.5.5.2 Schizophrenia, Oral Dosage.

The initial dosage is 20 mg twice daily taken with food. The maximum is 80 mg twice daily.

32.4.2.5.5.3 Schizophrenia, Intramuscular Dosage.

Two dosing schedules may be employed: (1) 10-mg doses given at least 2 hours apart up to a maximum of 40 mg/day or (2) 20-mg doses administered at least 4 hours apart up to a maximum of 40 mg/day. Intramuscular therapy for more than 3 days has not been studied. If long-term treatment is indicated, switch to oral ziprasidone.

32.4.2.5.5.4 Bipolar Disorder.

Dosage for bipolar disorder is presented in [Chapter 33 \(Table 33-5\)](#).

32.4.2.6 Aripiprazole

32.4.2.6.1 Contrasts with Other Atypical Antipsychotic Agents.

Aripiprazole [Abilify, Abilify Discmelt] is the first representative of a new class of antipsychotic drugs, referred to by some as *dopamine system stabilizers* (DSSs). Approved indications are schizophrenia, acute bipolar mania, major depressive disorder, and agitation associated with schizophrenia or bipolar mania. Aripiprazole has a more favorable safety profile than other SGAs, but is less effective than some (see [Table 31-7](#)). In patients with schizophrenia, aripiprazole is like other SGAs: it improves cognitive function, positive symptoms, and negative symptoms, while posing little or no risk of EPS or TD. In contrast to other SGAs, aripiprazole is unlikely to cause significant metabolic effects, hypotension, or

prolactin release, and poses no risk of anticholinergic effects or dysrhythmias. However, like all other antipsychotics, the drug may increase mortality in elderly patients with dementia.

32.4.2.6.2 Mechanism of Action.

Like other antipsychotic drugs, aripiprazole can affect multiple receptor types. It blocks H_1 , $5-HT_2$, and α_1 receptors, and has mixed effects on $5-HT_1$ and D_2 receptors. The drug does not block cholinergic receptors.

As with other SGAs, therapeutic effects are believed to result from interaction with dopamine and serotonin receptors. However, the nature of the interaction differs: Whereas other SGAs act as *pure antagonists* at dopamine and serotonin receptors, aripiprazole acts as a *partial agonist* at $5-HT_1$ and D_2 receptors, and as a pure antagonist only at $5-HT_2$ receptors. Because aripiprazole is a partial agonist at $5-HT_1$ and D_2 receptors, net effects on receptor activity will depend on how much transmitter (dopamine or serotonin) is present. Specifically, at synapses where transmitter concentrations are *low*, aripiprazole will bind to receptors and thereby cause *moderate activation*. Conversely, at synapses where transmitter concentrations are *high*, aripiprazole will compete with the transmitter for receptor binding, and hence will *reduce receptor activation*. It is because of this ability to modulate the activity of dopamine receptors—rather than simply cause receptor activation or blockade—that aripiprazole has been dubbed a DSS. Researchers suggest that dopamine system stabilization explains why aripiprazole can improve positive and negative symptoms of schizophrenia while having little or no effect on the extrapyramidal system or prolactin release.

32.4.2.6.3 Pharmacokinetics.

Aripiprazole is well absorbed following oral administration, both in the presence and absence of food. Plasma levels peak 3 to 5 hours after dosing. Protein binding in blood is high—more than 99%. In the liver, aripiprazole undergoes metabolism by two isozymes of cytochrome P450, designated CYP3A4 and CYP2D6. Aripiprazole and its active metabolite—dehydro-aripiprazole—have prolonged half-lives: 75 hours and 94 hours, respectively. Because elimination is slow, (1) dosing can be done once a day and (2) about 14 days (four half-lives) are required to achieve steady-state (plateau) plasma drug levels.

32.4.2.6.4 Adverse Effects.

In clinical trials, aripiprazole was well tolerated. The most common side effects were headache, agitation, nervousness, anxiety, insomnia, nausea, vomiting, dizziness, and

somnolence. The incidence of EPS was the same as in patients taking placebo. Tardive dyskinesia has not been observed. To date, only a few cases of NMS have been reported. Among the SGAs, aripiprazole (along with ziprasidone) poses the lowest risk of weight gain, diabetes, and dyslipidemia. Although aripiprazole can block α_1 adrenergic receptors, the incidence of orthostatic hypotension is low (1.9% vs. 1% in patients on placebo).

Aripiprazole does not prolong the QT interval, and hence does not pose a risk of dysrhythmias. Also, the drug does not increase prolactin levels, and hence does not cause gynecomastia or galactorrhea.

TABLE 31-7 Relative Effectiveness of Second-Generation Antipsychotics

Generic Name	Trade Name	Effectiveness
Aripiprazole	Abilify	+ +
Clozapine	Clozaril, FazaClo	+ + + +
Olanzapine	Zyprexa	+ + +
Paliperidone	Invega	+ + +
Quetiapine	Seroquel	+ +
Risperidone	Risperdal	+ + +
Ziprasidone	Geodon	+ +

32.4.2.6.5 Drug Interactions.

Drugs that induce CYP3A4 (eg, barbiturates, carbamazepine, phenytoin, rifampin) can accelerate metabolism of aripiprazole, and can thereby reduce its blood level. Conversely, drugs that inhibit CYP3A4 (eg, ketoconazole, itraconazole, fluconazole, erythromycin) can increase aripiprazole levels, as can drugs that inhibit CYP2D6 (eg, quinidine, fluoxetine, paroxetine).

32.4.2.6.6 Preparations, Dosage, and Administration.

32.4.2.6.6.1 Preparations.

Aripiprazole for *oral therapy* is available in standard tablets (2, 5, 10, 15, 20, and 30 mg) and solution (1 mg/mL), both sold as *Abilify*, and in orally disintegrating tablets (10 and 15 mg) sold as *Abilify Discmelt*. Aripiprazole for IM therapy is available in single-use vials (7.5 mg/mL) sold as *Abilify*.

32.4.2.6.6.2 Oral Dosage for Schizophrenia.

The recommended dosage—both initial and maintenance—is 10 or 15 mg once a day, administered with or without food. Dosages above 15 mg/day do not increase therapeutic effects, but can intensify side effects. Dosage should be doubled for patients taking inducers of CYP3A4, and cut in half for patients taking inhibitors of CYP3A4 or CYP2D6.

32.4.2.6.6.3 Oral Dosage for Major Depressive Disorder.

The recommended initial dosage is 2 to 5 mg/day. Dosage may be increased by up to 5 mg/day, but at intervals of no less than 1 week. Dosages above 15 mg/day have not been studied. As with oral therapy of schizophrenia, dosage should be doubled for patients taking inducers of CYP3A4, and cut in half for patients taking inhibitors of CYP3A4 or CYP2D6.

32.4.2.6.6.4 Oral Dosage for Bipolar Disorder.

Dosage for bipolar disorder is presented in [Chapter 33 \(Table 33-5\)](#).

32.4.2.6.6.5 Intramuscular Dosage for Agitation Associated with Schizophrenia or Bipolar Mania.

The recommended dosage is 9.75 mg once. As with oral therapy, dosage should be doubled for patients taking inducers of CYP3A4, and cut in half for patients taking inhibitors of CYP3A4 or CYP2D6.

32.5 DEPOT ANTIPSYCHOTIC PREPARATIONS

Depot antipsychotics are long-acting, injectable formulations used for long-term maintenance therapy of schizophrenia. The objective is to prevent relapse and maintain the highest possible level of functioning. The rate of relapse is lower with depot therapy than with oral therapy. Depot preparations are valuable for all patients who need long-term treatment—not just for patients who have difficulty with adherence. There is no evidence that depot preparations pose an increased risk of side effects, including NMS and TD. In fact, because depot therapy permits a reduction in the total drug burden (the dose per unit time is lower than with oral therapy), the risk of TD is actually reduced.

Three depot preparations are currently available—*haloperidol decanoate* [Haldol Decanoate], *fluphenazine decanoate* [Prolixin Decanoate], and *risperidone microspheres* [Risperdal Contra]—and at least two more preparations—*paliperidone palmitate* and *iloperidone*—are in development.

Following IM or subQ injection, active drug (fluphenazine, haloperidol, or risperidone) is slowly absorbed into the blood. Because of this slow, steady absorption, plasma levels remain relatively constant between injections. The dosing interval is 2 to 4 weeks. Typical maintenance dosages are presented in [Table 31-8](#).

32.6 MANAGEMENT OF SCHIZOPHRENIA

32.6.1 Drug Therapy

Drug therapy of schizophrenia has three major objectives: (1) suppression of acute episodes, (2) prevention of acute exacerbations, and (3) maintenance of the highest possible level of functioning.

TABLE 31-8 Depot Antipsychotic Preparations

Generic Name [Trade Name]	Route	Typical Maintenance Dosage
Haloperidol decanoate [Haldol Decanoate]	IM	50–200 mg every 4 wk
Fluphenazine decanoate [Prolixin Decanoate]	IM, subQ	12.5–50 mg every 2 wk
Risperidone microspheres [Risperdal Contra]	IM	25–50 mg every 2 wk

32.6.1.1 Drug Selection

Like all other drugs, antipsychotics should be selected on the basis of effectiveness, tolerability, and cost. Currently, SGAs are prescribed 10 times more often than FGAs, but that may change. When the SGAs were introduced, available data suggested they were more effective than FGAs and also safer. However, we now know otherwise. The *Clinical Antipsychotic Trials in Intervention Effectiveness* (CATIE) study, published in 2005, compared four SGAs—olanzapine [Zyprexa], quetiapine [Seroquel], risperidone [Risperdal], and ziprasidone [Geodon]—with the FGA perphenazine. This result? The SGAs were no more effective than perphenazine. These data were confirmed by a second study, conducted in Great Britain, which showed again that perphenazine was just as effective as several SGAs. These two trials were the first large studies to directly compare FGAs and SGAs—and their surprising results were completely unexpected. Regarding serious side effects, SGAs were initially thought safer than FGAs. Why? Because SGAs posed a low risk of EPS. However, over time, it became clear that SGAs posed a serious risk of their own: potentially fatal metabolic effects. Hence, rather than being *free* of serious side effects, the SGAs simply substituted a new serious effect for the old one. As for cost, the

FGAs are much cheaper. For example, whereas haloperidol costs only \$50 a year, risperidone costs about \$2000 a year, and olanzapine costs about \$4000. In summary, here's what we know:

- Most FGAs and SGAs are equally effective, except for clozapine, which is more effective than the rest.
- Whereas FGAs pose a significant risk of EPS, SGAs pose a significant risk of metabolic effects, which may be more detrimental than EPS.
- FGAs cost about 10 times less than SGAs.

Given this information, which drug should we choose? That's still hard to answer. With regard to efficacy and safety, no single agent is clearly superior to the others. So we're back to our initial selection criteria: efficacy, safety, and cost. For a patient who is treatment resistant, a trial with clozapine might be reasonable. For a patient with a history of diabetes or dyslipidemia, an FGA might be a good choice, as might aripiprazole or ziprasidone, two SGAs with a low risk of metabolic effects. If there's no clinical reason to select an SGA over an FGA, cost considerations would suggest choosing the FGA.

32.6.1.2 Dosing

Dosing with antipsychotics is highly individualized. Elderly patients require relatively small doses—typically 30% to 50% of those for younger patients. Poorly responsive patients may need larger doses. However, very large doses should generally be avoided. Why? Because huge doses are probably no more effective than moderate doses, and will increase the risk of side effects.

329

330

Dosage size and timing are likely to change over the course of therapy. During the initial phase, antipsychotics should be administered in divided daily doses. Once an effective dosage has been determined, the entire daily dose can often be given at bedtime. Since antipsychotics cause sedation, bedtime dosing helps promote sleep while decreasing daytime drowsiness. Doses used early in therapy to gain rapid control of behavior are often very high. For long-term therapy, the dosage should be reduced to the lowest effective amount.

32.6.1.3 Routes

32.6.1.3.1 Oral.

Oral administration is preferred for most patients. Antipsychotics are available in tablets, capsules, and liquids for oral dosing.

The liquid formulations require special handling. These preparations are concentrated and must be diluted prior to use. Dilution may be performed with a variety of fluids, including milk, fruit juices, and carbonated beverages. Some oral liquids are light sensitive and must be stored in amber or opaque containers. Liquid formulations of *phenothiazines* can cause contact dermatitis; nurses and patients should take care to avoid skin contact with these preparations.

32.6.1.3.2 Intramuscular.

Intramuscular injection is generally reserved for patients with severe, acute schizophrenia and for long-term maintenance. Depot preparations are given every 2 to 4 weeks (see [Table 31-8](#)).

32.6.1.4 Initial Therapy

With adequate dosing, symptoms begin to resolve within 1 to 2 days. However, significant improvement takes 1 to 2 weeks, and a full response may not be seen for several months.

Some symptoms resolve sooner than others. During the first week, the goal is to reduce agitation, hostility, anxiety, and tension and to normalize patterns of sleeping and eating. Over the next 6 to 8 weeks, symptoms should continue to steadily improve. The goals over this interval are increased socialization and improved self-care, mood, and formal thought processes. Of the patients who have not responded within 6 weeks, 50% are likely to respond by the end of 12 weeks.

It is important to note that not all symptoms respond equally. With FGAs, positive symptoms respond better than negative symptoms or cognitive dysfunction. However, with the SGAs, all three types of symptoms may respond well.

32.6.1.5 Maintenance Therapy

Schizophrenia is a chronic disorder that usually requires prolonged treatment. The purpose of long-term therapy is to reduce the recurrence of acute florid episodes and to maintain the highest possible level of functioning. Unfortunately, although long-term treatment can be very effective, it also carries a risk of adverse effects, especially TD.

Following control of an acute episode, antipsychotic therapy should continue for at least 12 months. Withdrawal of medication prior to this time is associated with a 55% incidence of relapse, compared with only 20% in patients who continue drug use. Accordingly, patients must

be convinced to continue therapy for the entire 12-month course, even though they may be symptom free and consider themselves “cured.”

After 12 months, an attempt should be made to discontinue drug use, provided symptoms are absent. About 25% of patients do not need drugs beyond this time. To avoid a withdrawal reaction, dosage should be tapered gradually. It is important that medication not be withdrawn at a time of stress (eg, when the patient is being discharged following hospitalization). If relapse occurs in response to withdrawal, treatment should be reinstituted. For many patients, resumption of therapy controls symptoms and prevents further deterioration.

When long-term therapy is conducted, dosage should be adjusted with care. To reduce the risk of TD and other adverse effects, a minimum effective dosage should be established. Annual attempts should be made to lower the dosage or to discontinue treatment entirely.

Long-acting (depot) antipsychotics are especially well suited for prolonged treatment. Depot therapy has three major advantages compared with oral therapy: (1) the relapse rate is lower, (2) drug levels are more stable between doses, and (3) the total dose per unit time is lower, thereby reducing the risk of adverse effects, including TD. In the United States, only 10% of patients receive depot therapy. This low rate is based in large part on the widely held (but unfounded) perception that depot therapy is for “losers”—patients who suffer recurrent relapse because of persistent nonadherence with oral therapy.

32.6.1.6 Adjunctive Drugs

Benzodiazepines (eg, lorazepam, alprazolam) can suppress anxiety and promote sleep. Whether they also improve core symptoms of schizophrenia is uncertain. In patients experiencing an acute psychotic episode, benzodiazepines can help suppress anxiety, irritability, and agitation. In addition, benzodiazepines may allow the dosage of antipsychotic medication to be reduced.

Antidepressants are appropriate when schizophrenia is associated with depressive symptoms. A tricyclic antidepressant (eg, imipramine) is usually chosen. Antidepressant dosage is the same as for major depression. The ideal duration is unknown.

32.6.1.7 Promoting Adherence

Poor adherence is a common cause of therapeutic failure, and underlies a significant proportion of hospital readmissions. Adherence can be difficult to achieve because treatment is prolonged and because patients may fail to appreciate the need for therapy, or they may be unwilling or

unable to take medicine as prescribed. In addition, side effects can discourage adherence.

Adherence can be enhanced by

- Ensuring that the medication given to hospitalized patients is actually swallowed and not “cheeked”
- Encouraging family members to oversee medication for outpatients
- Providing patients with written and verbal instructions on dosage size and timing, and encouraging them to take their medicine exactly as prescribed
- Informing patients and their families that antipsychotics must be taken on a regular schedule to be effective, and hence cannot be used PRN
- Informing patients about side effects of treatment and teaching them how to minimize undesired responses

330

- Assuring patients that antipsychotic drugs do not cause addiction
- Establishing a good therapeutic relationship with the patient and family
- Using an IM depot preparation (fluphenazine decanoate, haloperidol decanoate, risperidone microspheres) for long-term therapy

331

32.6.2 Nondrug Therapy

Although drugs can be of great benefit in schizophrenia, medication alone does not constitute optimal treatment. The acutely ill patient needs care, support, and protection; a period of hospitalization may be essential. Counseling can offer the patient and family insight into the nature of schizophrenia and can facilitate adjustment and rehabilitation. Although conventional psychotherapy is of little value in reducing symptoms of schizophrenia, establishing a good therapeutic relationship can help promote adherence and can help the prescriber evaluate the patient, which in turn can facilitate dosage adjustment and drug selection. Behavioral therapy can help reduce stress. Vocational training in a sheltered environment offers the hope of productivity and some measure of independence. Ideally, the patient will be provided with a comprehensive therapeutic program to complement the benefits of medication. Unfortunately, ideal situations don't always exist, leaving many patients to rely on drugs as their sole treatment modality.

32.6.2.1

KEY POINTS

- Schizophrenia is the principal indication for antipsychotic drugs, although many are also used for bipolar disorder.
- Schizophrenia is a chronic illness characterized by disordered thinking and reduced comprehension of reality. Positive symptoms include hallucinations, delusions, and agitation. Negative symptoms include blunted affect, poverty of speech, and social withdrawal. Cognitive dysfunction manifests as disordered thinking, reduced ability to focus attention, plus learning and memory difficulties.
- Antipsychotic drugs fall into two major groups: first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs).
- First-generation antipsychotics are thought to relieve symptoms of schizophrenia by blocking D₂ receptors.
- First-generation antipsychotics improve positive symptoms of schizophrenia more effectively than negative symptoms or cognitive dysfunction.
- Therapeutic responses to antipsychotic drugs develop slowly, often taking several months to become maximal.
- Low-potency FGAs and high-potency FGAs produce equal therapeutic effects.
- First-generation antipsychotic drugs produce three types of early EPS: acute dystonia, parkinsonism, and akathisia.
- Acute dystonia and parkinsonism respond to anticholinergic drugs (eg, benztropine). Akathisia is harder to treat, but may respond to anticholinergic drugs, benzodiazepines, or beta blockers.
- Tardive dyskinesia (TD), a late EPS, has no reliable treatment. For patients with severe TD, switching to an SGA may help.
- The risk of early EPS is much greater with high-potency FGAs than with low-potency FGAs, whereas the risk of TD is equal with both groups.

- Neuroleptic malignant syndrome, which can be fatal, is characterized by muscular rigidity, high fever, and autonomic instability. Dantrolene and bromocriptine are used for treatment.
- Low-potency FGAs produce more sedation, orthostatic hypotension, and anticholinergic effects than high-potency FGAs.
- Antipsychotic drugs increase levels of circulating prolactin by blocking the inhibitory action of dopamine on prolactin release.
- Levodopa can counteract the beneficial effects of FGA drugs and vice versa. Why? Because levodopa activates dopamine receptors, whereas FGAs block dopamine receptors.
- Chlorpromazine [Thorazine] is the prototype of the low-potency FGAs.
- Haloperidol [Haldol] is the prototype of the high-potency FGAs.
- Second-generation antipsychotics differ from FGAs in three important ways: (1) they block receptors for serotonin in addition to receptors for dopamine; (2) they cause few or no EPS, including TD; and (3) they carry a higher risk of serious metabolic effects—weight gain, diabetes, and dyslipidemia—that can lead to adverse cardiovascular events and premature death.
- Among the SGAs, the risk of metabolic effects is greatest with clozapine and olanzapine.
- Like FGAs, the SGAs increase the risk of mortality in elderly patients with dementia.
- Clozapine, the first SGA, is the most effective antipsychotic drug available.
- Clozapine can cause potentially fatal agranulocytosis. Hence, (1) regular blood tests are mandatory and (2) this drug is reserved for patients who have not responded to other SGAs or FGAs.
- Antipsychotic depot preparations—haloperidol decanoate, fluphenazine decanoate, and risperidone microspheres—are used for long-term maintenance therapy of schizophrenia.

- In general, and despite initial impressions, the SGAs are neither safer nor more effective than FGAs.

331

32.6.2.2

Summary of Major Nursing Implications*

332

32.6.2.2.1

FIRST-GENERATION (CONVENTIONAL) ANTIPSYCHOTICS

Chlorpromazine

Fluphenazine

Haloperidol

Loxapine

Molindone

Perphenazine

Pimozide

Thioridazine

Thiothixene

Trifluoperazine

Except where indicated, the nursing implications below apply to all FGAs.

32.6.2.2...

Preadministration Assessment

32.6.2.2...

Therapeutic Goal

Treatment of schizophrenia has three goals: suppression of acute episodes, prevention of acute exacerbations, and maintenance of the highest possible level of functioning.

32.6.2.2...

Baseline Data

Patients should receive a thorough mental status examination and a physical examination.

Observe and record such factors as overt behavior (eg, gait, pacing, restlessness, volatile outbursts), emotional state (eg, depression, agitation, mania), intellectual function (eg, stream of thought, coherence, hallucinations, delusions), and responsiveness to the environment.

Obtain a complete family and social history.

Determine vital signs and obtain complete blood counts, electrolytes, and evaluations of hepatic, renal, and cardiovascular function.

32.6.2.2...

Identifying High-Risk Patients

First-generation antipsychotics are *contraindicated* for patients who are comatose or severely depressed and for patients with Parkinson's disease, prolactin-dependent carcinoma of the breast, bone marrow depression, and severe hypotension or hypertension. Use with *caution* in patients with glaucoma, adynamic ileus, prostatic hypertrophy, cardiovascular disease, hepatic or renal dysfunction, and seizure disorders.

Avoid *chlorpromazine*, *thioridazine*, *haloperidol*, and *pimozide* in patients with risk factors for torsades de pointes (eg, hypokalemia, hypomagnesemia, bradycardia, congenital QT prolongation, or a history of dysrhythmias, myocardial infarction, or severe heart failure) and for those taking drugs that prolong the QT interval.

Generally *avoid all FGAs* in elderly patients with dementia.

32.6.2.2...

Implementation: Administration

32.6.2.2...

Routes

Oral, IM, IV, subQ, rectal (suppository). Routes for individual agents are summarized in [Tables 31-4](#) and [31-8](#).

32.6.2.2...

Administration

32.6.2.2...

Dosing.

Divided daily doses are employed initially. Once an effective dosage has been determined, the entire daily dose is usually administered at bedtime, thereby promoting sleep and minimizing daytime sedation. For long-term therapy, the smallest effective dosage should be employed.

32.6.2.2...

Oral Liquids.

Oral liquid formulations must be protected from light. Concentrated formulations should be diluted just prior to use. Dilution in fruit juice improves palatability.

Oral liquids can cause contact dermatitis. **Warn patients against making skin contact with these drugs, and instruct them to flush the affected area with water if a spill occurs.** Take care to avoid skin contact with these preparations yourself.

32.6.2.2...

Intramuscular.

Make injections into the deltoid or gluteal muscle. Rotate the injection site. Depot preparations are administered every 2 to 4 weeks (see [Table 31-8](#)).

32.6.2.2...

Implementation: Measures to Enhance Therapeutic Effects

32.6.2.2...

Promoting Adherence

Poor adherence is a common cause of therapeutic failure and rehospitalization. Adherence can be improved by

- Ensuring that medication is actually swallowed and not “cheeked”
- **Encouraging family members to oversee medication for outpatients**
- **Providing patients with written and verbal instructions on dosage size and timing, and encouraging them to take their medicine as prescribed**
- **Informing patients and their families that antipsychotic drugs must be taken on a regular schedule**

- Informing patients about side effects and teaching them how to minimize undesired responses
- Assuring patients that antipsychotic drugs do not cause addiction
- Establishing a good therapeutic relationship with the patient and family
- Using a depot preparation (eg, fluphenazine decanoate) for long-term therapy

32.6.2.2...

Nondrug Therapy

Acutely ill patients need care, support, and protection; hospitalization may be essential. **Educate the patient and family about the nature of schizophrenia to facilitate adjustment and rehabilitation.** Behavioral therapy can help reduce stress. Vocational training in a sheltered environment offers the hope of productivity and some measure of independence.

32.6.2.2...

Ongoing Evaluation and Interventions

32.6.2.2...

Evaluating Therapeutic Effects

Success is indicated by improvement in psychotic symptoms. Evaluate for suppression of hallucinations, delusions, agitation, tension, and hostility, and for improvement in judgment, insight, motivation, affect, self-care, social skills, anxiety management, and patterns of sleeping and eating.

332

32.6.2.2...

Minimizing Adverse Effects

32.6.2.2...

Early EPS: Acute Dystonia, Parkinsonism, and Akathisia.

These reactions develop within hours to months of the onset of treatment. The risk is greatest with high-potency FGAs. Take care to differentiate these reactions from worsening of psychotic symptoms. **Inform patients and their families about symptoms (eg, muscle spasm of tongue, face, neck, or back; tremor; rigidity; restless movement), and instruct them to notify the prescriber if these appear.** Acute dystonia and parkinsonism respond to anticholinergic drugs (eg, benztropine). Akathisia may respond to anticholinergic drugs, beta blockers, or benzodiazepines. For severe parkinsonism, switch to an SGA.

333

32.6.2.2...

Late EPS: Tardive Dyskinesia.

TD develops after months or years of continuous therapy. The risk is equal with all FGAs. **Inform patients and their families about early signs (eg, fine, worm-like movements of the tongue), and instruct them to notify the prescriber if these develop.** Although there is no reliable treatment, the following measures are recommended: discontinue all anticholinergic drugs; give a benzodiazepine; and discontinue the antipsychotic, or at least reduce the dosage. For severe TD, switch to an SGA.

32.6.2.2...

Neuroleptic Malignant Syndrome.

NMS is a rare reaction that carries a 4% risk of mortality. Symptoms include rigidity, fever, sweating, dysrhythmias, and fluctuations in blood pressure. NMS is most likely with highpotency FGAs.

Treatment consists of supportive measures (use of cooling blankets, rehydration), drug therapy (dantrolene, bromocriptine), and immediate withdrawal of the neuroleptic. If neuroleptic therapy is resumed after symptoms have subsided, the lowest effective dosage of a low-potency drug should be employed. If a second episode occurs, switching to an SGA may be helpful.

32.6.2.2...

Anticholinergic Effects.

Inform patients about possible anticholinergic reactions (dry mouth, blurred vision, photophobia, urinary hesitancy, constipation, tachycardia, suppression of sweating), and teach them how to minimize discomfort. A complete summary of nursing implications for anticholinergic effects is given in [Chapter 14](#).

Anticholinergic effects are most likely with low-potency FGAs.

32.6.2.2...

Orthostatic Hypotension.

Inform patients about signs of hypotension (lightheadedness, dizziness) and advise them to sit or lie down if these occur. Inform patients that hypotension can be minimized by moving slowly when assuming an erect posture. Orthostatic hypotension is most likely with low-potency FGAs.

In hospitalized patients, measure blood pressure and pulses before dosing and 1 hour after. Make these measurements while the patient is lying down and again after he or

she has been sitting or standing for 1 to 2 minutes. If blood pressure is low, withhold medication and consult the prescriber.

32.6.2.2...

Sedation.

Sedation is most intense during the first weeks of therapy and declines with continued drug use. **Warn patients about sedative effects, and advise them to avoid hazardous activity until sedation subsides.** Sedation is most likely with low-potency FGAs.

32.6.2.2...

Seizures.

Neuroleptics reduce seizure threshold, thereby increasing the risk of seizures, especially in patients with epilepsy and other seizure disorders. For patients with seizure disorders, adequate doses of antiseizure medication must be employed. Monitor the patient for seizure activity; if loss of seizure control occurs, dosage of antiseizure medication must be increased.

32.6.2.2...

Sexual Dysfunction.

In women, FGAs can suppress libido and impair the ability to achieve orgasm. In men, FGAs can suppress libido and cause erectile and ejaculatory dysfunction. **Counsel patients about possible sexual dysfunction and encourage them to report problems.** Dosage reduction or switching to a high-potency FGA may be helpful.

32.6.2.2...

Dermatologic Effects.

Inform patients that phenothiazines can sensitize the skin to ultraviolet light, thereby increasing the risk of sunburn. Advise them to avoid excessive exposure to sunlight, apply a sunscreen, and wear protective clothing.

Oral liquid formulations can cause contact dermatitis. **Warn patients to avoid skin contact with these drugs.**

32.6.2.2...

Neuroendocrine Effects.

Inform patients that FGAs can cause galactorrhea, gynecomastia, and menstrual irregularities.

Antipsychotics can promote growth of prolactin-dependent carcinoma of the breast and must not be used by patients with this cancer.

32.6.2.2...

Agranulocytosis.

Agranulocytosis greatly diminishes the ability to fight infection. **Inform patients about early signs of infection (fever, sore throat), and instruct them to notify the prescriber if these develop.** If blood tests indicate agranulocytosis, the antipsychotic should be withdrawn.

32.6.2.2...

Severe Dysrhythmias.

Chlorpromazine, thioridazine, haloperidol, and pimozide prolong the QT interval, and can thereby induce torsades de pointes, a dysrhythmia that can progress to fatal ventricular fibrillation. The risk of dysrhythmias can be reduced by (1) ensuring that potassium and magnesium levels are normal, (2) avoiding other drugs that cause QT prolongation, and (3) avoiding drugs that can increase levels of the antipsychotic drug being used.

32.6.2.2...

Death in Elderly Dementia Patients.

All FGAs increase the risk of mortality when used to treat dementia in elderly patients, an application use for which these drugs are not approved. Avoid FGAs in these patients.

32.6.2.2...

Minimizing Adverse Interactions

32.6.2.2...

Anticholinergics.

Drugs with anticholinergic properties will intensify anticholinergic responses to FGAs. **Instruct patients to avoid all drugs with anticholinergic properties, including the antihistamines and certain over-the-counter sleep aids.**

32.6.2.2...

CNS Depressants.

First-generation agents will intensify CNS depression caused by other drugs. **Warn patients against use of alcohol and all other drugs with CNS-depressant properties (eg, barbiturates, opioids, antihistamines, benzodiazepines).**

32.6.2.2...	Levodopa and Direct Dopamine Receptor Agonists.	333
	Levodopa and the dopamine receptor agonists (eg, bromocriptine) promote activation of dopamine receptors, and may thereby diminish the therapeutic effects of FGAs. Accordingly, patients taking FGAs should not use these drugs.	334
32.6.2.2...	QT-Prolonging Drugs. Drugs that prolong the QT interval increase the risk of dysrhythmias in patients taking <i>chlorpromazine</i>, <i>thioridazine</i>, <i>haloperidol</i>, and <i>pimozide</i>, and hence must be avoided. Agents to avoid include tricyclic antidepressants, thioridazine, several antidysrhythmic drugs (eg, amiodarone, dofetilide, quinidine), and certain antibiotics (eg, clarithromycin, erythromycin, moxifloxacin, gatifloxacin, sparfloxacin).	
32.6.2.2.2	SECOND-GENERATION (ATYPICAL) ANTIPSYCHOTICS Aripiprazole Clozapine Olanzapine Paliperidone Quetiapine Risperidone Ziprasidone Except where indicated, the nursing implications below apply to all SGAs. Preadministration Assessment Therapeutic Goal See <i>First-Generation (Conventional) Antipsychotics</i>.	

32.6.2.2...

Baseline Data

See *First-Generation (Conventional) Antipsychotics*. Also, obtain baseline measurements of weight, waist circumference, fasting blood glucose, and fasting lipid levels. For patients taking *quetiapine*, examine the lens for cataracts. For patients taking *clozapine*, obtain baseline values for total WBC and ANC.

32.6.2.2...

Identifying High-Risk Patients

Use all SGAs, and especially *clozapine* and *olanzapine*, with *caution* in patients with diabetes.

Clozapine is *contraindicated* for patients with a history of bone marrow depression or clozapine-induced agranulocytosis, and for those taking myelosuppressive drugs (eg, many anticancer drugs).

Use *clozapine* with *caution* in patients with seizure disorders.

Ziprasidone is *contraindicated* for patients with risk factors for torsades de pointes (eg, hypokalemia, hypomagnesemia, bradycardia, congenital QT prolongation, or a history of dysrhythmias, myocardial infarction, or severe heart failure) and for those taking drugs that prolong the QT interval.

Generally *avoid all SGAs* in elderly patients with dementia.

32.6.2.2...

Implementation: Administration

32.6.2.2...

Routes

Oral, IM. Routes for individual agents are summarized in [Tables 31-4](#) and [31-8](#).

32.6.2.2...

Dosing

To minimize side effects, dosage should be low initially and then gradually increased.

32.6.2.2...

Implementation: Measures to Enhance Therapeutic Effects

32.6.2.2...

Promoting Adherence

See *First-Generation (Conventional) Antipsychotics*.

32.6.2.2... Ongoing Evaluation and Interventions

32.6.2.2... Evaluating Therapeutic Effects

See *First-Generation (Conventional) Antipsychotics*.

32.6.2.2... Minimizing Adverse Effects

In contrast to FGAs, the SGAs carry a low risk of sexual dysfunction, neuroendocrine effects, and extrapyramidal reactions, including TD.

32.6.2.2... Orthostatic Hypotension and Anticholinergic Effects.

See *First-Generation (Conventional) Antipsychotics*.

32.6.2.2... Agranulocytosis.

Clozapine produces agranulocytosis in 1% to 2% of patients, typically during the first 6 months of treatment. Deaths from gram-negative septicemia have occurred.

Regular hematologic monitoring is mandatory: WBC and ANC must be determined weekly for the first 6 months, every 2 weeks for the next 6 months, and monthly thereafter. If the total WBC count falls below $3000/\text{mm}^3$ or if the ANC falls below $1500/\text{mm}^3$, treatment should be interrupted. When subsequent *daily* monitoring indicates that cell counts have risen above these values, clozapine can be resumed. If the total WBC count falls below $2000/\text{mm}^3$ or if the ANC falls below $1000/\text{mm}^3$, clozapine should be permanently discontinued. Continue monitoring blood counts for 4 weeks.

Warn patients about the risk of agranulocytosis, and inform them that clozapine will not be dispensed without repeated proof of blood counts. Inform patients about early signs of infection (fever, sore throat, fatigue, mucous membrane ulceration), and instruct them to report these immediately.

32.6.2.2... Metabolic Effects: Weight Gain, Diabetes, and Dyslipidemia.

All SGAs—and especially *clozapine* and *olanzapine*—can promote weight gain, which can lead to diabetes and dyslipidemia. To monitor weight gain, determine weight at baseline; 4, 8, and 12 weeks later; and every 3 months thereafter. Also,

334

determine waist circumference at baseline and annually thereafter. **Inform patients about the risk of weight gain and encourage them to control caloric intake and get regular exercise.** If significant weight gain occurs, it can be managed with a combination of diet, exercise, and metformin.

To monitor for diabetes, measure fasting blood glucose at baseline, 12 weeks later, and annually thereafter. In patients with documented diabetes at baseline, monitor for worsening of glucose control. **Inform all patients about symptoms of diabetes—hyperglycemia, polyuria, polydipsia, polyphagia, dehydration—and instruct them to tell the prescriber if they occur.** If diabetes develops, it can be managed with insulin or an oral hypoglycemic drug (eg, metformin).

To monitor for *dyslipidemia*, obtain a fasting lipid profile at baseline, 12 weeks later, and every 5 years thereafter.

32.6.2.2...

Seizures.

Clozapine causes generalized tonic-clonic seizures in 3% of patients. **Warn patients against driving and other hazardous activities if seizures have occurred.**

32.6.2.2...

Sedation.

All SGAs—and especially *clozapine* and *olanzapine*—can cause sedation. **Warn patients against driving and participating in other hazardous activities if impairment is significant.**

32.6.2.2...

Myocarditis.

Very rarely, *clozapine* causes myocarditis. **Inform patients about signs and symptoms (eg, unexplained fatigue, dyspnea, tachypnea, chest pain, palpitations), and advise them to seek immediate medical attention if these develop.** Withhold clozapine until myocarditis has been ruled out. If myocarditis is diagnosed, the drug should never be used again.

32.6.2.2...

Dysrhythmias.

Ziprasidone prolongs the QT interval, posing a risk of torsades de pointes, a potentially fatal dysrhythmia. The risk of dysrhythmias can be reduced by (1) ensuring that potassium and magnesium levels are normal, (2) avoiding other drugs

that cause QT prolongation, and (3) avoiding drugs that can increase levels of ziprasidone.

32.6.2.2...

Death in Elderly Dementia Patients.

All SGAs increase the risk of mortality when used to treat dementia in elderly patients, an application for which these drugs are not approved. Avoid SGAs in these patients.

32.6.2.2...

Cataracts.

Quetiapine may pose a risk of cataracts. Examine the lens for cataracts at baseline and every 6 months thereafter.

32.6.2.2...

Minimizing Adverse Interactions

32.6.2.2...

CNS Depressants.

Second-generation antipsychotics may intensify CNS depression caused by other drugs. **Warn patients against use of alcohol and all other drugs with CNS-depressant properties (eg, barbiturates, opioids, antihistamines, benzodiazepines).**

32.6.2.2...

Levodopa and Direct Dopamine Receptor Agonists.

Levodopa and the dopamine receptor agonists (eg, bromocriptine) promote activation of dopamine receptors, and may thereby diminish therapeutic effects of the SGAs. Patients taking antipsychotics should not use these drugs.

32.6.2.2...

Myelosuppressive Drugs.

Clozapine must not be given to patients taking other drugs that can suppress bone marrow function (eg, many anticancer agents).

32.6.2.2...

QT-Prolonging Drugs.

Drugs that prolong the QT interval increase the risk of dysrhythmias in patients taking *ziprasidone*, and hence must be avoided. Agents to avoid include tricyclic antidepressants, thioridazine, several antidysrhythmic drugs (eg, amiodarone,

dofetilide, quinidine), and certain antibiotics (eg, clarithromycin, erythromycin, moxifloxacin, gatifloxacin, sparfloxacin).

32.6.2.2...

Inducers and Inhibitors of CYP3A4.

Drugs that induce CYP3A4 (eg, barbiturates, carbamazepine, phenytoin, rifampin) can accelerate metabolism of *aripiprazole*, *quetiapine*, and *ziprasidone*, and can thereby reduce blood levels of these three drugs. Conversely, drugs that inhibit CYP3A4 (eg, ketoconazole, itraconazole, fluconazole, erythromycin) can increase levels of these three drugs.

* Patient education information is highlighted as **blue text**.

³³CHAPTER 32 Antidepressants

As their name suggests, the antidepressants are used primarily to relieve symptoms of depression. In addition, these drugs can help patients with anxiety disorders. As a rule, antidepressants are not indicated for uncomplicated bereavement. The antidepressants fall into five major groups: tricyclic antidepressants, selective serotonin reuptake inhibitors, serotonin and norepinephrine reuptake inhibitors, monoamine oxidase inhibitors, and atypical antidepressants.

^{33.1} MAJOR DEPRESSION: CLINICAL FEATURES, PATHOGENESIS, AND TREATMENT MODALITIES

Depression is the most common psychiatric disorder. In the United States, about 30% of the population will experience some form of depression during their lives. At any given time, about 5% of the adult population is depressed. The incidence in women is twice that in men. The risk of suicide among depressed people is high. Unfortunately, depression is underdiagnosed and undertreated: Only 30% of depressed individuals receive treatment. This is especially sad in that treatment can help many people: about 40% of those given antidepressants achieve full remission; another 20% to 30% achieve at least a 50% reduction in symptom severity.

TABLE 32-1 DSM-IV-TR Diagnostic Criteria for a Major Depressive Episode

A. For a diagnosis of major depression, at least five of the following symptoms must be present for 2 weeks or more, and must represent a change from previous functioning. Furthermore, at least one symptom must be (1) depressed mood or (2) loss of interest or pleasure. (*Note:* Do not include mood-incongruent delusions or hallucinations, or symptoms that are due to a general medical condition.)

- Depressed mood most of the day, nearly every day (*Note:* In children and adolescents, can be irritable mood.)
- Loss of interest or pleasure in all or almost all activities
- Significant weight loss or weight gain without dieting or decrease or increase in appetite (*Note:* In children, consider failure to make expected weight gains.)
- Insomnia or hypersomnia
- Psychomotor agitation or retardation
- Fatigue or loss of energy
- Feelings of worthlessness or excessive or inappropriate guilt
- Diminished ability to think or concentrate or indecisiveness
- Recurrent thoughts of death, recurrent suicidal ideation, a suicide attempt, or a specific suicide plan

B. The symptoms do not meet the criteria for a Mixed Episode (ie, an episode in which criteria are met for a Major Depressive Episode *and* a Manic Episode).

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The symptoms are not due to the direct physiologic effects of a substance (eg, drug of abuse, medication) or a general condition (eg, hypothyroidism).

E. Major depression should not be diagnosed in the context of bereavement (ie, after the loss of a loved one), unless the symptoms persist for longer than 2 months, or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Adapted from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Press, 2000, with permission. Copyright © 2000 American Psychiatric Association.

33.1.1 Clinical Features

Diagnostic criteria for a major depressive episode are summarized in [Table 32-1](#). As indicated, the principal symptoms are *depressed mood* and *loss of pleasure or interest in all or nearly all of*

one's usual activities and pastimes. Associated symptoms include insomnia (or sometimes hypersomnia); anorexia and weight loss (or sometimes hyperphagia and weight gain); mental slowing and loss of concentration; feelings of guilt, worthlessness, and helplessness; thoughts of death and suicide; and overt suicidal behavior. For a diagnosis to be made, symptoms must be present most of the day, nearly every day, for at least 2 weeks.

336

337

It is important to distinguish between major depression and normal grief or sadness. Whereas major depression is an illness, grief or sadness is not. Rather, grief and sadness are appropriate reactions to a major life stressor (eg, death of a loved one, loss of a job). In most cases, grief and sadness resolve spontaneously over several weeks and do not require medical intervention. However, if symptoms are unusually intense, and if they fail to abate within an appropriate time, a major depressive episode may have been superimposed. If this occurs, treatment is indicated.

33.1.2 Pathogenesis

The etiology of major depression is complex and incompletely understood. For some individuals, depression seems to descend “out of the blue”; otherwise healthy people—unexpectedly and without apparent cause—find themselves feeling profoundly depressed. For many others, depressive episodes are brought on by stressful life events, such as bereavement, loss of a job, or childbirth ([Box 32-1](#)). Since depression does not occur in everyone, it would appear that some people are more vulnerable than others. Factors that may contribute to vulnerability include genetic heritage, a difficult childhood, and chronic low self-esteem.

Clinical observations made in the 1960s led to formulation of the *monoamine-deficiency hypothesis of depression*, which asserts that depression is caused by a functional deficiency of monoamine neurotransmitters (norepinephrine, serotonin, or both). Findings that support the hypothesis include (1) induction of depression with reserpine, a drug that depletes monoamines from the brain; (2) induction of depression with inhibitors of tyrosine hydroxylase, an enzyme needed for monoamine transmitter synthesis; and (3) relief of depression with drugs that intensify monoamine-mediated neurotransmission. Although these observations lend support to the monoamine-deficiency hypothesis, it is clear that the hypothesis is too simplistic. However, despite its shortcomings, the monoamine-deficiency hypothesis does provide a useful conceptual framework for understanding antidepressant drugs.

33.1.3 Treatment Modalities

Depression can be treated with four modalities: (1) pharmacotherapy, (2) depression-specific psychotherapy (eg, cognitive behavioral therapy), (3) electroconvulsive therapy (ECT), and (4) vagus nerve stimulation. The first three modalities offer clear benefits. Benefits of vagus nerve stimulation are questionable. For patients with mild to moderate depression, drug therapy and

psychotherapy can be equally effective. For those with more severe depression, a combination of drugs and psychotherapy is better than either intervention alone. ECT is used when a rapid response is needed, or when drugs and psychotherapy have not worked. Vagus nerve stimulation is tried only after treatment with at least four drugs has failed.

Drugs are the primary therapy for major depression. Available antidepressants are listed in [Table 32-2](#). For many patients, the *tricyclic antidepressants* (TCAs) are drugs of first choice. These agents are inexpensive, effective, relatively safe, and easy to administer. *Selective serotonin reuptake inhibitors* (SSRIs) are just as effective as the tricyclics and better tolerated. Because of these qualities—and despite their high cost—the SSRIs have become our most widely prescribed antidepressant drugs. *Monoamine oxidase inhibitors* (MAOIs) are generally reserved for patients who have not responded to TCAs or SSRIs. However, for patients with *atypical* depression, MAOIs are drugs of choice.

337

338

33.1.3.1

BOX 32-1 Special Interest Topic

33.1.3.1.1

POSTPARTUM DEPRESSION

The vast majority (about 80%) of women experience depressive symptoms after giving birth. For most, the symptoms are mild and transient, reflecting a condition known as the “baby blues.” For others, symptoms are severe and persistent, reflecting true postpartum depression, a condition that merits rapid medical attention.

An estimated 60% to 70% of women get the postpartum blues. Symptoms include tearfulness, sadness, nervousness, irritability, and anxiety, along with difficulty eating and sleeping. The new mom may feel overwhelmed, vulnerable, weak, and alone. She may cry for no clear reason. Her self-esteem and self-confidence may decline, and she may feel unqualified to care for her baby. Fortunately, all of these symptoms pass quickly: As a rule, they develop a few days after delivery and are gone by day 10. Because the baby blues are so common, they're considered a normal postpartum event. Treatment is neither necessary nor recommended.

True postpartum depression is a different matter. The condition is much less common than the baby blues, but much more serious. Left untreated, postpartum depression typically lasts for months, and is likely to become worse as time passes. Not only is the condition detrimental to the mother, it can adversely affect the child, preventing secure attachment and impairing cognitive, emotional, and behavioral development. Accordingly, immediate intervention is indicated.

Just what is postpartum depression? Simply put, it's an episode of major depression that starts after giving birth. Otherwise, the diagnostic criteria are the same as for all other episodes of major depression (see [Table 32-1](#)). According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV), for a depressive episode to qualify as having postpartum onset, symptoms must begin within *4 weeks* of delivery. However, most clinicians who study the disorder use a different criterion: To them, depression is considered postpartum if it begins within *3 months* of delivery—not just within 4 weeks.

Who is likely to suffer postpartum depression? Sometimes the condition occurs in first-time mothers, and sometimes it doesn't strike until a second, third, or fourth child is born. Among first-time mothers, the incidence is between 8% and 15% (about 1 in 8). For women with a history of the disorder, the risk increases to 33% (1 in 3). In addition to a prior history of the disorder, risk factors include a history of depression unrelated to childbirth, a history of premenstrual dysphoric disorder (ie, severe premenstrual syndrome), and major stress related to family, work, or residence (eg, death of a loved one, loss of a job, moving away from a familiar town or city).

The underlying cause of postpartum depression is unknown, but several factors are thought to contribute. Heading the list is the sharp drop in estrogen and progesterone levels that occurs after delivery. (Levels of these hormones increase 10-fold during pregnancy, and then return to baseline after the placenta is expelled.) However, since hormone levels fall in all women, but only some get postpartum depression, other factors—physical, emotional, and social—must be involved. The birthing process leaves women feeling weak and fatigued. Caring for a baby, who needs round-the-clock attention and feeding, exacerbates tiredness and exhaustion. Emotional and social factors may also play a role. Feelings of loss are common: Women experience loss of freedom, loss of control, and even loss of identity. In addition, they may feel loss of attractiveness. Stress increases substantially, owing to increased workload and responsibilities, coupled with feelings of self-doubt and inadequacy, and compounded by a self-imposed (albeit highly unrealistic) expectation to be a “perfect” mom. Stress can be made even worse by financial insecurity and inadequate support from one's partner, family, and friends. Thyroid insufficiency may also contribute: Levels of thyroid hormone often decline after delivery, thereby causing symptoms that can mimic depression. Accordingly, thyroid levels should be checked and, if indicated, replacement therapy should be implemented.

Screening for postpartum depression can be accomplished with a quick test: the Edinburgh Postnatal Depression Scale. The test is administered 6 to 8 weeks after delivery and contains the following short statements:

1. I have been able to laugh and see the funny side of things.
2. I have looked forward with enjoyment to things.
3. I have blamed myself unnecessarily when things went wrong.
4. I have been anxious or worried for no good reason.
5. I have felt scared or panicky for no very good reason.
6. Things have been getting on top of me.
7. I have been so unhappy that I have had difficulty sleeping.
8. I have felt sad or miserable.
9. I have been so unhappy that I have been crying.
10. The thought of harming myself has occurred to me.

Each statement has four possible responses, such as these for statement 10: (1) yes, quite often, (2) sometimes, (3) hardly ever, and (4) never. When taking the test, the mother simply underlines the option that best reflects her feelings during the previous week. If her responses indicate she probably has postpartum depression, she should undergo clinical evaluation to establish a definitive diagnosis.

Treatment of postpartum depression is much like treatment of major depression unrelated to pregnancy. The goal is to normalize mood, and optimize maternal and social functioning. The principal treatment modalities are psychotherapy and antidepressant drugs, both of which can be effective. In addition, the woman should be encouraged to nurture herself as well as her baby: She should reduce isolation (by going out for at least a short time each day), she should ensure adequate rest (by doing only what's really needed and letting the rest go), and she should spend time alone with her partner. Other beneficial measures include joining a support group for new mothers and recruiting family members and friends to assist with household and baby-related chores.

Although antidepressants are clearly appropriate, there are few published data to guide selection. In one study of women with postpartum depression, fluoxetine [Prozac], a selective serotonin reuptake inhibitor (SSRI), was compared with psychotherapy. Both treatments were equally effective, and both were superior to placebo. Efficacy has also been demonstrated for sertraline [Zoloft], venlafaxine [Effexor], and certain tricyclic antidepressants (TCAs). For initial therapy, the SSRIs are an attractive choice. Why?

Because they are effective and well tolerated, and present little risk of toxicity if taken in overdose. However, if a woman has responded to an antidepressant from a different class in the past, that drug should be tried first. To minimize side effects, dosage should be low initially (50% of the usual starting dosage) and then gradually increased. To reduce the risk of relapse, treatment should continue for at least 6 months after symptoms have resolved. Unfortunately, even then the relapse rate is high: Between 50% and 85% of patients experience at least one more depressive episode. With each succeeding episode, the risk of another recurrence increases. Accordingly, long-term prophylactic therapy should be considered.

Which antidepressants can be taken safely while breastfeeding? All of these drugs can be detected in breast milk—but levels of some are much lower (safer) than levels of others. Sertraline, for example, appears very safe. Studies show that drug activity in breast-fed infants is extremely low, and no adverse reactions have been observed. The TCAs (eg, nortriptyline, desipramine) also appear safe: Levels are too low for detection in breast-fed infants, and follow-up studies have found no developmental deficits. In contrast to sertraline and the TCAs, fluoxetine appears unsafe: The drug and its metabolites reach therapeutic levels in breast-fed infants; potential consequences include colic and impaired weight gain.

Electroconvulsive therapy is a valuable tool for treating depression. This procedure is safe and effective, and benefits develop more rapidly than with drugs or psychotherapy. Accordingly, ECT is especially appropriate when speed is critical. Candidates for ECT include (1) severely depressed, suicidal patients; (2) elderly patients at risk of starving to death because of depression-induced lack of appetite; and (3) patients who have not responded to antidepressant drugs.

338

TABLE 32-2 Antidepressants: Adverse Effects and Impact on Neurotransmitters

		Adverse Effects								
	Transmitters Affected ^a	Agitation/Insomnia	Anticholinergic Activity	Sedation	Hypotension	Seizure Risk	Cardiac Toxicity	Weight Gain	Sexual Dysfunction	Other Adverse Effects
Tricyclic Antidepressants (TCAs)										
Amitriptyline	NE, 5-HT	0/+	+++	+++	++	++	+++	+++	++	
Clomipramine	NE, 5-HT	+	++	++	++	+++	+++	++	++	
Doxepin	NE, 5-HT	0/+	++	+++	++	++	+++	+++	++

Fluvoxamine	5-HT	++	0/+	0/+	0	0/+		+	+++	
Paroxetine	5-HT	++	0/+	b	0	0/+	0	+	+++	
Sertraline	5-HT	++	0	b	0	0/+	0	+	+++	
Serotonin/Norepinephrine Reuptake Inhibitors (SNRIs)										
Venlafaxine	NE, 5-HT	++	0	0	0	0/+	0/+	0	+++	Hepatotoxicity
Desvenlafaxine	NE, 5-HT	++	0	0	0	0/+	0/+	0	++	
Duloxetine	NE, 5-HT	++	0	0	0/+	0/+	0/+	0/+	+	
Monoamine Oxidase Inhibitors (MAOIs)										
Isocarboxazid	NE, 5-HT, DA	++	0	+	+	0	0	+	++	Hypertensive crisis from tyramine in food ^d
Phenelzine	NE, 5-HT, DA	++	0	+	+	0	0	+	++	
Selegiline	NE, 5-HT, DA	++	0	0	0	0	0	0	+	
Tranylcypromine	NE, 5-HT, DA	++	0	^b	+	0	0	+	++	
Atypical Antidepressants										
Amoxapine	NE, ↓ DA ^e	0/+	+	+	+	++	++	+	++	Parkinsonism
Bupropion	DA	++	0/+	b	0	+++	0	0	^f	Seizures
Mirtazapine	NE, 5-HT	0/+	0/+	++++	0/+	0	0	++++	0	
Nefazodone	5-HT	0/+	0/+	++	0	0	0/+	0/+	0/+	
Trazodone	5-HT	0/+	0/+	++++	+	0	0/+	+	^g	Priapism

a NE = norepinephrine; 5-HT = serotonin; DA = dopamine. All of the antidepressants *increase* synaptic activity of the transmitters indicated—with the exception of amoxapine, which increases activity of NE, but *blocks* receptors for DA. The TCAs, SSRIs, SNRIs, amoxapine, bupropion, nefazodone, and trazodone decrease transmitter reuptake; MAOIs block transmitter breakdown; and mir-tazapine promotes transmitter release.

- b Produces moderate *stimulation*, not sedation.
- c NAS = neonatal abstinence syndrome; PPHN = persistent pulmonary hypertension of the newborn.
- d Hypertensive crisis is not a risk with low-dose oral selegiline (10 mg/day or less) or with low-dose transdermal selegiline (6 mg/day), and possibly not with higher transdermal doses.
- e Amoxapine blocks *reuptake* of NE and blocks *receptors* for DA.
- f Bupropion may increase sexual desire.
- g Trazodone can cause priapism (persistent painful erection).

339

33.2 SUICIDE RISK WITH ANTIDEPRESSANT DRUGS

340

Patients with depression often think about or attempt suicide. During treatment with antidepressants, especially early on, the risk of suicide may actually *increase*. If mood deteriorates, or if thoughts of suicide intensify, the patient should see his or her prescriber immediately. Concerns about antidepressant-induced suicide apply mainly to children, adolescents, and adults under the age of 25.

To reduce the risk of suicide, patients taking antidepressant drugs should be observed closely for suicidality, worsening mood, and unusual changes in behavior. Close observation is especially important during the first few months of therapy and whenever antidepressant dosage is changed (either increased or decreased). Ideally, the patient or caregiver should meet with the prescriber at least weekly during the first 4 weeks of treatment, then biweekly for the next 4 weeks, then once 1 month later, and periodically thereafter. Phone contact may be appropriate between visits. In addition, family members or caregivers should monitor the patient *daily*, being alert for symptoms of decline (eg, anxiety, agitation, panic attacks, insomnia, irritability, hostility, impulsivity, hypomania, and, of course, emergence of suicidality). If these symptoms are severe or develop abruptly, the prescriber should be informed at once.

Because antidepressant drugs can be used to *commit* suicide, two precautions should be observed. First, prescriptions should be written for the smallest number of doses consistent with good patient management. Second, dosing of inpatients should be directly observed to ensure that each dose is swallowed and not “cheeked,” thereby preventing the patient from accumulating multiple doses that might be taken with suicidal intent.

What should be done if suicidal thoughts emerge during drug therapy, or if depression is persistently worse while taking drugs? One option is to switch to another antidepressant. Another is to stop antidepressants entirely. However, option two is probably unwise. Why? Because the long-term risk of suicide from untreated depression is much greater than the long-term risk associated with

antidepressant drugs. If the risk of suicide appears high, temporary hospitalization may be the best protection.

33.3 TRICYCLIC ANTIDEPRESSANTS (TCAs)

The TCAs are drugs of first choice for many patients with major depression. The first tricyclic agent—*imipramine*—was introduced to psychiatry in the late 1950s. Since then, the ability of TCAs to relieve depressive symptoms has been firmly established. The most common adverse effects are sedation, orthostatic hypotension, and anticholinergic effects. The most dangerous effect is cardiac toxicity. Like all other antidepressants, TCAs may increase the risk of suicide. Because all of the TCAs have similar properties, we will discuss these drugs as a group, rather than focusing on a representative prototype.

33.3.1 Chemistry

The structure of imipramine, a representative TCA, is shown in [Figure 32-1](#). As you can see, the nucleus of this drug has three rings, hence the classification *tricyclic* antidepressant.

Figure 32-1 Structural similarities between tricyclic antidepressants and phenothiazine antipsychotics.

Except for the areas highlighted, the phenothiazine nucleus is nearly identical to that of TCAs. Because of their structural similarities, TCAs and phenothiazines have several pharmacologic properties in common.

As indicated in [Figure 32-1](#), the three-ringed nucleus of the TCAs is very similar to the three-ringed nucleus of the phenothiazine antipsychotics. Because of this structural similarity, TCAs and phenothiazines have several actions in common. Specifically, both groups produce varying degrees of *sedation*, *orthostatic hypotension*, and *anticholinergic effects*.

33.3.2 Mechanism of Action

The proposed mechanism of action of the TCAs is depicted in [Figure 32-2](#). As shown, TCAs block neuronal reuptake of two monoamine transmitters: norepinephrine (NE) and serotonin (5-hydroxytryptamine, or 5-HT). By blocking reuptake of these transmitters, TCAs intensify their effects. This mechanism is consistent with the theory that depression stems from a *deficiency* in monoamine-mediated transmission—and hence should be relieved by drugs that can intensify monoamine effects. As indicated in [Table 32-2](#), some TCAs block reuptake of NE *and* 5-HT, whereas other only block reuptake of NE.

It is important to appreciate that blockade of reuptake, by itself, cannot fully account for therapeutic effects. Why? Because clinical responses to the TCAs (relief of depressive symptoms) and biochemical effects of the TCAs (blockade of transmitter reuptake) do not occur in the same time frame. That is, whereas TCAs block transmitter uptake within hours of dosing, relief of depression takes several weeks to fully develop. Hence, it would appear that, in the interval between the onset of uptake blockade and the onset of a therapeutic response, intermediary neurochemical events must be taking place. Just what these may be is unknown.

33.3.3 Pharmacokinetics

The half-lives of TCAs are long and variable. Because their half-lives are long, TCAs can usually be administered in a single daily dose. Because their half-lives are variable, TCAs require individualization of dosage.

33.3.4 Therapeutic Uses

33.3.4.1 Depression.

TCAs are preferred drugs for major depression. These medicines can elevate mood, increase activity and alertness, decrease morbid preoccupation, improve appetite, and normalize sleep patterns.

Like all other antidepressants, TCAs do not relieve symptoms immediately. *Initial* responses develop in 1 to 3 weeks.

Figure 32-2 Mechanism of action of tricyclic antidepressants.**A,** Under drug-free conditions, the actions of norepinephrine and serotonin are terminated by active uptake of these transmitters back into the nerve terminals from which they were released. **B,** By inhibiting the uptake pumps for norepinephrine and serotonin, tricyclic antidepressants cause these transmitters to accumulate in the synaptic space, thereby intensifying transmission. (P = uptake pump, T = transmitter [norepinephrine or serotonin], TCA = tricyclic antidepressant, P = uptake pump.)

Maximal responses develop over 1 to 2 months. Because therapeutic effects are delayed, TCAs cannot be used PRN. Furthermore, a therapeutic trial should not be considered a failure until medication has been administered for at least 1 month without success.

33.3.4.2 Bipolar Disorder.

Bipolar disorder (manic-depressive illness) is characterized by alternating episodes of mania and depression (see [Chapter 33](#)). TCAs can help during depressive episodes.

33.3.4.3 Other Uses.

TCAs can benefit patients with neuropathic pain (see [Chapter 29](#)), chronic insomnia (see [Chapter 34](#)), attention-deficit/hyperactivity disorder (see [Chapter 36](#)), and panic disorder or obsessive-compulsive disorder (see [Chapter 35](#)).

33.3.5 Adverse Effects

The most common adverse effects are orthostatic hypotension, sedation, and anticholinergic effects. The most serious adverse effect is cardiotoxicity. These effects occur because, in addition to blocking uptake of monoamine transmitters, TCAs cause direct blockade of receptors for histamine, acetylcholine, and NE. Adverse effects of individual agents are summarized in [Table 32-2](#).

33.3.5.1 Orthostatic Hypotension.

Orthostatic hypotension is the most serious of the common adverse responses to TCAs. Hypotension is due in large part to blockade of α_1 adrenergic receptors on blood vessels. Patients should be informed that they can minimize orthostatic hypotension by moving slowly when assuming an upright posture. In addition, patients should be instructed to sit or lie down if symptoms (dizziness, lightheadedness) occur. For hospitalized patients, blood pressure and pulse rate should be monitored on a regular schedule (eg, 4 times a day). These measurements should be taken while the patient is lying down and again after the patient has been sitting or standing for 1 to 2 minutes. If blood pressure is low or pulse rate is high, medication should be withheld and the prescriber notified.

33.3.5.2 Anticholinergic Effects.

The TCAs block muscarinic cholinergic receptors, and can thereby cause an array of anticholinergic effects (dry mouth, blurred vision, photophobia, constipation, urinary hesitancy, and tachycardia). Patients should be informed about possible anticholinergic responses and instructed in ways to minimize discomfort. A detailed discussion of anticholinergic effects and their management is presented in [Chapter 14](#).

33.3.5.3 Diaphoresis.

Despite their anticholinergic properties, TCAs often cause diaphoresis (sweating). The mechanism of this paradoxical effect is unknown.

33.3.5.4 Sedation.

Sedation is a common response to TCAs. The cause is blockade of histamine receptors in the central nervous system (CNS). Patients should be advised to avoid hazardous activities if sedation is prominent.

33.3.5.5 Cardiac Toxicity.

Tricyclics can adversely affect cardiac function. However, in the absence of an overdose or pre-existing cardiac impairment, serious effects are rare. The TCAs affect the heart by (1) decreasing vagal influence on the heart (secondary to muscarinic blockade) and (2) acting directly on the bundle of His to slow conduction. Both effects increase the risk of dysrhythmias. To minimize risk, all patients should undergo electrocardiographic (ECG) evaluation prior to treatment and periodically thereafter.

33.3.5.6 Seizures.

TCAs lower seizure threshold. Exercise caution in patients with epilepsy and other seizure disorders.

33.3.5.7 Hypomania.

On occasion, TCAs produce too much of a good thing, elevating mood from depression all the way to hypomania (mild mania). If hypomania develops, the patient should be evaluated to determine whether elation is drug induced or the result of bipolar disorder.

33.3.5.8 Suicide Risk.

As discussed above, TCAs and all other antidepressants may increase the risk of suicide in depressed patients, especially during the early phase of treatment. The risk of antidepressant-induced suicide is greatest among children, adolescents, and young adults.

33.3.5.9 Yawngasm.

Rarely, patients taking *clomipramine* [Anafranil] experience yawngasm. Experience *what?* A spontaneous orgasm while yawning. Honest. This unusual side effect, which affects both males and females, may be considered adverse or beneficial, depending on your view of such things. In at least one documented case, yawngasms strongly influenced adherence, as evidenced by the patient asking how long she would be “allowed” to continue treatment. Although data are scarce, one might guess that the occasional yawngasm would help relieve depression.

341

342

33.3.6 Drug Interactions

33.3.6.1 Monoamine Oxidase Inhibitors.

The combination of a TCA with an MAOI can lead to *severe hypertension*, owing to excessive adrenergic stimulation of the heart and blood vessels. Excessive adrenergic stimulation occurs because (1) inhibition of monoamine oxidase (MAO) causes accumulation of NE in adrenergic neurons and (2) blockade of NE reuptake by the tricyclics decreases NE inactivation. Because of the potential for hypertensive crisis, combined therapy with TCAs and MAOIs is generally avoided.

33.3.6.2 Direct-Acting Sympathomimetic Drugs.

Tricyclics *potentiate* responses to direct-acting sympathomimetics (ie, drugs such as epinephrine and dopamine that produce their effects by direct interaction with adrenergic receptors). Why are responses increased? Because TCAs block uptake of these agents into adrenergic nerve terminals, and thereby prolong their presence in the synaptic space.

33.3.6.3 Indirect-Acting Sympathomimetic Drugs.

TCAs *decrease* responses to indirect-acting sympathomimetics (ie, drugs such as ephedrine and amphetamine that promote release of transmitter from adrenergic nerves). Why? Because TCAs block uptake of these agents into adrenergic nerves, thereby preventing them from reaching their site of action within the nerve terminal.

33.3.6.4 Anticholinergic Agents.

Since TCAs have anticholinergic actions of their own, they will intensify the effects of other anticholinergic medications. Consequently, patients receiving TCAs should be advised to avoid all other drugs with anticholinergic properties, including antihistamines and certain over-the-counter sleep aids.

33.3.6.5 CNS Depressants.

CNS depression caused by TCAs will add with CNS depression caused by other drugs. Accordingly, patients should be warned against taking all other CNS depressants, including alcohol, antihistamines, opioids, and barbiturates.

33.3.7 Toxicity

Overdose with a TCA can be life threatening. (The lethal dose is only 8 times the average daily dose.) To minimize the risk of death by suicide, acutely depressed patients should be given no more than a 1-week supply of their TCA at a time.

33.3.7.1 Clinical Manifestations.

Symptoms result primarily from anticholinergic and cardiotoxic actions. The combination of cholinergic blockade and direct cardiotoxicity can produce *dysrhythmias*, including tachycardia, intraventricular blocks, complete atrioventricular block, ventricular tachycardia, and ventricular fibrillation. Responses to peripheral muscarinic blockade include hyperthermia, flushing, dry mouth, and dilation of the pupils. CNS symptoms are prominent. Early responses are confusion, agitation, and hallucinations. Seizures and coma may follow.

33.3.7.2 Treatment.

Absorption of ingested drug can be reduced with gastric lavage followed by ingestion of activated charcoal. Physostigmine (a cholinesterase inhibitor) is given to counteract anticholinergic actions. Propranolol, lidocaine, or phenytoin can control dysrhythmias. Dysrhythmias should not be treated with procainamide or quinidine, because these drugs cause cardiac depression.

33.3.8 Dosage and Routes of Administration

33.3.8.1 Dosage.

Dosages for individual TCAs are summarized in [Table 32-3](#). General guidelines for dosing are discussed below.

Initial doses of TCAs should be low (eg, 50 mg of imipramine a day for adult outpatients). Low initial doses minimize adverse reactions and thereby help promote adherence. High initial doses are both undesirable and unnecessary. High doses are undesirable in that they pose an increased risk of adverse reactions. They are unnecessary in that onset of therapeutic effects is delayed regardless of dosage, and hence aggressive initial dosing offers no benefit.

Because of interpatient variability in TCA metabolism, dosing is highly individualized. As a rule, dosage is adjusted on the basis of clinical response. However, if there is no observable response, plasma drug levels can be used as a guide. For example, levels of imipramine must be above 225 ng/mL to be effective. If a patient has not responded to imipramine, measurements

should be made to ensure that the plasma level is adequate. If the level is below 225 ng/mL, dosage should be increased.

Once an effective dosage has been established, most patients can take their entire daily dose at bedtime; the long half-lives of the TCAs make divided daily doses unnecessary. Once-a-day dosing at bedtime has three advantages: (1) it's easy, and hence facilitates adherence; (2) it promotes sleep by causing maximal sedation at night; and (3) it reduces the intensity of side effects during the day. If bedtime dosing causes residual sedation in the morning, dosing earlier in the evening can help. Although once-a-day dosing is generally desirable, not all patients can use this schedule. The elderly, for example, can be especially sensitive to the cardiotoxic actions of the tricyclics. As a result, if the entire daily dose were taken at one time, effects on the heart might be intolerable.

Once remission has been produced, therapy should continue for 6 months to a year. Failure to take medication for this period is likely to result in relapse. Patients should be encouraged to continue drug therapy even if they are symptom free and hence feel that further medication is unnecessary.

33.3.8.2 Routes of Administration.

All TCAs can be administered by mouth, and they usually are. One agent—*imipramine*—may be given IM. Since effects take weeks to develop, there is no benefit to IV administration, and hence, this route is not used.

33.3.9 Preparations and Drug Selection

33.3.9.1 Preparations.

In the United States, nine TCAs are available (see [Tables 32-2](#) and [32-3](#)). All nine are equally effective. Principal differences among these drugs concern side effects (see [Table 32-2](#)).

33.3.9.2 Drug Selection.

Selection among TCAs is based on side effects. For example, if the patient is experiencing insomnia, a drug with prominent sedative properties (eg, doxepin) might be selected.

Conversely, if daytime sedation is undesirable, a less sedating agent (eg, desipramine) might be preferred. Elderly patients with glaucoma or constipation and males with prostatic hypertrophy can be especially sensitive to anticholinergic effects. Hence, for these patients, a drug with weak anticholinergic properties (eg, nortriptyline) would be appropriate.

342

343

TABLE 32-3 Adult Dosages for Antidepressants

Generic Name	Trade Name	Initial Dose*† (mg/day)	Dose after 4–8 Wk* (mg/day)	Maximum Dose† (mg/day)
Tricyclic Antidepressants (TCAs)				
Amitriptyline	generic only	50	100–200	300
Clomipramine	Anafranil	25	100–200	250
Desipramine	Norpramin	50	100–200	300
Doxepin	Sinequan	50	75–150	300
Imipramine	Tofranil	50	75–150	300
Maprotiline	generic only	50	100–150	225
Nortriptyline	Aventyl, Pamelor	20	75–100	125
Protriptyline	Vivactil	10	15–40	60
Trimipramine	Surmontil	50	100–200	300
Selective Serotonin Reuptake Inhibitors (SSRIs)				
Citalopram	Celexa	20	20–60	60
Escitalopram	Lexapro	10	10	20
Fluoxetine	Prozac	20	20–80	80
Fluvoxamine	Luvox	50	50–300	300
Paroxetine	Paxil, Pexeva	10	20–50	50
Sertraline	Zoloft	50	50–150	200
Serotonin/Norepinephrine Reuptake Inhibitors (SNRIs)				
Venlafaxine	Effexor	37.5	75–225	375
Desvenlafaxine	Pristiq	50	50	100
Duloxetine	Cymbalta	40–60	40–60	60
Monoamine Oxidase Inhibitors (MAOIs)				
Isocarboxazid	Marplan	20	20–60	80
Phenelzine	Nardil	15	45–60	90
Selegiline (transdermal)	Emsam	6	6–12	12
Tranylcypromine	Parnate	10	30–40	60
Atypical Antidepressants				
Amoxapine	generic only	50	200–300	400
Bupropion	Wellbutrin, others	150	50–300	450

Mirtazapine	Remeron	15	15–45	60
Nefazodone	generic only	200	300–600	600
Trazodone	generic only	150	150–400	600

* Doses listed are *total daily doses*. Depending on the drug and the patient, the total dose may be given in a single dose or in divided doses.

† Initial doses are employed for 4 to 8 weeks, the time required for most symptoms to respond. Dosage is gradually increased as required.

‡ Doses higher than these may be needed for some patients with severe depression.

33.4 SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs)

The SSRIs were introduced in 1987 and have since become our most commonly prescribed antidepressants, accounting for over \$3 billion in annual sales. These drugs are as effective as the TCAs, but do not cause hypotension, sedation, or anticholinergic effects. Moreover, overdose does not cause cardiotoxicity. Death by overdose is extremely rare. Characteristic side effects are nausea, agitation/insomnia, and sexual dysfunction (especially anorgasmia). SSRIs can interact adversely with MAOIs and other serotonergic drugs, and hence these combinations must be avoided. In addition, when used late in pregnancy, they can lead to a withdrawal syndrome and persistent pulmonary hypertension in the infant. Like all other antidepressants, SSRIs may increase the risk of suicide. The SSRIs are used to treat major depression and a variety of other psychologic disorders ([Table 32-4](#)). Fluoxetine, the first SSRI available, will serve as our prototype for the group.

33.4.1 Fluoxetine

Fluoxetine [Prozac, Sarafem] is the most widely prescribed antidepressant in the United States. The drug is as effective as the TCAs, causes fewer side effects, and is less dangerous when taken in overdose. Combined use with MAOIs and other serotonergic drugs can cause serious adverse effects, and therefore must be avoided.

33.4.1.1 Mechanism of Action

Fluoxetine produces selective inhibition of 5-HT reuptake, and thereby intensifies transmission at serotonergic synapses. As with TCAs, blockade of transmitter uptake occurs quickly, whereas therapeutic effects develop slowly. This delay suggests that therapeutic effects are the result of adaptive cellular changes that take place in response to prolonged uptake blockade. Fluoxetine does not block uptake of dopamine or NE. In contrast to the TCAs, fluoxetine does not block cholinergic, histaminergic, or α_1 -adrenergic receptors. Furthermore, fluoxetine produces CNS excitation rather than sedation.

343

344

TABLE 32-4 Therapeutic Uses of Selective Serotonin Reuptake Inhibitors

Drug	Therapeutic Use ^{*,†}							Bulimia Nervosa
	Major Depression	OCD	Panic Disorder	Social Phobia	GAD	PTSD	PMDD	
Citalopram [Celexa]	A	U	U	U	U	U	U	
Escitalopram [Lexapro]	A	A	U					
Fluoxetine [Prozac]	A	A	A	U	U	U	A	
Fluvoxamine [Luvox]	U	A	U	A	U	U	U	U
Paroxetine [Paxil]	A	A	A	A	A	A	A	
Sertraline [Zoloft]	A	A	A	A	U	A	A	

* A = approved use, U = unlabeled use.

† GAD = generalized anxiety disorder; OCD = obsessive-compulsive disorder; PMDD = premenstrual dysphoric disorder; PTSD = post-traumatic stress disorder.

33.4.1.2 Therapeutic Uses

Fluoxetine is used primarily for major depression. Antidepressant effects begin in 1 to 3 weeks and are equivalent to those produced by TCAs. Fluoxetine is also approved for bipolar disorder ([Chapter 33](#)), obsessive-compulsive disorder ([Chapter 35](#)), panic disorder ([Chapter 35](#)), bulimia nervosa, and premenstrual dysphoric disorder ([Chapter 60](#)). Unlabeled uses include post-traumatic stress disorder, social phobia, alcoholism, attention-deficit/hyperactivity disorder, migraine, Tourette's syndrome, and obesity.

33.4.1.3 Pharmacokinetics

Fluoxetine is well absorbed following oral administration, even in the presence of food. The drug is widely distributed and highly bound (94%) to plasma proteins. Fluoxetine undergoes extensive hepatic conversion to norfluoxetine, an active metabolite. Norfluoxetine is eventually converted to inactive metabolites that are excreted in the urine. The half-life of fluoxetine is 2

days and the half-life of norfluoxetine is 7 days. Because the effective half-life is prolonged, about 4 weeks are required to produce steady-state plasma drug levels—and about 4 weeks are required for washout after dosing stops.

33.4.1.4 Adverse Effects

Fluoxetine is safer and better tolerated than TCAs and MAOIs. Death from overdose with fluoxetine alone has not been reported. In contrast to TCAs, fluoxetine does not block receptors for histamine, NE, or acetylcholine, and hence does not cause sedation, orthostatic hypotension, anticholinergic effects, or cardiotoxicity. The most common side effects are sexual dysfunction (70%), nausea (21%), headache (20%), and manifestations of CNS stimulation, including nervousness (15%), insomnia (14%), and anxiety (10%). Weight gain can also occur. Fluoxetine and most other SSRIs appear safe for use during pregnancy.

33.4.1.4.1 Sexual Dysfunction.

Fluoxetine causes sexual problems (impotence, delayed or absent orgasm, delayed or absent ejaculation, decreased sexual interest) in nearly 70% of men and women. The underlying mechanism is unknown.

Sexual dysfunction can be managed in several ways. In some cases, reducing the dosage or taking “drug holidays” (eg, discontinuing medication on Fridays and Saturdays) can help. Another solution is to add a drug that can overcome the problem. Among these are yohimbine, buspirone [BuSpar], and three atypical antidepressants: bupropion [Wellbutrin, others], nefazodone, and mirtazapine [Remeron]. Sildenafil [Viagra] can also help: In *men*, the drug improves erectile dysfunction, as well as arousal, ejaculation, orgasm, and overall satisfaction; in *women*, the drug can improve delayed orgasm. If all of these measures fail, the patient can try a different antidepressant. Agents that cause the least sexual dysfunction are the same three atypical antidepressants named above.

Sexual problems often go unreported, either because patients are uncomfortable discussing them or because patients don't realize their medicine is the cause. Accordingly, patients should be informed about the high probability of sexual dysfunction and told to report any problems so they can be addressed.

33.4.1.4.2 Weight Gain.

Like many other antidepressants, fluoxetine and other SSRIs cause weight gain. When these drugs were first introduced, we thought they caused weight *loss*. Why? Because during the first few weeks of therapy patients do lose weight, perhaps because of drug-induced nausea

and vomiting. However, with long-term treatment, the lost weight is regained. Furthermore, about one-third of patients continue putting on weight—up to 20 pounds or more. Although the reason for weight gain is unknown, a good possibility is decreased sensitivity of 5-HT receptors that regulate appetite.

33.4.1.4.3 Serotonin Syndrome.

By increasing serotonergic transmission in the brainstem and spinal cord, fluoxetine and other SSRIs can cause serotonin syndrome. This syndrome usually begins 2 to 72 hours after initiation of treatment. Signs and symptoms include altered mental status (agitation, confusion, disorientation, anxiety, hallucinations, poor concentration) as well as incoordination, myoclonus, hyperreflexia, excessive sweating, tremor, and fever. Deaths have occurred. The syndrome resolves spontaneously after discontinuing the drug. The risk of serotonin syndrome is increased by concurrent use of MAOIs and other serotonergic drugs (see [Table 32-5](#)), and by use of ritonavir [Norvir, Kaletra] and other drugs that can increase fluoxetine levels.

33.4.1.4.4 Withdrawal Syndrome.

Abrupt discontinuation of SSRIs can cause a withdrawal syndrome. Symptoms include dizziness, headache, nausea, sensory disturbances, tremor, anxiety, and dysphoria. These begin within days to weeks of the last dose, and then persist for 1 to 3 weeks. Resumption of drug use will make symptoms subside. The withdrawal syndrome can be minimized by tapering the dosage slowly. Of the SSRIs in use today, fluoxetine is least likely to cause a withdrawal reaction. Why? Because fluoxetine has a prolonged half-life; hence, when dosing is stopped, plasma levels decline slowly. When SSRIs are discontinued, it is important to distinguish between symptoms of withdrawal and return of depression.

33.4.1.4.5 Neonatal Effects from Use in Pregnancy.

Use of fluoxetine and others SSRIs late in pregnancy poses a small risk of two adverse effects in the newborn: (1) *neonatal abstinence syndrome* (NAS) and (2) *persistent pulmonary hypertension of the newborn* (PPHN). NAS is characterized by irritability, abnormal crying, tremor, respiratory distress, and possibly seizures. The syndrome can be managed with supportive care and generally abates within a few days. PPHN, which compromises tissue oxygenation, carries a significant risk of death, and, among survivors, a risk of cognitive delay, hearing loss, and neurologic abnormalities. Treatment measures include providing ventilatory support, giving oxygen and nitric oxide (to dilate pulmonary blood vessels), and giving IV sodium bicarbonate (to maintain alkalosis) and dopamine or dobutamine (to

increase cardiac output, and thereby maintain pulmonary perfusion). Infants exposed to SSRIs late in gestation should be monitored closely for NAS and PPHN.

33.4.1.4.6 Teratogenesis.

Do fluoxetine and other SSRIs cause birth defects? Probably not. And if they do, the risk appears to be very low. Two SSRIs—*paroxetine* and *fluoxetine*—may cause heart defects. But even with these agents, the absolute risk is very low.

33.4.1.4.7 Suicide Risk.

As discussed above, antidepressants may increase the risk of suicide in depressed patients, especially during the early phase of treatment. The risk of antidepressant-induced suicide is greatest among children, adolescents, and young adults.

33.4.1.4.8 Extrapyramidal Side Effects.

SSRIs cause extrapyramidal symptoms (EPS) in about 0.1% of patients. This is much less frequent than among patients taking antipsychotic medications (see [Chapter 31](#)). Among patients taking SSRIs, the most common of the EPS is akathisia, characterized by restlessness and agitation. However, parkinsonism, dystonic reactions, and tardive dyskinesia can also occur. EPS typically develop during the first month of treatment. The risk is increased by concurrent use of an antipsychotic drug. The underlying cause of SSRI-induced EPS may be alteration of serotonergic transmission within the extrapyramidal system. For a detailed discussion of EPS, refer to [Chapter 31](#).

33.4.1.4.9 Bruxism.

SSRIs may cause bruxism (clenching and grinding of teeth). However, since bruxism usually occurs during sleep, the condition often goes unrecognized. Sequelae of bruxism include headache, jaw pain, and dental problems (eg, cracked fillings).

TABLE 32-5 Drugs That Can Increase Serotonin Activity at CNS Synapses

Drug	Impact on Serotonin
Selective Serotonin Reuptake Inhibitors (SSRIs)	
Citalopram [Celexa]	Block 5-HT reuptake and thereby increase 5-HT in the synapse
Escitalopram [Lexapro]	
Fluoxetine [Prozac]	
Fluvoxamine [Luvox]	
Paroxetine [Paxil]	
Sertraline [Zoloft]	
Serotonin/Norepinephrine Reuptake Inhibitors (SNRIs)	
Desvenlafaxine [Pristiq]	Same as SSRIs
Duloxetine [Cymbalta]	
Venlafaxine [Effexor]	
Tricyclic Antidepressants (TCAs)	
Amitriptyline	Same as SSRIs
Clomipramine [Anafranil]	
Doxepin [Sinequan]	
Imipramine [Tofranil]	
Trimipramine [Surmontil]	
Monoamine Oxidase Inhibitors (MAOIs)	
Desipramine [Norpramin]	Inhibit neuronal breakdown of 5-HT, by MAO, and thereby increase stores of 5-HT available for release
Isocarboxazid [Marplan]	
Phenelzine [Nardil]	
Selegiline [Emsam]	
Atypical Antidepressants	
Mirtazapine [Remeron]	Promotes release of 5-HT
Nefazodone	Same as SSRIs
Trazodone	Same as SSRIs
Analgesics	
Meperidine [Demerol]	Same as SSRIs
Tramadol [Ultram]	Same as SSRIs

Pharmacology for Nursing Care, 7th Edition

Meperidine [Demerol]	Same as MAOIs
Methadone [Dolophine]	Same as MAOIs?
Others	
St. John's wort	Same as SSRIs <i>and</i> MAOIs
Linezolid [Zyvox]	Same as MAOIs
CNS = central nervous system; 5-HT = serotonin; MAO = monoamine oxidase.	

How do SSRIs cause bruxism? One theory is that they inhibit release of dopamine, a neurotransmitter that suppresses activity in certain muscles, including those of the jaw. By decreasing dopamine availability, SSRIs could release these muscles from inhibition, and excessive activity could result. This same mechanism may be responsible for SSRI-induced EPS.

How can bruxism be managed? One option is to reduce the SSRI dosage. However, this may cause depression to return. Other options include switching to a different class of antidepressant, use of a mouth guard, and treatment with low-dose buspirone (5 to 10 mg 1 to 3 times a day).

33.4.1.4.10 Bleeding Disorders.

Fluoxetine and other SSRIs can increase the risk of bleeding in the GI tract and at other sites. How? By impeding platelet aggregation: Platelets require 5-HT for aggregation, but can't make it themselves, and hence must take 5-HT up from the blood; by blocking 5-HT uptake, SSRIs suppress aggregation. The SSRIs cause a threefold increase in the risk of GI bleeding. However, the *absolute* risk is still low (about 1 case for every 8000 prescriptions). Caution is advised in patients with ulcers or a history of GI bleeding, in patients older than 60, and in patients taking nonsteroidal anti-inflammatory drugs or anticoagulants.

33.4.1.4.11 Hyponatremia.

Fluoxetine can cause hyponatremia (serum sodium below 135 mEq/L), probably by increasing secretion of antidiuretic hormone. Most cases involve older patients taking thiazide diuretics. Accordingly, when fluoxetine is used in older patients, sodium should be measured at baseline and periodically thereafter.

33.4.1.4.12 Other Adverse Effects.

Fluoxetine can cause *dizziness* and *fatigue*; patients should be warned against driving and other hazardous activities. *Skin rash*, which can be severe, has occurred in 4% of patients; in most cases, rashes readily respond to drug therapy (antihistamines, glucocorticoids) or to

345

346

withdrawal of fluoxetine. Other common reactions include *diarrhea* (12%) and *excessive sweating* (8%).

33.4.1.5 Drug Interactions

33.4.1.5.1 MAOIs and Other Serotonergic Drugs.

Fluoxetine should not be combined with MAOIs and other serotonergic drugs (see [Table 32-5](#)) owing to a risk of serotonin syndrome. Because MAOIs cause irreversible MAO inhibition (see below), their effects persist long after dosing stops. Accordingly, these drugs should be withdrawn at least 14 days before starting fluoxetine. When fluoxetine is discontinued, at least 5 weeks should elapse before giving an MAOI.

33.4.1.5.2 Warfarin.

Because fluoxetine is highly bound to plasma proteins, it can displace other highly bound drugs. Displacement of warfarin (an anticoagulant) is of particular concern. Monitor responses to warfarin closely.

33.4.1.5.3 Tricyclic Antidepressants and Lithium.

Fluoxetine can elevate plasma levels of TCAs and lithium. Exercise caution if fluoxetine is combined with these agents.

33.4.1.6 Preparations, Dosage, and Administration

33.4.1.6.1 Preparations.

Fluoxetine is available in several oral formulations and is sold under three trade names: Prozac, Prozac Weekly, and Sarafem. Products available under each trade name are as follows:

- *Prozac*—tablets (10 mg), pulvules (10 and 20 mg), oral solution (20 mg/5 mL)
- *Prozac Weekly*—delayed-release, enteric-coated capsules (90 mg)
- *Sarafem*—pulvules (10 and 20 mg)

In addition to these singleingredient products, fluoxetine is available in a fixed-dose combination with olanzapine (an antipsychotic), sold as *Symbyax*, for the treatment of bipolar disorder (see [Chapter 33](#)).

33.4.1.6.2 Dosage for Depression

33.4.1.6.2.1 Daily Dosing.

The recommended initial dosage is 20 mg/day, taken with or without food. If needed, dosage may be increased gradually to a maximum of 80 mg/day. However, doses greater than 20 mg/day may increase adverse effects without increasing benefits. If daily doses above 20 mg are used, they should be divided. For elderly patients and patients with impaired liver function, the dosage should be low initially and then cautiously increased if needed. Since fluoxetine often impairs sleep, evening dosing should generally be avoided.

33.4.1.6.2.2 Weekly Dosing.

Patients who have been treated successfully with 20 mg of fluoxetine daily for at least 13 weeks can be switched to once-weekly dosing (using 90-mg delayed-release capsules) for maintenance. Weekly dosing is initiated 7 days after the last 20-mg dose of daily fluoxetine.

33.4.1.6.2.3 Withdrawal.

When discontinuing the drug, dosage should be reduced gradually.

33.4.2 Other SSRIs

In addition to fluoxetine, five other SSRIs are available: citalopram [Celexa], escitalopram [Lexapro], fluvoxamine [Luvox], paroxetine [Paxil, Pexeva], and sertraline [Zoloft]. All five are similar to fluoxetine. Antidepressant effects equal those of TCAs. Like fluoxetine, the newer SSRIs do not cause hypotension or anticholinergic effects, and, with the exception of fluvoxamine, do not cause sedation. When taken in overdose, these drugs do not cause cardiotoxicity. Characteristic side effects are nausea, insomnia, headache, nervousness, weight gain, sexual dysfunction, hyponatremia, GI bleeding, and NAS and PPHN (in infants who were exposed to these drugs late in gestation). Serotonin syndrome is a potential complication with all SSRIs, especially if these agents are combined with MAOIs or other serotonergic drugs. The principal differences among the SSRIs relate to duration of action. Patients who experience intolerable adverse effects with one SSRI may find a different SSRI more acceptable. As with fluoxetine, withdrawal should be done slowly. Therapeutic uses for individual agents are summarized in [Table 32-4](#).

33.4.2.1 Sertraline

Sertraline [Zoloft] is much like fluoxetine: both drugs block uptake of 5-HT, both relieve symptoms of major depression, both cause CNS stimulation rather than sedation, and both have minimal effects on seizure threshold and the ECG. Sertraline is indicated for major depression, panic disorder, obsessive-compulsive disorder, post-traumatic stress disorder, premenstrual dysphoric disorder, and social anxiety disorder (social phobia). The drug is used off-label to treat generalized anxiety disorder.

Sertraline is slowly absorbed following oral administration. Food increases the extent of absorption. In the blood, the drug is highly bound (99%) to plasma proteins. Sertraline undergoes extensive hepatic metabolism followed by elimination in the urine and feces. The plasma half-life is approximately 1 day.

Common side effects include headache, tremor, insomnia, agitation, nervousness, nausea, diarrhea, weight gain, and sexual dysfunction. Treatment may also increase the risk of suicide. Because of the risk of serotonin syndrome, sertraline must not be combined with MAOIs and other serotonergic drugs (see [Table 32-5](#)). MAOIs should be withdrawn at least 14 days before starting sertraline, and sertraline should be withdrawn at least 14 days before starting an MAOI. Because of a risk of pimozide-induced dysrhythmias, sertraline (which raises pimozide levels) and pimozide should not be combined. Like fluoxetine and other SSRIs, sertraline poses a risk of hyponatremia, GI bleeding, and NAS and PPHN when used late in pregnancy.

Sertraline is available in tablets (25, 50, and 100 mg) and a concentrated oral solution (20 mg/mL). For treatment of depression, the initial adult daily dosage is 50 mg, administered in the morning or evening. After 4 to 8 weeks, the dosage may be increased by 50-mg increments to a maximum of 200 mg/day. When discontinuing the drug, dosage should be reduced gradually.

33.4.2.2 Fluvoxamine

Like other SSRIs, fluvoxamine [Luvox] produces powerful and selective inhibition of 5-HT reuptake. The drug is approved for obsessive-compulsive disorder and social anxiety disorder. Unlabeled uses include major depression, panic disorder, generalized anxiety disorder, post-traumatic stress disorder, premenstrual dysphoric disorder, and bulimia nervosa.

Fluvoxamine is rapidly absorbed from the GI tract, both in the presence and absence of food. The drug undergoes extensive hepatic metabolism followed by excretion in the urine. The half-life is about 15 hours.

Common side effects include nausea, vomiting, dry mouth, headache, constipation, weight gain, and sexual dysfunction. In contrast to other SSRIs, fluvoxamine has moderate sedative effects, although it nonetheless can cause insomnia. Some patients have developed abnormal liver function tests. Accordingly, liver function should be assessed prior to treatment and weekly during the first month of therapy. Like other SSRIs, fluvoxamine interacts adversely with MAOIs and other serotonergic drugs, and hence these combinations must be avoided. As with other SSRIs, fluvoxamine poses a risk of hyponatremia, GI bleeding, and NAS and PPHN in infants exposed to the drug *in utero*.

Fluvoxamine is available in immediate-release tablets (25-, 50-, and 100-mg), sold as *Luvox*, and controlled-release capsules (100 and 150 mg), sold as *Luvox CR*. With the immediate-release formulation, dosing begins at 50 mg once a day at bedtime, and can be gradually increased to a maximum of 300 mg/day, given in two divided doses when the daily total exceeds 100 mg. With the controlled-release capsules, dosing begins at 100 mg once daily, and can be gradually increased to 300 mg once daily. With either formulation, drug withdrawal should be done gradually.

33.4.2.3 Paroxetine

Like other SSRIs, paroxetine [Paxil, Paxil CR, Pexeva] produces powerful and selective inhibition of 5-HT uptake. The drug is indicated for major depression, obsessive-compulsive disorder, social anxiety disorder, panic disorder, generalized anxiety disorder, post-traumatic stress disorder, and premenstrual dysphoric disorder. Paroxetine is used off-label to treat bipolar disorder and postmenopausal hot flashes.

Paroxetine is well absorbed following oral administration, even in the presence of food. The drug is widely distributed and highly bound (95%) to plasma proteins. Concentrations in breast milk equal those in plasma. The drug undergoes hepatic metabolism followed by renal excretion. The half-life is about 20 hours.

Side effects are dose dependent and generally mild. Early reactions include nausea, somnolence, sweating, tremor, and fatigue. These tend to diminish over time. After 5 to 6 weeks, the major complaints are headache, weight gain, and sexual dysfunction. Like fluoxetine, paroxetine causes signs of CNS stimulation (increased awakenings, reduced time in rapid-eye-movement sleep, insomnia). In contrast to TCAs, paroxetine has no effect on heart rate, blood pressure, or the ECG—but does have some antimuscarinic effects. Like other SSRIs, paroxetine interacts adversely with MAOIs and other serotonergic drugs, and hence these combinations must be avoided. Also, like other SSRIs, paroxetine can increase the risk of GI bleeding, and can cause hyponatremia (especially in elderly patients taking thiazide diuretics). As with other SSRIs, use

346

347

late in pregnancy can result in NAS and PPHN. In addition, paroxetine, but not other SSRIs, poses a small risk of cardiovascular birth defects, primarily ventral septal defects. Because of this risk, the drug is now classified in FDA Pregnancy Risk Category D. Like all other antidepressants, paroxetine may increase the risk of suicide, especially in children and young adults.

Paroxetine is available as two salts: paroxetine *hydrochloride* and paroxetine *mesylate*. Although the two preparations have not been compared directly, effects are likely to be identical. The hydrochloride salt is available in immediate-release (IR) tablets (10, 20, 30, and 40 mg) and an oral suspension (2 mg/mL) as *Paxil*, and controlled-release (CR) tablets (12.5, 25, and 37.5 mg) as *Paxil CR*. Please note that the CR tablets are *not* longer acting than the IR tablets. Rather, the CR tablets are designed to dissolve in the lower intestine, and hence may cause less GI disturbance than the IR tablets. The mesylate salt [Pexeva] is available only in tablets (10, 20, 30, and 40 mg).

The initial dosage for depression is 20 mg/day. The entire daily dose is administered in the morning (to minimize sleep disturbance) and with food (to minimize GI upset). Dosage may be increased gradually (every 3 to 4 weeks) to a maximum of 50 mg/day. When discontinuing the drug, dosage should be reduced gradually.

33.4.2.4 Citalopram

Citalopram [Celexa] is very similar to fluoxetine and the other SSRIs. Benefits derive from selective blockade of 5-HT uptake. The drug does not block receptors for 5-HT, acetylcholine, NE, or histamine. Its only approved indication is major depression. Unlabeled uses include panic disorder, social anxiety disorder, generalized anxiety disorder, obsessive-compulsive disorder, post-traumatic stress disorder, and premenstrual dysphoric disorder.

Citalopram is rapidly absorbed from the GI tract, both in the presence and absence of food. Plasma levels peak about 4 hours after administration. The drug undergoes hepatic metabolism followed by excretion in the urine and feces. The half-life is about 35 hours.

The most common adverse effects are nausea, somnolence, dry mouth, and sexual dysfunction. Additional side effects include weight gain, tachycardia, postural hypotension, headache, paresthesias, hyponatremia, and increased risk of GI bleeding. Large doses are teratogenic in animals. Citalopram enters breast milk in amounts sufficient to cause somnolence, reduced feeding, and weight loss in the infant. Use late in pregnancy can result in NAS and PPHN in the infant. Like all other antidepressants, citalopram may increase the risk of suicide, especially in children and young adults.

Because of the risk of serotonin syndrome, citalopram should not be combined with MAOIs or other serotonergic drugs. Allow at least 14 days to pass between stopping an MAOI and starting citalopram, or vice versa.

Citalopram is available in tablets (10, 20, and 40 mg) and an oral solution (2 mg/mL). The drug may be taken in the morning or evening, with or without food. The initial dosage for depression is 20 mg once a day. Dosage may be increased slowly to a maximum of 60 mg/day. Dosage should remain low in elderly patients and those with liver impairment. When discontinuing the drug, dosage should be reduced gradually.

33.4.2.5 Escitalopram

Escitalopram [Lexapro] is the *S*-isomer of citalopram [Celexa], which is a 50:50 mixture of *S*- and *R*-isomers. The *S*-isomer (escitalopram) is responsible for antidepressant effects. The *R*-isomer has no antidepressant actions, but does contribute to side effects. Accordingly, escitalopram retains the therapeutic benefits of citalopram, but may be better tolerated. Otherwise, the pharmacology of the two drugs is largely the same. Escitalopram is approved for major depression and generalized anxiety disorder, and has been used off-label for panic disorder.

Like citalopram and other SSRIs, escitalopram is generally well tolerated. In clinical trials, the most common side effects were nausea (15%), insomnia (9%), somnolence (6%), sweating (5%), and fatigue (5%). In addition, 9% of males reported ejaculatory disorders. However, the true incidence of sexual dysfunction may be higher. Why? Because, with other SSRIs, the incidence of sexual problems reported during clinical trials was considerably lower than the incidence seen in actual practice. As with other SSRIs, combined use with MAOIs and other serotonergic drugs increases the risk of serotonin syndrome. At least 14 days should separate use of MAOIs and escitalopram. Like citalopram and other SSRIs, escitalopram increases the risk of hyponatremia and GI bleeding, and, when used late in pregnancy, may cause NAS or PPHN in the newborn. Like all other antidepressants, this drug can increase the risk of suicide, especially in children and young adults.

Escitalopram is available in tablets (5, 10, and 20 mg) and an oral solution (1 mg/mL). The recommended initial dosage is 10 mg/day, taken in the morning or evening, with or without food. In clinical trials, dosages above 10 mg/day did not increase antidepressant effects, but did intensify side effects. There is no need to reduce the dosage in elderly patients or in patients with either hepatic impairment or mild to moderate renal impairment. However, in patients with severe renal impairment, a dosage reduction may be required. When discontinuing the drug, dosage should be reduced gradually.

33.5 SEROTONIN/NOREPINEPHRINE REUPTAKE INHIBITORS (SNRIs)

Three drugs—venlafaxine, desvenlafaxine, and duloxetine—block neuronal reuptake of serotonin *and* norepinephrine, with minimal effects on other transmitters or receptors. Pharmacologic effects are similar to those of the SSRIs, although the SSRIs may be better tolerated.

33.5.1 Venlafaxine

Venlafaxine [Effexor, Effexor XR], the first SNRI available, is indicated for major depression, generalized anxiety disorder, and social anxiety disorder (social phobia). The drug produces powerful blockade of NE and 5-HT uptake and weak blockade of dopamine uptake. The relationship of these actions to therapeutic effects is uncertain. Venlafaxine does not block cholinergic, histaminergic, or α_1 -adrenergic receptors. Despite impressions that venlafaxine may be superior to SSRIs, when compared directly in clinical trials, the drugs were about equally effective—and SSRIs are probably safer.

Venlafaxine is well absorbed following oral administration, both in the presence and absence of food. In the liver, much of each dose is converted to desvenlafaxine, an active metabolite. The half-life is 5 hours for the parent drug and 11 hours for the active metabolite.

Venlafaxine can cause a variety of adverse effects. The most common is nausea (37%), followed by headache, anorexia, nervousness, sweating, somnolence, and insomnia. Dose-dependent weight loss may occur secondary to anorexia. Venlafaxine can also cause dose-related sustained diastolic hypertension; blood pressure should be monitored. Sexual dysfunction (eg, impotence, anorgasmia) may occur too. Like the SSRIs, venlafaxine can cause hyponatremia, especially in elderly patients taking diuretics. Like all other antidepressants, venlafaxine may increase the risk of suicide, especially in children and young adults.

Abrupt discontinuation can cause an intense withdrawal syndrome. Symptoms include anxiety, agitation, tremors, headache, vertigo, nausea, tachycardia, and tinnitus. Worsening of pretreatment symptoms may also occur. Withdrawal symptoms can be minimized by tapering the dosage over 2 to 4 weeks. Warn patients not to stop venlafaxine abruptly.

As with the SSRIs, use of venlafaxine late in pregnancy can result in a neonatal withdrawal syndrome, characterized by irritability, abnormal crying, tremor, respiratory distress, and possibly seizures. Symptoms, which can be managed with supportive care, generally abate within a few days.

Combined use of venlafaxine with MAOIs and other serotonergic drugs (see [Table 32-5](#)) increases the risk of serotonin syndrome, a potentially fatal reaction. If the clinical situation demands,

venlafaxine may be cautiously combined with an SSRI or another SNRI. However, combined use with an MAOI is *contraindicated*. Accordingly, MAOIs should be withdrawn at least 14 days before starting venlafaxine. When switching from venlafaxine to an MAOI, venlafaxine should be discontinued 7 days before starting the MAOI.

Venlafaxine is available in immediate-release tablets (25, 37.5, 50, 75, and 100 mg) sold as Effexor, and extended-release capsules (37.5, 75, and 150 mg) sold as Effexor XR. The recommended initial dosage for depression is 75 mg/day (in two or three divided doses) taken with food. If needed, the dosage may be gradually increased. The usual maximum dosage is 225 mg/day. However, dosages as large as 375 mg/day have been used for severely depressed patients. Dosage should be reduced in patients with liver disease, and possibly in those with kidney disease.

33.5.2 Desvenlafaxine

Desvenlafaxine [Pristiq], approved in 2008, is the major active metabolite of venlafaxine. Accordingly, the actions and adverse effects of both drugs are similar. Like venlafaxine, desvenlafaxine is a strong inhibitor of 5-HT and NE reuptake, and does not block cholinergic, histaminergic, or α_1 -adrenergic receptors. At this time, desvenlafaxine is approved only for major depression, in contrast to venlafaxine, which is approved for major depression, generalized anxiety disorder, and social phobia.

347

348

Desvenlafaxine is well absorbed following oral administration, both in the presence and absence of food. Plasma levels peak about 7.5 hours after dosing. The drug undergoes some hepatic metabolism, and is excreted in the urine as metabolites and parent drug. The elimination half-life is 1 hour.

Adverse effects are like those of venlafaxine. The most common reactions are nausea (22%), headache (20%), dizziness (13%), insomnia (9%), diarrhea (11%), dry mouth (11%), sweating (10%), and constipation (9%). Sexual effects include erectile dysfunction (3%) and decreased libido (4%). Like all other antidepressants, desvenlafaxine may increase the risk of suicide in children and young adults. Some neonates exposed to the drug *in utero* have required prolonged hospitalization, respiratory support, and tube feeding. Additional concerns include hyponatremia, sustained hypertension, serotonin syndrome, bleeding, seizures, and withdrawal symptoms if the drug is discontinued abruptly.

As with venlafaxine, combining desvenlafaxine with another serotonergic drug increases the risk of serotonin syndrome. Combined use with an SSRI or another SNRI may be done cautiously. In contrast, combined use with an MAOI is *contraindicated*. Accordingly, MAOIs should be withdrawn at least 14 days before starting desvenlafaxine, and desvenlafaxine should be withdrawn at least 7 days before starting an MAOI.

Desvenlafaxine [Pristiq] is available in 50- and 100-mg extended-release tablets, which should be swallowed whole with fluid, and not be crushed, chewed, or dissolved. The recommended dosage is 50 mg once daily, taken with or without food, about the same time each day. Increasing the dose to 100 mg/day offers no benefit, but does increase the risk of side effects. In patients with severe renal impairment (creatinine clearance less than 30 mL/min), the dosage should be reduced to 50 mg every other day. There is no need to reduce the dosage in patients with moderate renal impairment or in those with liver impairment of any degree. To minimize withdrawal reactions, the drug should be discontinued slowly (by gradually increasing the dosing interval).

33.5.3 Duloxetine

33.5.3.1 Mechanism of Action and Therapeutic Use.

Duloxetine [Cymbalta] was the second SNRI approved for major depression. The drug is a powerful inhibitor of 5-HT and NE reuptake, and a much weaker inhibitor of dopamine reuptake. Duloxetine does not bind with receptors for NE, serotonin, dopamine, acetylcholine, or histamine, and does not inhibit MAO.

Data on the antidepressant effects of duloxetine are limited. Clinical trials have shown that duloxetine is clearly superior to *placebo*: Treatment reduces depressive symptoms and may also reduce physical pain associated with depression (eg, backache). Furthermore, benefits may develop quickly, in some cases within 2 weeks of starting treatment. Unfortunately, there have been no trials comparing duloxetine directly with other antidepressants, such as venlafaxine or the SSRIs. Also, there is little information on the drug's long-term efficacy or safety. As a result, there is no basis for choosing this newer drug over older ones.

In addition to its use in depression, duloxetine is approved for *fibromyalgia*, *generalized anxiety disorder*, and *pain of diabetic peripheral neuropathy*, and is being studied for treatment of *stress urinary incontinence* (in contrast to *urge urinary incontinence*).

33.5.3.2 Pharmacokinetics.

Duloxetine is well absorbed following oral administration. Food reduces the rate of absorption but not the extent. In the blood, duloxetine is highly (90%) bound to albumin. The drug undergoes extensive hepatic metabolism, primarily by the CYP2D6 and CYP1A2 isozymes of cytochrome P450. Metabolites are excreted in the urine (70%) and feces (20%). The elimination half-life is 12 hours. In patients with severe renal impairment, levels of duloxetine and its metabolites are greatly increased, and in those with severe hepatic impairment, the half-life is

greatly prolonged. Accordingly, duloxetine is not recommended for patients with severe renal or hepatic dysfunction.

33.5.3.3 Adverse Effects.

Duloxetine is generally well tolerated. In clinical trials, the most common adverse effects were nausea (20% vs. 7% with placebo), dry mouth (15% vs. 6%), insomnia (11% vs. 6%), somnolence (7% vs. 3%), constipation (11% vs. 4%), reduced appetite (8% vs. 2%), fatigue (8% vs. 4%), increased sweating (6% vs. 2%), and blurred vision (4% vs. 1%). Duloxetine can cause a small increase in blood pressure, and hence blood pressure should be measured at baseline and periodically thereafter. Some males experience sexual dysfunction (loss of libido, impotence). Duloxetine promotes mydriasis, and hence should not be used by patients with uncontrolled narrow-angle glaucoma. Weight gain has not been observed.

Liver toxicity is a concern. Elevation of serum transaminases, indicating liver damage, occurs in about 1% of patients. There have been reports of hepatitis, hepatomegaly, cholestatic jaundice, and elevation of transaminases to more than 20 times the upper limit of normal. To reduce risk, duloxetine should not be given to patients with pre-existing liver disease or to those who drink alcohol heavily.

As with venlafaxine, abrupt cessation of treatment can cause a withdrawal syndrome. Symptoms include nausea, vomiting, dizziness, headache, nightmares, and paresthesias. To minimize risk, duloxetine should be withdrawn slowly. Use of duloxetine late in pregnancy can lead to a withdrawal syndrome in the infant.

Like all other antidepressants, duloxetine may increase the risk of suicide, especially in children and young adults.

33.5.3.4 Effects in Pregnancy and Lactation.

Animal studies indicate that duloxetine interferes with fetal and postnatal development, causing reduced fetal weight, decreased postnatal survival, and neurologic disturbances. The drug is excreted in the milk of lactating rats. Studies in pregnant or lactating women have not been conducted. Until human data are available, use of duloxetine during pregnancy and lactation is not recommended.

33.5.3.5 Drug Interactions.

The combination of duloxetine with heavy alcohol consumption greatly increases the risk of liver damage. Accordingly, duloxetine should not be prescribed to heavy drinkers.

Like venlafaxine and other drugs that block 5-HT reuptake, duloxetine can cause serotonin syndrome if combined with an MAOI or any other serotonergic drug. MAOIs should be withdrawn at least 14 days before starting duloxetine, and duloxetine should be withdrawn at least 5 days before starting an MAOI.

Drugs that inhibit CYP1A2 or CYP2D6 (the P450 isozymes that metabolize duloxetine) can increase duloxetine levels, and may thereby cause toxicity. Inhibitors of CYP1A2 include cimetidine [Tagamet], fluvoxamine [Luvox], and ciprofloxacin [Cipro]. Inhibitors of CYP2D6 include fluoxetine [Prozac], paroxetine [Paxil], and quinidine [Quinidex].

Duloxetine is a moderate inhibitor of CYP2D6, and hence may raise levels of drugs that are extensively metabolized by this enzyme. Among these are certain TCAs (eg, amitriptyline, nortriptyline), type IC antidysrhythmics (propafenone [Rythmol] and flecainide [Tambocor]), and phenothiazines, including thioridazine [Mellaril]. Interaction with thioridazine is of special concern owing to a risk of serious ventricular dysrhythmias. Accordingly, the two drugs should not be combined.

33.5.3.6 Preparations, Dosage, and Administration.

Duloxetine is available in capsules (20, 30, and 60 mg) that should be swallowed whole, with or without food. The dosage range is 40 mg/day (given as 20 mg twice a day) to 60 mg/day (given as 60 mg once a day or 30 mg twice a day). When treatment is discontinued, dosage should be tapered slowly.

33.6 MONOAMINE OXIDASE INHIBITORS (MAOIs)

The MAOIs are second or third-choice antidepressants for most patients. Although these drugs are as effective as the tricyclics and SSRIs, they are more dangerous. Of particular concern is the risk of triggering a hypertensive crisis by eating foods rich in tyramine. At this time, MAOIs are drugs of choice only for atypical depression. Three MAOIs—isonicarbazine [Marplan], phenelzine [Nardil], and tranylcypromine [Parnate]—are administered orally, and one MAOI—selegiline [Emsam]—is administered by transdermal patch.

33.6.1 Oral MAOIs

33.6.1.1 Mechanism of Action

Before discussing the MAOIs, we need to discuss MAO itself. MAO is an enzyme found in the liver, the intestinal wall, and terminals of monoamine-containing neurons. The function of MAO in neurons is to convert monoamine neurotransmitters—NE, 5-HT, and dopamine—into

inactive products. In the liver and intestine, MAO serves to inactivate tyramine and other biogenic amines in food. In addition, these enzymes inactivate biogenic amines administered as drugs.

348

349

Figure 32-3 Mechanism of action of monoamine oxidase inhibitors. **A**, Under drug-free conditions, much of the norepinephrine or serotonin that undergoes reuptake into nerve terminals becomes inactivated by MAO. Inactivation helps maintain an appropriate concentration of transmitter within the terminal. **B**, MAO inhibitors prevent inactivation of norepinephrine and serotonin, thereby increasing the amount of transmitter available for release. Release of supranormal amounts of transmitter intensifies transmission. (MAO = monoamine oxidase, P = uptake pump, T = transmitter [norepinephrine or serotonin].)

The body has two forms of MAO, named MAO-A and MAO-B. In the brain, MAO-A inactivates NE and 5-HT, whereas MAO-B inactivates dopamine. In the intestine and liver,

MAO-A acts on dietary tyramine and other compounds. All of the MAOIs used for depression are *nonselective*. That is, at *therapeutic* doses, they inhibit both MAO-A and MAO-B. One agent—selegiline (used for depression *and* Parkinson's disease)—is selective for MAO-B at the low doses used for Parkinson's disease, but is nonselective at the higher doses used for depression.

Antidepressant effects of the MAOIs result from inhibiting MAO-A in nerve terminals ([Fig. 32-3](#)). By inhibiting intraneuronal MAO-A, these drugs increase the amount of NE and 5-HT available for release, and thereby intensify transmission at noradrenergic and serotonergic junctions.

Please note that antidepressant effects of the MAOIs cannot be fully explained by MAO inhibition alone. Why? Because the biochemical action of MAOIs (inhibition of MAO) takes place rapidly, whereas the clinical response to MAOIs (relief of depression) develops slowly. In the interval between initial inhibition of MAO and relief of depression, secondary neurochemical events must be taking place. It is these as-yet unknown events that are ultimately responsible for the beneficial response to treatment.

The MAOIs can act on MAO in two ways: reversibly and irreversibly. All of the MAOIs in current use cause *irreversible* inhibition. Since recovery from irreversible inhibition requires synthesis of new MAO molecules, effects of the irreversible inhibitors persist for about 2 weeks after drug withdrawal. In contrast, recovery from reversible inhibition is more rapid, occurring in 3 to 5 days.

33.6.1.2 Therapeutic Uses

33.6.1.2.1 Depression.

MAOIs are as effective as TCAs and SSRIs for relieving depression. However, because they can be hazardous, MAOIs are generally reserved for patients who have not responded to TCAs, SSRIs, and other safer drugs. Nonetheless, there *is* one group of patients—those with *atypical depression*—for whom MAOIs are the treatment of choice. As with other antidepressants, beneficial effects do not reach their peak for several weeks.

33.6.1.2.2 Other Psychiatric Uses.

MAOIs have been used with some success to treat *bulimia nervosa* and *obsessive-compulsive disorder*. Like TCAs and SSRIs, MAOIs can reduce *panic attacks* in patients with panic disorder.

33.6.1.3 Adverse Effects

33.6.1.3.1 CNS Stimulation.

In contrast to TCAs, MAOIs cause direct CNS stimulation (in addition to exerting antidepressant effects). Excessive stimulation can produce anxiety, insomnia, agitation, hypomania, and even mania.

33.6.1.3.2 Orthostatic Hypotension.

Despite their ability to increase the NE content of peripheral sympathetic neurons, the MAOIs *reduce blood pressure* when administered in usual therapeutic doses. Patients should be informed about signs of hypotension (dizziness, lightheadedness) and advised to sit or lie down if these occur. Also, they should be informed that hypotension can be minimized by moving slowly when assuming an erect posture. For the hospitalized patient, blood pressure and pulse rate should be monitored on a regular schedule (eg, 4 times daily). These measurements should be taken while the patient is lying down and again after the patient has been sitting or standing for 1 to 2 minutes.

MAOIs lower blood pressure through actions in the CNS. The following sequence has been proposed: (1) Inhibition of MAO increases the NE content of neurons within the vasomotor center. (2) When NE is released, it binds to postsynaptic alpha receptors on neurons within the vasomotor center, thereby decreasing the firing rate of sympathetic nerves that control vascular tone. (3) This reduction in sympathetic activity results in vasodilation, causing blood pressure to fall.

33.6.1.3.3 Hypertensive Crisis from Dietary Tyramine.

Although the MAOIs normally produce *hypotension*, they can be the

349

Figure 32-4 **Interaction between dietary tyramine and MAOIs.****A**, In the absence of MAOIs, much of ingested tyramine is inactivated by MAO in the intestinal wall (not shown in the figure). Any dietary tyramine that is not metabolized in the intestinal wall is transported directly to the liver, where it undergoes immediate inactivation by hepatic MAO. No tyramine reaches the general circulation. **B**, Three events occur in the presence of MAOIs: (1) Inhibition of neuronal MAO raises levels of norepinephrine in sympathetic nerve terminals. (2) Inhibition of intestinal and hepatic MAO allows dietary tyramine to pass through the intestinal wall and liver to enter the systemic circulation intact. (3) Upon reaching peripheral sympathetic nerve terminals, tyramine promotes the release of accumulated norepinephrine stores, thereby causing massive vasoconstriction and excessive stimulation of the heart. (MAO = monoamine oxidase, NE = norepinephrine, R = receptor for norepinephrine.)

cause of severe *hypertension* if the patient eats food that is rich in *tyramine*, a substance that promotes the release of NE from sympathetic neurons. Hypertensive crisis is characterized by headache, tachycardia, hypertension, nausea, and vomiting.

Before considering the mechanism by which hypertensive crisis is produced, let's consider the effect of dietary tyramine under drug-free conditions. In the absence of MAO inhibition, dietary tyramine is not a threat. Much of the tyramine in food is metabolized by MAO in the intestinal wall. Furthermore, as shown in [Figure 32-4A](#), any dietary tyramine that gets through the intestinal wall intact passes directly to the liver via the hepatic portal circulation. Once in the liver, tyramine is immediately inactivated by MAO there. Hence, as long as intestinal and hepatic MAO are functioning, dietary tyramine is prevented from reaching the general circulation, and therefore is devoid of adverse effects.

In the presence of MAOIs, the picture is very different: dietary tyramine can produce a life-threatening hypertensive crisis. Three steps are involved ([Fig. 32-4B](#)). First, inhibition of *neuronal* MAO augments NE levels within the terminals of sympathetic neurons that regulate cardiac function and vascular tone. Second, inhibition of *intestinal* and *hepatic* MAO allows dietary tyramine to pass directly through the intestinal wall and liver, and then enter the systemic circulation intact. Third, upon reaching peripheral sympathetic nerves, tyramine stimulates the release of the accumulated NE, thereby causing massive vasoconstriction and excessive stimulation of the heart. Hypertensive crisis results. To reduce the risk of tyramine-induced hypertensive crisis, the following precautions must be taken:

- MAOIs must not be dispensed to patients considered incapable of rigid adherence to dietary restrictions.
- Before an MAOI is dispensed, the patient must be fully informed about the hazard of ingesting tyramine-rich foods.
- The patient must be given a detailed list of foods and beverages to avoid. These foods—
which include yeast extracts, most cheeses, fermented sausages (eg, salami, pepperoni,
bologna), and aged fish or meat—are listed in [Table 32-6](#).

350

351

TABLE 32-6 Foods That Can Interact with MAO Inhibitors

Foods That Contain Tyramine		
Category	Unsafe Foods (High Tyramine Content)	Safe Foods (Little or No Tyramine)
Vegetables	Avocados, especially if overripe; fermented bean curd; fermented soybean; soybean paste	Most vegetables
Fruits	Figs, especially if overripe; bananas, in large amounts	Most fruits
Meats	Meats that are fermented, smoked, or otherwise aged; spoiled meats; liver, unless <i>very</i> fresh	Meats that are known to be fresh (exercise caution in restaurants; meat may not be fresh)
Sausages	Fermented varieties: bologna, pepperoni, salami, others	Nonfermented varieties
Fish	Dried or cured fish; fish that is fermented, smoked, or otherwise aged; spoiled fish	Fish that is known to be fresh; vacuum-packed fish, if eaten promptly or refrigerated only briefly after opening
Milk, milk products	Practically all cheeses	Milk, yogurt, cottage cheese, cream cheese
Foods with yeast	Yeast extract (eg, Marmite, Bovril)	Baked goods that contain yeast
Beer, wine	Some imported beers, Chianti wine	Major domestic brands of beer, most wines
Other foods	Protein dietary supplements; soups (may contain protein extract), shrimp paste; soy sauce	
Foods That Contain Nontyramine Vasopressors		
Food	Comments	
Chocolate	Contains phenylethylamine, a pressor agent; large amounts can cause a reaction.	
Fava beans	Contain dopamine, a pressor agent; reactions are most likely with overripe beans.	
Ginseng	Headache, tremulousness, and manic-like reactions have occurred.	
Caffeinated beverages	Caffeine is a weak pressor agent; large amounts may cause a reaction.	

- The patient should be instructed to avoid all drugs not specifically approved by the prescriber.

The patient should be educated about the symptoms of hypertensive crisis (headache, tachycardia, palpitations, nausea, vomiting) and instructed to seek immediate medical attention if these develop. In the event of hypertensive crisis, blood pressure can be lowered with IV *phentolamine*, a short-acting alpha-adrenergic antagonist; blood pressure declines because of vasodilation secondary to blockade of α_1 receptors on blood vessels.

Sublingual *nifedipine*, a calcium channel blocker, is an alternative; like IV phentolamine, sublingual nifedipine acts rapidly to promote vasodilation. Some authorities recommend that patients carry a 10-mg nifedipine capsule for use in emergencies.

In addition to tyramine, several other dietary constituents (eg, caffeine, phenylethylamine) can precipitate hypertension in patients taking MAOIs. Foods that contain these compounds are listed in [Table 32-6](#). The patient should be instructed to avoid them.

33.6.1.4 Drug Interactions

The MAOIs can interact with many drugs to cause potentially disastrous results. Accordingly, patients should be instructed to avoid all medications—prescription agents and over-the-counter drugs—that have not been specifically approved by the prescriber.

33.6.1.4.1 Indirect-Acting Sympathomimetic Agents.

Indirect-acting sympathomimetics (eg, ephedrine, amphetamine) are drugs that promote the release of NE from sympathetic nerves. In patients taking MAOIs, these drugs can produce *hypertensive crisis*. The mechanism is the same as that described for tyramine. Patients should be instructed to avoid all sympathomimetic drugs, including ephedrine, methylphenidate, amphetamines, and cocaine. Sympathomimetic agents may be present in cold remedies, nasal decongestants, and asthma medications; all of these should be avoided unless approved by the prescriber.

33.6.1.4.2 Interactions Secondary to Inhibition of Hepatic MAO.

Inhibition of MAO in the liver can decrease the metabolism of several drugs, including epinephrine, NE, and dopamine. These drugs must be used with caution because their effects will be intensified and prolonged.

33.6.1.4.3 Tricyclic Antidepressants.

The combination of a TCA with an MAOI may produce hypertensive episodes or hypertensive crisis. As a result, this combination of antidepressants is not employed routinely. However, although potentially dangerous, the combination can benefit certain patients. If this combination is employed, caution must be exercised.

33.6.1.4.4 Serotonergic Drugs.

Combining MAOIs with SSRIs and other serotonergic drugs (see [Table 32-5](#)) poses a risk of serotonin syndrome. Accordingly, these combinations should be avoided.

33.6.1.4.5 Antihypertensive Drugs.

Combined use of MAOIs and antihypertensive agents may result in excessive lowering of blood pressure. This response should be no surprise considering that MAOIs, by themselves, can cause hypotension.

33.6.1.4.6 Meperidine.

Meperidine [Demerol] can cause hyperpyrexia (excessive elevation of temperature) in patients receiving MAOIs. Accordingly, if a strong analgesic is required, an agent other than meperidine should be chosen. Furthermore, the analgesic should be administered in its lowest effective dosage.

33.6.1.5 Preparations, Dosage, and Administration

Three oral MAOIs are available. Formulations are as follows: isocarboxazid [Marplan], 10-mg tablets; phenelzine [Nardil], 15-mg tablets; and tranylcypromine [Parnate], 10-mg tablets. Dosages are presented in [Table 32-3](#).

351

33.6.2 Transdermal MAOI: Selegiline

352

Transdermal selegiline [Emsam], approved in 2006, is the first transdermal treatment for major depression. An oral formulation, available for decades, is approved for Parkinson's disease (see [Chapter 21](#)). At the blood levels achieved during oral therapy of Parkinson's disease, selegiline produces selective inhibition of MAO-B. However, at the blood levels achieved with transdermal therapy of depression, this selectivity is lost, and hence the drug inhibits MAO-A as well as MAO-B. Like other MAOIs, selegiline should be reserved for patients who have not responded to preferred antidepressant drugs.

The pharmacology of transdermal selegiline is much like that of the oral MAOIs, but with one important difference: The risk of hypertensive crisis from dietary tyramine is much lower with transdermal dosing than with oral dosing. Why? Because with transdermal dosing, selegiline enters the systemic circulation without first passing through the GI tract. As a result, it can achieve therapeutic levels in the CNS while preserving activity of MAO-A in the intestinal wall and liver. Therefore, dietary tyramine will be destroyed before it can promote NE release in the periphery. Clinical trials have shown that restricting dietary tyramine is unnecessary with low-dose selegiline (24 mg/24 hr). However, owing to a lack of data, tyramine restriction *is* recommended at higher selegiline doses. Furthermore, with *all* doses of selegiline, sympathomimetic drugs (eg, phenylephrine, ephedrine, pseudoephedrine, amphetamines) are still be able to promote NE release, and hence must be avoided, just as they must be with *oral* MAOIs.

Two drugs—carbamazepine [Tegretol] and oxcarbazepine [Trileptal]—can significantly raise levels of selegiline. Accordingly, these drugs are contraindicated during selegiline therapy.

The most common adverse reaction is localized rash, which develops in about one-third of patients. Rash can be managed with topical glucocorticoids.

Selegiline transdermal patches are available in three strengths, delivering 6, 9, and 12 mg over 24 hours. Application is done every 24 hours to intact, dry skin of the upper torso, upper thigh, or outer surface of the upper arm. The recommended starting dose is 6 mg/24 hr. If necessary, dosage may be increased to 9 mg/24 hr, and then to 12 mg/24 hr after a minimum of 2 weeks at the lower dose.

33.7 ATYPICAL ANTIDEPRESSANTS

33.7.1 Bupropion

33.7.1.1 Actions and Uses.

Bupropion [Wellbutrin, Aplenzin, Budeprion] is a unique antidepressant similar in structure to amphetamine. Like amphetamine, bupropion has stimulant actions and suppresses appetite. Antidepressant effects begin in 1 to 3 weeks and equal those of amitriptyline (a TCA). The mechanism by which depression is relieved is unclear, but may be related to blockade of dopamine uptake. The drug does not affect serotonergic, cholinergic, or histaminergic transmission. In contrast to SSRIs, bupropion does not cause weight gain or sexual dysfunction. In fact, it appears to *increase* sexual desire and pleasure—hence bupropion has been used to (1) counteract sexual dysfunction in patients taking SSRIs, and (2) heighten sexual interest in women with hypoactive sexual desire disorder. Because of its efficacy and side effect profile,

bupropion is a good alternative to SSRIs for patients who cannot tolerate SSRI side effects. The most serious adverse effect is seizures, which can occur when dosage is too high. Bupropion has two antidepressant indications: (1) major depressive disorder and (2) *prevention* of seasonal affective disorder (SAD). In addition to its use in depression, bupropion is approved as an aid to quit smoking (see [Chapter 39](#)). Unlabeled uses include relief of neuropathic pain and management of attention-deficit/hyperactivity disorder.

33.7.1.2 Adverse Effects.

Bupropion is generally well tolerated, but can cause seizures. The most common adverse effects are agitation (31%), headache (27%), dry mouth (27%), constipation (26%), weight loss (23%), GI upset (22%), dizziness (21%), tremor (21%), insomnia (19%), blurred vision (15%), and tachycardia (11%). Like other antidepressants, bupropion may increase the risk of suicide in children, adolescents, and young adults.

At doses greater than 450 mg/day, bupropion produces seizures in about 0.4% of patients. The risk is greatly increased in patients with predisposing factors, such as head trauma, pre-existing seizure disorder, CNS tumor, and use of other drugs that lower seizure threshold. Careful dosing reduces seizure risk.

33.7.1.3 Drug Interactions.

MAOIs can increase the risk of bupropion toxicity. Accordingly, patients should discontinue MAOIs at least 2 weeks before starting bupropion.

33.7.1.4 Preparations, Dosage, and Administration.

33.7.1.4.1 Preparations for Depression.

For treatment of depression, bupropion is available as two salts: bupropion hydrochloride and bupropion hydrobromide. Bupropion *hydrochloride* is available in immediate-release tablets (75 and 100 mg) as *Wellbutrin*, sustained-release tablets (100, 150, and 200 mg) as *Wellbutrin SR*, and extended-release tablets (150 and 300 mg) as *Wellbutrin XL* and *Budeprion XL*.^{*} Bupropion *hydrobromide* is available in extended-release alcohol-resistant tablets (174, 348, and 522 mg) as *Aplenzin*.

* Some patients who have switched from Wellbutrin XL to the generic Budeprion XL have reported worsening of side effects and relapse of previously controlled depressive symptoms. Whether these experiences are due to differences in the formulations or are just a coincidence has not been established.

33.7.1.4.2 Preparations for Smoking Cessation.

Bupropion hydrochloride marketed for smoking cessation is available in 150-mg sustained-release tablets sold as *Zyban*. Dosages are presented in [Chapter 39](#).

33.7.1.4.3 Dosage for Major Depression.

Dosing must be done carefully to minimize the risk of seizures. Dosage escalation should be done slowly. The dosing schedule depends on the formulation being used. With the immediate-release tablets, the initial dosage is 75 mg twice a day. After 4 days, the dosage can be increased to 100 mg 3 times a day. If necessary, the dosage can be increased to a maximum of 150 mg 3 times a day. For maintenance therapy, once-daily dosing with Wellbutrin XL, Budeprion XL, or Aplenzin are attractive options.

33.7.1.4.4 Dosage for Seasonal Affective Disorder.

To prevent SAD, dosing should begin in the fall—using Wellbutrin XL—and taper off in the spring. The dosage is 150 mg/day initially, and can later increase to 300 mg/day, if needed.

33.7.2 Other Atypical Antidepressants

33.7.2.1 Nefazodone

Nefazodone, formerly available as *Serzone*, is a novel drug indicated only for depression. Neuropharmacologic actions include blockade of 5-HT₂ receptors and alpha₁-adrenergic receptors, and weak inhibition of NE and 5-HT reuptake. The contribution of these actions to therapeutic effects is unknown. Life-threatening liver failure is the adverse effect of greatest concern.

Nefazodone is rapidly and completely absorbed following oral administration. Food delays absorption and decreases bioavailability by 20%. Plasma drug levels peak about 1 hour after oral dosing. In the liver, nefazodone undergoes conversion to three active metabolites. The effective half-life of the parent drug and metabolites is 11 to 24 hours.

352

Nefazodone is generally well tolerated. The most common side effects are sedation, headache, somnolence, dry mouth, nausea, dizziness, blurred vision, and other visual disturbances. Weight gain and sexual dysfunction are minimal.

353

Nefazodone can cause life-threatening liver failure. However, the incidence is extremely low: only 1 case leading to death or liver transplantation for every 250,000 to 300,000 patient-years.

As a rule, nefazodone should not be given to patients with pre-existing liver disease. Patients who develop signs of liver injury (eg, nausea, anorexia, abdominal pain, malaise, jaundice) should seek immediate medical attention. If laboratory tests confirm hepatocellular injury, nefazodone should be withdrawn.

Drugs that block uptake of 5-HT, NE, or both can cause serious reactions if combined with an MAOI. Accordingly, nefazodone and MAOIs must not be combined. If the patient has been taking an MAOI, it should be discontinued at least 2 weeks before starting nefazodone. Conversely, when switching from nefazodone to an MAOI, nefazodone should be discontinued at least 7 days before starting the MAOI.

Nefazodone inhibits hepatic drug-metabolizing enzymes, and can thereby raise levels of other drugs. When present at high levels, terfenadine or astemizole (two nonsedating antihistamines no longer available in the United States) can cause fatal ventricular dysrhythmias. Accordingly, since nefazodone can raise levels of these drugs, it must not be combined with either one.

Nefazodone is available in tablets (50, 100, 150, 200, and 250 mg) for oral use. Dosing is begun at 100 mg twice daily. If needed, the dosage can be gradually increased to between 150 and 300 mg twice daily. For elderly patients, dosing is begun at 50 mg twice daily; the usual effective range is 50 to 200 mg twice daily.

33.7.2.2 Mirtazapine

Mirtazapine [Remeron] is the first representative of a new class of antidepressants. Benefits appear to result from increased *release* of 5-HT and NE. The mechanism is blockade of presynaptic α_2 -adrenergic receptors that serve to inhibit release. In addition to promoting transmitter release, mirtazapine is a powerful blocker of two serotonin receptor subtypes: 5-HT₂ and 5-HT₃. The contribution of this effect is unclear. Mirtazapine blocks histamine receptors, and thereby promotes sedation and weight gain. Antidepressant effects equal those of SSRIs and may develop faster.

Mirtazapine is well absorbed following oral administration and reaches peak plasma levels in 2 hours. The drug undergoes extensive hepatic metabolism followed by excretion in the urine (75%) and feces (25%). The elimination half-life is 20 to 40 hours.

Mirtazapine is generally well tolerated. Somnolence is the most prominent adverse effect, occurring in 54% of patients. Weight gain, increased appetite, and elevated cholesterol are also common. Sexual dysfunction is minimal. Reversible agranulocytosis and neutropenia occur rarely. Blockade of muscarinic receptors is moderate, and hence anticholinergic effects are mild. Mirtazapine-induced somnolence can be exacerbated by alcohol, benzodiazepines, and other

CNS depressants. Accordingly, these agents should be avoided. Mirtazapine should not be combined with MAOIs.

Mirtazapine is available in standard tablets (7.5, 15, 30, and 45 mg) under the trade name *Remeron*, and in orally disintegrating tablets (15, 30, and 45 mg) under the trade name *SolTab*. The initial dosage is 15 mg once a day at bedtime. Dosage may be gradually increased to a maximum of 45 mg/day.

33.7.2.3 Amoxapine

Amoxapine, formerly available as *Asendin*, is chemically related to the antipsychotic agent loxapine, and has both antidepressant and neuroleptic properties. Antidepressant effects are equivalent to those of the TCAs. Because it can cause serious side effects, amoxapine should be reserved for patients with psychotic depression.

Amoxapine is generally well tolerated. Anticholinergic and sedative effects are moderate. Following overdose, the risk of seizures is greater than with TCAs. Exercise caution in patients with epilepsy.

Like loxapine and the other antipsychotics, amoxapine can block receptors for dopamine. As a result, the drug can cause extrapyramidal side effects (eg, parkinsonism, akathisia). Because of the risk of tardive dyskinesia (an extrapyramidal effect that develops with prolonged use of dopamine antagonists), long-term use of amoxapine should generally be avoided.

Amoxapine is available in tablets (25, 50, 100, and 200 mg). The usual dosage for depression is 200 to 300 mg/day.

33.7.2.4 Reboxetine

Reboxetine [Vestra] is the first representative of a new class of antidepressants: the *selective norepinephrine reuptake inhibitors*. The drug is not related chemically to TCAs, MAOIs, SSRIs, or SNRIs. Biochemical effects are limited almost entirely to enhancing transmission at receptors for NE. The drug has little or no impact on receptors for 5-HT, dopamine, acetylcholine, or histamine. Reboxetine is available in 50 countries, but not in the United States.

In clinical trials, antidepressant effects were comparable to those of TCAs and fluoxetine [Prozac], an SSRI. With short-term use, reboxetine induced remission and, with long-term use, prevented relapse. Because reboxetine is a new drug, its therapeutic niche has not been established. However, available data suggest that it may be especially good for patients with severe depression and for those in whom social functioning is severely impaired.

Reboxetine is rapidly absorbed following oral administration. Plasma levels peak within 2 hours. High-fat meals reduce the rate of absorption, but not the extent. Reboxetine undergoes extensive hepatic metabolism followed by excretion in the urine. The drug's half-life is 12 to 16 hours, but may be prolonged in patients with liver dysfunction.

Reboxetine is generally well tolerated. The most common side effects are dry mouth, hypotension, constipation, urinary hesitancy or retention, and decreased libido. Other effects include dizziness, headache, nausea, insomnia, tremor, diaphoresis, and tachycardia. Reboxetine does not cause sedation or weight gain, and has minimal effects on psychomotor or cognitive function.

Combining reboxetine with an MAOI may pose a risk of hypertensive crisis. Accordingly, MAOIs should be withdrawn at least 14 days before giving reboxetine.

The recommended starting dosage is 4 mg twice daily. In patients with liver dysfunction, the initial dosage should be reduced to 2 mg twice daily. In clinical trials, dosages ranged between 4 and 12 mg/day.

33.7.2.5 Trazodone

Trazodone, formerly available as *Desyrel*, is a second-line agent for depression. The drug is not very effective when used alone, but, because of its pronounced sedative effects, can be a helpful adjunct for patients with antidepressant-induced insomnia. Trazodone produces selective (but moderate) blockade of 5-HT reuptake. Antidepressant effects take several weeks to develop.

Common side effects are sedation, orthostatic hypotension, and nausea. In contrast to the tricyclic agents, trazodone has minimal anticholinergic actions and is not cardiotoxic. Accordingly, trazodone may be useful for elderly patients and other individuals for whom the cardiac and anticholinergic effects of the tricyclics may be intolerable.

Trazodone can cause priapism (prolonged, painful erection). In some cases, surgical intervention has been required. Priapism itself or the procedures required for relief can result in permanent impotence. Patients should be instructed to notify their prescriber or to go to an emergency department if persistent erection occurs. Prolonged clitoral erection can also occur, but the incidence is extremely low (0.016%).

Overdose with trazodone is considered safer than with TCAs or MAOIs. Death from overdose with trazodone alone has not been reported (although death has occurred following overdose with trazodone in combination with another CNS depressant).

Drugs that inhibit CYP3A4 (the 3A4 isozyme of cytochrome P450) can decrease metabolism of trazodone, and thereby increase its concentration. Toxicity may result. Accordingly, if trazodone is combined with a strong CYP3A4 inhibitor (eg, ketoconazole, ritonavir), dosage of trazodone should be reduced.

Trazodone is available in tablets (50, 100, 150, and 300 mg). The initial dosage is 150 mg/day in divided doses. Dosage may be gradually increased to a maximum of 400 mg/day (for outpatients) and 600 mg/day (for hospitalized patients).

33.8 NONDRUG THERAPY OF DEPRESSION

33.8.1 Electroconvulsive Therapy

Although outside the realm of pharmacology, ECT is a valuable treatment for depression and deserves our consideration. Success requires a series of treatments, typically three per week for 2 to 4 weeks. Since ECT as practiced today does not cause convulsions, a more appropriate name might be *electroshock therapy*.

ECT has two characteristics that are especially desirable: *effectiveness* and *rapid onset* (relative to antidepressant drugs). Because of these properties, ECT is indicated primarily for two types of patients: (1) those who have failed to respond to pharmacologic treatment for depression (50% to 60% will respond to ECT), and (2) severely depressed, suicidal patients who need rapid relief of symptoms.

353

354

Thanks to the adjunctive use of drugs, ECT is much less dramatic and traumatic than in the past. Prior to the delivery of electroshock, patients are treated with a combination of *thiopental* and *succinylcholine*. Thiopental is an injectable, ultrashort-acting anesthetic that prevents conscious awareness of the ECT procedure (without interfering with beneficial actions). Succinylcholine is a short-acting neuromuscular blocker that prevents shock-induced convulsive movements, which are both hazardous and unnecessary for a therapeutic response.

ECT can terminate an ongoing depression episode, but a single series of treatments cannot prevent recurrence. Accordingly, some patients are now given “maintenance” treatments, at weekly or monthly intervals. In one study, the relapse rate at 6 months in the absence of maintenance was 73%, compared with only 8% when maintenance ECT was used. Maintenance with antidepressant drugs (eg, lithium plus amitriptyline) is another option, but appears significantly less effective than maintenance with ECT.

The principal adverse effect of ECT is some loss of memory for events immediately surrounding treatment. Patients do not lose other memories. There is also transient impairment of cognitive

function. Minor adverse effects, which occur immediately after treatment, include nausea, headache, confusion, and muscle discomfort.

33.8.2 Vagus Nerve Stimulation

In 2005, the Food and Drug Administration (FDA) approved the Vagus Nerve Stimulation (VNS) Therapy System for adjunctive, long-term therapy of patients with “treatment-resistant depression” (TRD), which the manufacturer defines as major depression that has not responded to at least four different antidepressant drugs. The VNS Therapy System—an implanted device that delivers electrical pulses to the vagus nerve—was first developed to treat drug-resistant epilepsy. In the course of that research, mood elevation was observed in some patients. A trial was then conducted in patients with TRD. However, the results were equivocal, and led the FDA review team to request more data. The data never came, but the device was approved anyway—thanks to the intervention of Daniel Schultz, director of the FDA's Center for Devices and Radiological Health, who overruled his own team of reviewers. So, depending on who you believe, the device works, or it doesn't. Nonetheless, it's still available for use. The mechanism by which VNS alleviates depression (if it really does) is unknown. The principal side effects of VNS are hoarseness, voice alteration, cough, and dyspnea, all of which tend to diminish over time. The cost of the VNS system along with surgical implantation and calibration is about \$25,000. The VNS Therapy System and its use in epilepsy are discussed further in [Box 24-1](#) (Nondrug Therapies for Epilepsy).

33.8.2.1

KEY POINTS

- The principal symptoms of major depression are depressed mood and loss of pleasure or interest in one's usual activities and pastimes.
- Patients with mild depression can be treated equally well with antidepressant drugs or psychotherapy. Patients with severe depression respond better to a combination of drugs plus psychotherapy than to either intervention alone.
- Patients with depression often think about or attempt suicide. During treatment with antidepressants, especially initially, the risk of suicide may *increase*. To reduce the risk of suicide, patients should be followed closely by family members, caregivers, and the prescriber. Suicide risk is greatest in children and young adults.
- Therapeutic responses to antidepressants develop slowly. Initial responses develop in 1 to 3 weeks. Maximal responses develop in 1 to 2 months.

- Antidepressant therapy should continue for 6 months to 1 year after symptoms have abated.
- TCAs block reuptake of NE and 5-HT, and thereby intensify transmission at noradrenergic and serotonergic synapses. Over time, this induces adaptive cellular responses that are ultimately responsible for relieving depression.
- The most common adverse effects of TCAs are sedation, orthostatic hypotension, and anticholinergic effects (eg, dry mouth, constipation).
- The most serious adverse effect of TCAs is cardiotoxicity, which can be lethal if an overdose is taken.
- TCAs can cause a hypertensive crisis if combined with an MAOI. Accordingly, the combination is generally avoided.
- TCAs intensify responses to direct-acting sympathomimetics (eg, epinephrine) and diminish responses to indirect-acting sympathomimetics (eg, amphetamine).
- SSRIs block reuptake of serotonin, and thereby intensify transmission at serotonergic synapses. Over time, this induces adaptive cellular responses that are ultimately responsible for relieving depression.
- SSRIs have two major advantages over TCAs: they cause fewer side effects and are safer when taken in overdose.
- Most SSRIs have stimulant properties, and hence can cause insomnia and agitation. This contrasts with TCAs, which cause sedation.
- Like most other antidepressants, SSRIs can cause weight gain.
- Sexual dysfunction (eg, impotence, anorgasmia) is more common with SSRIs than with most other antidepressants.
- SSRIs can cause serotonin syndrome, especially when combined with MAOIs and other serotonergic drugs. Symptoms include agitation, confusion, hallucinations, hyperreflexia, tremor, and fever.
- MAOIs increase neuronal stores of NE and 5-HT, and thereby intensify transmission at noradrenergic and serotonergic synapses. Over time, this induces adaptive cellular responses that are ultimately responsible for relieving depression.

- MAOIs are as effective as TCAs and SSRIs, but are much more dangerous.

354

- MAOIs are first-choice drugs only for patients with atypical depression.
- Like SSRIs (and unlike TCAs), MAOIs cause direct CNS stimulation.
- Like TCAs (and unlike SSRIs), MAOIs cause orthostatic hypotension.
- Patients taking MAOIs must not eat tyramine-rich foods because hypertensive crisis can result.
- MAOIs must not be combined with indirect-acting sympathomimetics (eg, ephedrine, amphetamine) because hypertensive crisis can result.
- MAOIs must not be combined with SSRIs and other serotonergic drugs because serotonin syndrome could result.
- ECT relieves depression faster than antidepressant drugs, and often helps when antidepressants have failed.
- ECT as practiced today is safer and less traumatic than in the past, owing to adjunctive use of thiopental (which produces unconsciousness) and succinylcholine (which prevents convulsions).

355

33.8.2.2

Summary of Major Nursing Implications*

33.8.2.2.1

IMPLICATIONS THAT APPLY TO ALL ANTIDEPRESSANTS

33.8.2.2...

Psychologic Assessment

Observe and record the patient's behavior. Factors to assess include affect, thought content, interest in the environment, appetite, sleep patterns, and appearance.

33.8.2.2...

Reducing the Risk of Suicide

Depression carries a risk of suicide, which may increase during the initial phase of antidepressant therapy or when antidepressant dosage is changed. The risk is greatest among children and young adults. **Advise family members and caregivers to monitor for symptoms of clinical decline (eg, anxiety, agitation, panic attacks, insomnia, irritability, hostility, impulsivity, hypomania, and emergence of suicidal thoughts), and to immediately report symptoms that are severe or develop abruptly.** To help

reduce suicide risk, the patient or caregiver should meet with the prescriber at least weekly during the first 4 weeks of treatment, then biweekly for the next 4 weeks, then once 1 month later, and periodically thereafter.

Patients who are so depressed that they are a risk to themselves and others should be hospitalized until symptoms are under control. Suicide potential should be evaluated carefully. To prevent patients from accumulating a potentially lethal supply of medication, ensure that each dose is swallowed and not cheeked. Provide outpatients with no more than a 1-week supply of medication at a time. For patients considered at high risk of suicide, TCAs and MAOIs should be avoided; SSRIs are much safer.

33.8.2.2...

Promoting Adherence

Inform the patient that antidepressant effects usually develop slowly, over 1 to 3 weeks. This knowledge will make expectations more realistic, which should help promote adherence.

Premature discontinuation of therapy can result in relapse. **Educate patients about the importance of taking their medication as prescribed, even though they may be symptom free and therefore feel “cured.”** In general, treatment should continue for 6 months to a year after symptoms have subsided.

33.8.2.2...

Nondrug Therapy

For patients with severe depression, treatment with drugs alone is not optimal. Emotional support and psychotherapy can complement and reinforce responses to antidepressants. ECT may be indicated for suicidal patients and for patients who fail to respond to antidepressant drugs and psychotherapy. As a last resort, vagus nerve stimulation can be tried.

33.8.2.2...

Evaluating Therapeutic Effects

Assess patients for improvement in symptoms, especially depressed mood and loss of interest or pleasure in usual activities.

33.8.2.2.2

TRICYCLIC ANTIDEPRESSANTS

Amitriptyline

Clomipramine

	Desipramine Doxepin Imipramine Maprotiline Nortriptyline Protriptyline Trimipramine In addition to the implications summarized below, see <i>Implications That Apply to All Antidepressants</i> above.	
33.8.2.2...	Preadministration Assessment	
33.8.2.2...	Therapeutic Goal Alleviation of symptoms of major depression.	
33.8.2.2...	Baseline Data Assess psychologic status. Arrange for an ECG, especially for patients with cardiac disease and those over 40.	
33.8.2.2...	Identifying High-Risk Patients TCAs are generally <i>contraindicated</i> for patients taking MAOIs. Use TCAs with <i>caution</i> in patients with cardiac disorders (eg, coronary heart disease, progressive heart failure, paroxysmal tachycardia), elevated intraocular pressure, urinary retention, hyperthyroidism, seizure disorders, and liver or kidney dysfunction.	355 356
	<i>Doxepin</i> is <i>contraindicated</i> for patients with glaucoma or a tendency to urinary retention.	

Maprotiline is contraindicated for patients with seizure disorders.

Implementation: Administration

Routes

Oral (usual); IM (occasional).

Administration

Instruct patients to take medication daily as prescribed and not PRN. Warn patients not to discontinue treatment once mood has improved, since doing so may result in relapse. Once an effective dosage has been established, the entire daily dose can usually be taken at bedtime.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Suicide Risk.

See Implications That Apply to All Antidepressants.

Orthostatic Hypotension.

Inform patients about symptoms of hypotension (dizziness, lightheadedness), and advise them to sit or lie down if these occur. Inform patients that hypotension can be minimized by moving slowly when assuming an erect posture. For hospitalized patients, monitor blood pressure and pulse rate on a regular schedule; take measurements while the patient is lying down and again after the patient has been sitting or standing for 1 to 2 minutes. If blood pressure is low or pulse rate is high, withhold medication and inform the prescriber.

Anticholinergic Effects.

Inform patients about possible anticholinergic effects (dry mouth, blurred vision, photophobia, urinary hesitancy, constipation, tachycardia), and advise them to notify the prescriber if these are troublesome. A detailed summary of nursing implications for anticholinergic drugs is presented in [Chapter 14](#).

33.8.2.2...

Diaphoresis.

TCAs promote sweating (despite their anticholinergic properties). Excessive sweating may necessitate frequent changes of bedding and clothing.

33.8.2.2...

Sedation.

Sedation is most intense during the first weeks of therapy and declines with continued drug use. **Advise patients to avoid hazardous activities (eg, driving, operating dangerous machinery) if sedation is significant.** Giving TCAs at bedtime minimizes daytime sedation and promotes sleep.

33.8.2.2...

Cardiotoxicity.

TCAs can disrupt cardiac function, but usually only when taken in excessive doses or by patients with heart disease. All patients should receive an ECG prior to treatment and periodically thereafter.

33.8.2.2...

Seizures.

TCAs decrease seizure threshold. Exercise caution in patients with seizure disorders.

33.8.2.2...

Hypomania.

TCAs may shift mood from depression up to hypomania. If hypomania develops, the patient must be evaluated to determine if elation is drug induced or indicates bipolar disorder.

33.8.2.2...

Minimizing Adverse Interactions

33.8.2.2...

MAO Inhibitors.

Rarely, the combination of a TCA and an MAOI has produced hypertensive episodes and hypertensive crisis. Exercise caution if this combination is employed.

33.8.2.2...

Sympathomimetic Agents.

TCAs decrease the effects of indirect-acting sympathomimetics (eg, ephedrine, amphetamine), but potentiate the actions of direct-acting sympathomimetics (eg, epinephrine, dopamine). If sympathomimetics are to be used, these effects must be accounted for.

33.8.2.2...

Anticholinergic Agents.

Drugs capable of blocking muscarinic receptors will enhance the anticholinergic effects of TCAs. **Warn patients against concurrent use of other anticholinergic drugs (eg, scopolamine, antihistamines, phenothiazines).**

33.8.2.2...

CNS Depressants.

These will enhance the depressant effects of TCAs. **Warn patients against using alcohol and all other drugs with CNS-depressant properties (eg, opioids, antihistamines, barbiturates, benzodiazepines).**

33.8.2.2.3

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Citalopram

Escitalopram

Fluoxetine

Fluvoxamine

Paroxetine

Sertraline

In addition to the implications summarized below, see *Implications That Apply to All Antidepressants* above.

33.8.2.2...

Preadministration Assessment

33.8.2.2...

Therapeutic Goal

33.8.2.2...

Alleviation of Symptoms of Major Depression.

All SSRIs except fluvoxamine are approved for treating depression.

33.8.2.2...	Other Goals. SSRIs are used to relieve symptoms of many psychologic disorders, including obsessivecompulsive disorder, panic disorder, social phobia, generalized anxiety disorder, post-traumatic stress disorder, premenstrual dysphoric disorder, and bulimia nervosa (see Table 32-4).	
33.8.2.2...	Identifying High-Risk Patients SSRIs are <i>contraindicated</i> for patients taking MAOIs, and should be used with <i>caution</i> in patients taking other serotonergic drugs. Use with <i>caution</i> in patients with liver disease and in the elderly and in women who are pregnant or breast-feeding.	
33.8.2.2...	Implementation: Administration	
33.8.2.2...	Route Oral.	
33.8.2.2...	Administration All SSRIs may be administered with food. Administration in the morning minimizes sleep disruption.	356
	Warn patients not to discontinue treatment once mood has improved, since doing so could lead to relapse.	357
33.8.2.2...	Ongoing Evaluation and Interventions	
33.8.2.2...	Minimizing Adverse Effects	
33.8.2.2...	Suicide Risk. <i>See Implications That Apply to All Antidepressants.</i>	
33.8.2.2...	CNS Stimulation. <i>Citalopram, escitalopram, fluoxetine, paroxetine, and sertraline can cause nervousness, insomnia, and anxiety. These reactions may respond to a decrease in dosage. (Fluvoxamine causes mild sedation.)</i>	

33.8.2.2...

Serotonin Syndrome.

Symptoms of this potentially fatal syndrome include agitation, confusion, disorientation, anxiety, hallucinations, poor concentration, incoordination, myoclonus, hyperreflexia, excessive sweating, tremor, and fever. The risk is reduced by avoiding concurrent use of MAOIs and other serotonergic drugs (see [Table 32-5](#)). Serotonin syndrome resolves spontaneously after discontinuing the SSRI.

33.8.2.2...

Sexual Dysfunction.

Inform patients about possible sexual dysfunction (anorgasmia, impotence, decreased libido), and encourage them to report problems. Management strategies include dosage reduction, drug holidays, adding a drug to counteract sexual dysfunction (eg, sildenafil, bupirone), and switching to an antidepressant that causes less sexual dysfunction (eg, bupropion, nefazodone, mirtazapine).

33.8.2.2...

Dizziness and Fatigue.

Inform patients about possible dizziness and fatigue, and advise them to exercise caution while performing hazardous tasks (eg, driving).

33.8.2.2...

Rash.

Fluoxetine may cause rash. **Inform patients about the risk of rash and instruct them to notify the prescriber if one develops.** Treatment consists of drug therapy (antihistamines, glucocorticoids) or withdrawal of fluoxetine.

33.8.2.2...

Weight Gain.

Long-term therapy can result in significant weight gain. **Advise patients to restrict caloric intake and to get appropriate exercise.**

33.8.2.2...

Neonatal Abstinence Syndrome (NAH) and Persistent Pulmonary Hypertension of the Newborn (PPHN).

Use of SSRIs late in pregnancy poses a small risk of NAS and PPHN. Newborns exposed to SSRIs *in utero* should be monitored for both disorders. If NAS occurs, it can be managed with supportive care, and generally abates within a few days. Treatment measures for PPHN include providing mechanical ventilatory support,

giving inhaled nitric oxide and oxygen, and giving IV sodium bicarbonate and dopamine.

33.8.2.2...

Teratogenesis.

One SSRI—*paroxetine*—poses a small risk of birth defects, especially ventral septal defects and other cardiovascular anomalies. Other SSRIs are preferred during pregnancy.

33.8.2.2...

GI Bleeding.

SSRIs impair platelet aggregation, and can thereby increase the risk of GI bleeding. Exercise caution in elderly patients, patients with ulcers or a history of GI bleeding, and patients taking nonsteroidal anti-inflammatory drugs or anticoagulants.

33.8.2.2...

Hyponatremia.

SSRIs can cause hyponatremia, primarily in older patients taking diuretics. When SSRIs and diuretics are used in older patients, serum sodium should be measured at baseline and periodically thereafter.

33.8.2.2...

Bruxism.

SSRIs can cause bruxism (clenching and grinding of teeth), usually during sleep.

Alert patients to the sequelae of bruxism (headache, jaw pain, and dental problems, such as cracked fillings). If these develop, investigate whether an SSRI is the cause. Bruxism can be managed by (1) a reduction in SSRI dosage (but then depression may return), (2) switching to a different class of antidepressants, (3) use of a mouth guard, and (4) treatment with low-dose buspirone.

33.8.2.2...

Minimizing Adverse Interactions

33.8.2.2...

Serotonergic Drugs.

Combining SSRIs with MAOIs and other serotonergic drugs increases the risk of serotonin syndrome. Withdraw MAOIs at least 14 days before starting an SSRI. Withdraw fluoxetine 5 weeks before starting an MAOI; withdraw other SSRIs at least 2 weeks before starting an MAOI.

33.8.2.2...

TCAs and Lithium.

Fluoxetine can increase levels of these drugs. Exercise caution.

33.8.2.2... Nonsteroidal Anti-inflammatory Drugs and Anticoagulants.

These drugs increase the risk of GI bleeding. Exercise caution.

33.8.2.2.4 MONOAMINE OXIDASE INHIBITORS

Isocarboxazid

Phenelzine

Selegiline

Tranylcypromine

33.8.2.2... Preadministration Assessment

In addition to the implications summarized below, see *Implications That Apply to All Antidepressants* above.

33.8.2.2... Therapeutic Goal

Alleviation of symptoms of major depression, especially atypical depression.

33.8.2.2... Identifying High-Risk Patients

MAOIs are *contraindicated* for patients taking SSRIs; for patients with pheochromocytoma, heart failure, liver disease, severe renal impairment, cerebrovascular defect (known or suspected), cardiovascular disease, and hypertension; and for patients over the age of 60 (because of possible cerebral sclerosis associated with vessel damage).

Use with *caution* in patients taking serotonergic drugs.

33.8.2.2... Implementation: Administration

33.8.2.2... Route

33.8.2.2... Oral.

Isocarboxazid, phenelzine, tranylcypromine.

33.8.2.2...	Transdermal. Selegiline.	
33.8.2.2...	Administration	
33.8.2.2...	All MAOIs. Instruct patients to take MAOIs every day as prescribed—not PRN. Warn patients not to discontinue treatment once mood has improved, since doing so may result in relapse.	357
33.8.2.2...	Transdermal Selegiline. Instruct patients to apply the Emsam patch to intact, dry skin of the upper torso, upper thigh, or outer surface of the upper arm once every 24 hours.	358
33.8.2.2...	Ongoing Evaluation and Interventions	
33.8.2.2...	Minimizing Adverse Effects	
33.8.2.2...	Suicide Risk. <i>See Implications That Apply to All Antidepressants.</i>	
33.8.2.2...	Hypertensive Crisis. Dietary tyramine, certain other dietary constituents (see Table 32-6), and indirect-acting sympathomimetics (eg, amphetamine, methylphenidate, ephedrine, cocaine) can precipitate a hypertensive crisis in patients taking MAOIs. Inform patients about symptoms of hypertensive crisis (headache, palpitations, tachycardia, nausea, vomiting), and instruct them to seek immediate medical attention if these develop. To reduce the risk of hypertensive crisis, the following precautions must be observed: • Do not give MAOIs to patients who are suicidal or who are considered incapable of rigid adherence to dietary constraints. • Forewarn patients about the hazard of hypertensive crisis and the need to avoid tyramine-rich foods and sympathomimetic drugs. (Patients on low-	

dose transdermal selegiline needn't avoid tyramine containing foods, but do need to avoid sympathomimetic drugs.)

- **Provide patients with a list of specific foods to avoid (see [Table 32-6](#)).**
- **Instruct them to avoid all drugs not approved by the prescriber.**

If hypertensive crisis develops, blood pressure can be lowered with IV phentolamine or sublingual nifedipine.

33.8.2.2...

Orthostatic Hypotension.

Inform patients about signs of hypotension (dizziness, lightheadedness), and advise them to sit or lie down if these occur. Inform patients that hypotension can be minimized by moving slowly when assuming an erect posture. For the hospitalized patient, monitor blood pressure and pulse rate on a regular schedule. Take these measurements while the patient is lying down and again after the patient has been sitting or standing for 1 to 2 minutes. If blood pressure is low, withhold medication and inform the prescriber.

33.8.2.2...

Skin Rash.

Application-site rash is common with transdermal selegiline, and can be managed with a topical glucocorticoid.

33.8.2.2...

Minimizing Adverse Interactions

33.8.2.2...

All Drugs.

MAOIs can interact adversely with many other drugs. **Instruct the patient to avoid all medications—prescription and nonprescription—that have not been specifically approved by the prescriber.**

33.8.2.2...

Indirect-Acting Sympathomimetics.

Concurrent use with MAOIs can precipitate a hypertensive crisis. **Warn patients against use of any indirect-acting sympathomimetics (eg, ephedrine, methylphenidate, amphetamines, cocaine).**

33.8.2.2...

Tricyclic Antidepressants.

Concurrent use with MAOIs can produce hypertensive episodes and hypertensive crisis. Use this combination with caution.

33.8.2.2...

Serotonergic Drugs.

Combining MAOIs with other serotonergic drugs (see [Table 32-5](#)) poses a risk of serotonin syndrome. Accordingly, these combinations should generally be avoided.

33.8.2.2...

Antihypertensive Drugs.

These drugs will potentiate the hypotensive effects of MAOIs. If these agents are combined, monitor blood pressure periodically.

33.8.2.2...

Meperidine.

Meperidine can produce hyperthermia in patients taking MAOIs and hence should be avoided.

* Patient education information is highlighted as **blue text**.

³⁴CHAPTER 33 Drugs for Bipolar Disorder

Our topic for this chapter is bipolar disorder (BPD), formerly known as *manic-depressive illness*. The disease afflicts an estimated 3.7% of the adult population—more than 6.7 million Americans. The mainstays of therapy are lithium and valproic acid, drugs with the ability to stabilize mood. Many patients also receive an antipsychotic, and some may require an antidepressant. Bipolar disorder is a chronic condition that requires treatment lifelong.

^{34.1}CHARACTERISTICS OF BIPOLAR DISORDER

Bipolar disorder is a severe biologic illness characterized by recurrent fluctuations in mood. Typically, patients experience alternating episodes in which mood is abnormally elevated or abnormally depressed—separated by periods in which mood is relatively normal. Symptoms usually begin in adolescence or early adulthood, but can occur before adolescence or as late as the fifth decade of life. In the absence of treatment, episodes of mania or depression generally persist for several months. As time passes, manic and depressive episodes tend to recur more frequently. Although the precise etiology of BPD is unknown, it is clear that symptoms are caused by altered brain physiology—not by a character flaw or an unstable personality.

^{34.1.1}Types of Mood Episodes Seen in BPD

Patients with BPD may experience four types of mood episodes. These are described below.

^{34.1.1.1}Pure Manic Episode (Euphoric Mania).

Manic episodes are characterized by persistently heightened, expansive, or irritable mood—typically associated with hyperactivity, excessive enthusiasm, and flight of ideas. Manic individuals display overactivity at work and at play and have a reduced need for sleep. Mania produces excessive sociability and talkativeness. Extreme self-confidence, grandiose ideas, and delusions of self-importance are common. Manic individuals often indulge in high-risk activities (eg, questionable business deals, reckless driving, gambling, sexual indiscretions), giving no forethought to the consequences. In severe cases, symptoms may resemble those of paranoid schizophrenia (hallucinations, delusions, bizarre behavior). Specific diagnostic criteria for a manic episode, as described in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*, are summarized in [Table 33-1](#).

^{34.1.1.2}Hypomanic Episode (Hypomania).

Hypomania can be viewed as a mild form of mania. As in mania, mood is persistently elevated, expansive, or irritable. However, symptoms are not severe enough to cause marked impairment

in social or occupational functioning, or to require hospitalization. Psychotic symptoms are absent.

34.1.1.3 Major Depressive Episode (Depression).

A major depressive episode is characterized by depressed mood and loss of pleasure or interest in all or nearly all of one's usual activities and pastimes. Associated symptoms include disruption of sleeping and eating patterns; difficulty concentrating; feelings of guilt, worthlessness, and helplessness; and thoughts of death and suicide. The characteristics of major depression are discussed further in [Chapter 32](#).

34.1.1.4 Mixed Episode.

In a true mixed episode, patients experience symptoms of mania and depression simultaneously. Patients may be agitated and irritable (as in mania), but may also feel worthless and depressed. The combination of high energy and depression puts them at significant risk of suicide.

34.1.2 Patterns of Mood Episodes

Among people with BPD, mood episodes can occur in a variety of patterns. Contrary to popular belief, not all patients alternate repeatedly between mania and depression. Some experience repeated episodes of mania, and some experience repeated episodes of depression (with an occasional episode of mania). Mood may be normal between episodes of mania and depression, or it may be slightly elevated (hypomania) or slightly depressed (dysphoria).

Mood episodes can vary greatly with respect to duration and how often they occur. A single episode may last for days, weeks, months, or more than a year. In the absence of treatment, episodes of mania or hypomania typically last a few months, whereas episodes of major depression typically last at least 6 months. On average, people with BPD experience only 4 episodes during the first 10 years of their illness. However, some people cycle much more rapidly, experiencing many episodes every year.

359

TABLE 33-1 DSM-IV-TR Criteria for a Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary). B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree: • Inflated self-esteem or grandiosity • Decreased need for sleep (eg, feels rested after only 3 hours of sleep) • More talkative than usual or pressure to keep talking • Flight of ideas or subjective experience that thoughts are racing • Distractibility (ie, attention too easily drawn to unimportant or irrelevant external stimuli) • Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation • Excessive involvement in pleasurable activities that have a high potential for painful consequences (eg, engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments) C. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features. D. The symptoms are not due to the direct physiologic effects of a substance (eg, a drug of abuse, a medication, or other treatment) or a general medical condition (eg, hyperthyroidism).*
Modified from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Press, 2000, with permission. Copyright © 2000 American Psychiatric Association.

* Manic-like episodes that are clearly caused by somatic antidepressant treatment (eg, medication, electro-convulsive therapy, light therapy) should not count toward a diagnosis of bipolar disorder.

On the basis of mood episode type and frequency, BPD can be subdivided into three major categories:

- *Bipolar I Disorder*—Patients experience manic or mixed episodes, and usually depressive episodes too.
- *Bipolar II Disorder*—Patients experience hypomanic or depressive episodes, but not manic or mixed episodes.

- *Rapid-Cycling Bipolar Disorder*—Patients experience four or more episodes of any sort (manic, hypomanic, depressive, mixed) each year.

34.1.3 Etiology

Theories regarding the etiology of BPD continue to evolve. In the past, there was general agreement that BPD was due primarily to an imbalance in neurotransmitters. Today, researchers suspect the real cause may be disruption of neuronal growth and survival. Why? First, neuroimaging studies have shown an association between prolonged mood disorders and atrophy of specific brain regions—especially the subgenual prefrontal cortex, an area involved in emotionality. Second, mood-stabilizing drugs can prevent or reverse neuronal atrophy in patients with BPD, apparently by influencing signaling pathways that regulate neuronal growth and survival.

34.2 TREATMENT OF BIPOLAR DISORDER

34.2.1 Drug Therapy

34.2.1.1 Types of Drugs Employed

Bipolar disorder is treated with three major groups of drugs: mood stabilizers, antipsychotics, and antidepressants. In addition, benzodiazepines are frequently used for sedation.

34.2.1.1.1 Mood Stabilizers.

Mood stabilizers are drugs that (1) relieve symptoms during manic and depressive episodes, (2) prevent recurrence of manic and depressive episodes, and (3) do not worsen symptoms of mania or depression, or accelerate the rate of cycling. The principal mood stabilizers are *lithium* and two drugs originally developed for epilepsy: *valproic acid* (and its derivatives), and *carbamazepine*. These drugs are the mainstays of treatment. The pharmacology of lithium and the antiepileptic drugs is discussed below.

34.2.1.1.2 Antipsychotics.

In patients with BPD, antipsychotic drugs are given to help control symptoms during severe manic episodes, even if psychotic symptoms are absent. Although antipsychotics can be used alone, they are usually employed in combination with a mood stabilizer. For reasons discussed below, the atypical antipsychotics (eg, olanzapine, risperidone) are preferred to traditional antipsychotics (eg, haloperidol).

34.2.1.1.3 Antidepressants.

Antidepressants may be needed during a depressive episode. However, in patients with BPD, antidepressants are *always* combined with a mood stabilizer. Why? Because of the long-held belief that, when used alone, antidepressants may elevate mood so much that a hypomanic or manic episode will result. However, data published in 2007 indicate that the risk of inducing mania may be much lower than previously thought. Nonetheless, until the issue is fully resolved, it would seem prudent to continue the traditional practice of using an antidepressant only if a mood stabilizer is being used as well.

Although antidepressants have been studied extensively in patients with major depression, very little research has been done in patients with BPD. As a result, we lack reliable information on which to base drug selection. Even so, experts do have their preferences. Among clinicians with extensive experience in BPD, the following are considered antidepressants of choice: *bupropion* [Wellbutrin], *venlafaxine* [Effexor], and the *selective serotonin reuptake inhibitors* (SSRIs), such as fluoxetine [Prozac] and sertraline [Zoloft]. The pharmacology of these drugs is discussed in [Chapter 32](#).

34.2.1.2 Drug Selection

34.2.1.2.1 Acute Therapy: Manic Episodes.

Two mood stabilizers—lithium and valproic acid—are preferred drugs for acute management of manic episodes. The choice between them is based on clinical presentation (eg, euphoric mania, mania with psychosis, rapid-cycling BPD). As shown in [Table 33-2](#), valproic acid is preferred to lithium in most cases. In fact, the only exception is euphoric mania, for which lithium is the drug of choice. If the patient does not respond adequately to lithium or valproic acid alone, the drugs may be used together. Responses to mood stabilizers develop slowly, taking 2 or more weeks to become maximal.

360

361

TABLE 33-2 Initial Treatment of First Manic Episode

Clinical Presentation	Preferred Strategy	Preferred Drugs*	
		Mood Stabilizers	Antipsychotics
Euphoric mania	Mood stabilizer alone	Valproic acid or lithium	
Dysphoric mania or true mixed mania	Mood stabilizer alone	Valproic acid or lithium	
Mania with psychosis	Mood stabilizer plus an antipsychotic	Valproic acid or lithium	Olanzapine or risperidone
Rapid cycling (currently manic)	Mood stabilizer alone	Valproic acid	

* Drugs of choice, if established, are presented in **bold type**.

If needed, an antipsychotic agent or a benzodiazepine may be added to the regimen. These adjuvants can help relieve symptoms (eg, insomnia, anxiety, agitation) until the mood stabilizer takes full effect. For patients with mild mania, a benzodiazepine (eg, lorazepam [Ativan]) may be adequate. For patients with severe mania or with symptoms of psychosis, an antipsychotic is preferred; olanzapine or risperidone would be a good choice.

34.2.1.2.2 Acute Therapy: Depressive Episodes.

Depressive episodes may be treated with a mood stabilizer alone, or with a mood stabilizer *plus* an antidepressant—but *never* with an antidepressant alone (because hypomania or mania might result). If depression is mild, monotherapy with a mood stabilizer (lithium or valproic acid) may be sufficient. If the mood stabilizer is inadequate, an antidepressant can be added. However, recent data suggest that the benefits may be limited. Preferred agents are bupropion, venlafaxine, and the SSRIs.

34.2.1.2.3 Long-Term Preventive Treatment.

The purpose of long-term therapy is to prevent recurrence of both mania and depression. As a rule, one or more mood stabilizers are employed. Drug selection is based on what worked acutely. For example, if the patient responded to acute therapy with lithium alone, then lithium alone should be used long term. Other long-term options include valproic acid alone, and valproic acid plus lithium. More recently, antipsychotic agents have been employed for long-term maintenance, either as monotherapy or in combination with a mood stabilizer.

34.2.1.3 Promoting Adherence

Poor patient adherence can frustrate attempts to treat manic episodes. Patients may resist treatment because they fail to see anything wrong with their thinking or behavior. Furthermore, the experience is not necessarily unpleasant. In fact, individuals going through a manic episode may well enjoy it. As a result, in order to ensure adherence, short-term hospitalization may be required. To achieve this, collaboration with the patient's family may be needed. Since hospitalization per se won't guarantee success, lithium administration should be observed to ensure that each dose is actually taken.

After an acute manic episode has been controlled, long-term prophylactic therapy is indicated, making adherence an ongoing issue. To promote adherence, the patient and family should be educated about the nature of BPD and the importance of taking medication as prescribed. Family members can help ensure adherence by overseeing medication use, and by urging the patient to visit his or her prescriber or a psychiatric clinic if a pattern of nonadherence develops.

34.2.2 Nondrug Therapy

34.2.2.1 Education and Psychotherapy

Ideally, BPD should be treated with a combination of drugs and adjunctive psychotherapy (individual, group, or family); drug therapy alone is not optimal. Bipolar disorder is a chronic illness that requires supportive therapy and education for the patient and family. Counseling can help patients cope with the sequelae of manic episodes, such as strained relationships, reduced self-confidence, and a sense of shame regarding uncontrolled behavior. Certain life stresses (eg, moving, job loss, bereavement, childbirth) can precipitate a mood change. Therapy can help reduce the destabilizing impact of these events. Patients should be taught to recognize early symptoms of mood change, and encouraged to contact their primary clinician immediately if these develop. Additional measures by which patients can help themselves include

- Maintaining a stable sleep pattern
- Maintaining a regular pattern of activity
- Avoiding alcohol and psychoactive street drugs
- Enlisting the support of family and friends
- Taking steps to reduce stress at work
- Keeping a mood chart to monitor progress

34.2.2.2 Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is an effective intervention that can be lifesaving in patients with severe mania or depression. However, ECT is not a treatment of first choice. Rather, it should be reserved for patients who have not responded adequately to drugs. Candidates for ECT include patients with psychotic depression, severe nonpsychotic depression, severe mania, and rapid-cycling BPD. Details of ECT are discussed in [Chapter 32](#).

34.3 MOOD-STABILIZING DRUGS

As noted, mood stabilizers are drugs that can relieve an acute manic or depressive episode, and can prevent symptoms from recurring—all without aggravating mania or depression, and without accelerating cycling. The agents used most often are lithium, valproic acid, and carbamazepine.

361

34.3.1 BOX 33-1 Special Interest Topic

34.3... OMEGA-3 FATTY ACIDS FOR BIPOLAR DISORDER: A FISH STORY WITH A HAPPY ENDING

In 1999, researchers from Harvard University made an exciting discovery: Fish oil can stabilize mood in people with bipolar disorder. Their results were so striking, in fact, that the experiment was stopped after 4 months so that control patients could switch to the fish-oil regimen. All subjects in the study had diagnosed bipolar disorder. Some took 9.6 gm of fish oil daily, and some took olive oil as a control. All continued on their usual medications. Among the group that ate fish oil, 11 of 15 improved after 4 months—and only 2 suffered eventual relapse. Among the group that ate olive oil, only 6 of 20 improved after 4 months—and 11 experienced relapse. Patients taking the fish oil had longer periods of remission, and, when symptoms did appear, they were less severe. Several patients were able to discontinue their medications and remain symptom free on fish oil alone. Side effects of the fish oil were minor—nausea, belching, fishy taste, loose stools—and easily controlled. At this time, the long-term benefits or detriments of fish oil are unknown. This study is of special interest in that it suggests that dietary therapy for a major illness can be as effective as drugs.

How does fish oil work? No one knows. Fish oil is composed of omega-3 fatty acids*—specifically, eicosapentaenoic acid and docosahexaenoic acid. In humans, the highest concentrations of omega-3s are found in the eyes and brain, where they are present in cell membranes. It may be that eating fish oil increases the concentration of omega-3s in neuronal membranes, and thereby slows nerve signaling, which in turn may stabilize mood. There is some evidence that omega-6 fatty acids—the kind found in vegetable oils, margarine, and

362

mayonnaise—may negate the beneficial effects of omega-3s. Accordingly, patients taking fish oil for bipolar disorder should probably decrease intake of omega-6s.

- * Omega-3 fatty acids are long-chain polyunsaturated fats that have a double bond located three carbons from the methyl terminus of the chain.

34.3.2 Lithium

Lithium [Lithobid, Lithonate, Lithotabs] can stabilize mood in patients with BPD. Beneficial effects were first described in 1949 by John Cade, an Australian psychiatrist. Because of concerns about toxicity, lithium was not approved for use in the United States until 1970. Lithium has a low therapeutic index. As a result, toxicity can occur at blood levels only slightly greater than therapeutic levels. Accordingly, monitoring lithium levels is mandatory.

34.3.2.1 Chemistry

Lithium is a simple inorganic ion that carries a single positive charge. In the periodic table of elements, lithium is in the same group as potassium and sodium. Not surprisingly, lithium has properties in common with both elements. Lithium is found naturally in animal tissues but has no known physiologic function.

34.3.2.2 Therapeutic Uses

34.3.2.2.1 Bipolar Disorder.

Lithium is a drug of choice for controlling acute manic episodes in patients with BPD and for long-term prophylaxis against recurrence of mania or depression. In manic patients, lithium reduces euphoria, hyperactivity, and other symptoms but does not cause sedation. Antimanic effects begin 5 to 7 days after treatment onset—but full benefits may not develop for 2 to 3 weeks. In the past, lithium was considered the drug of choice for all patients experiencing an acute manic episode, regardless of clinical presentation. Today, however, lithium is reserved primarily for patients with classic (euphoric) mania; valproic acid is generally preferred for all other patients (see [Table 33-2](#)). However, recent data show that lithium is superior to valproate at preventing suicide in patients with BPD, and hence use of lithium is likely to increase.

34.3.2.2.2 Other Uses.

Although approved only for treatment of BPD, lithium has been used with varying degrees of success in other psychiatric disorders, including *alcoholism*, *bulimia*, *schizophrenia*, and *glucocorticoid-induced psychosis*. Nonpsychiatric uses include *hyperthyroidism*, *cluster*

headache, migraine, and syndrome of inappropriate secretion of antidiuretic hormone. In addition, lithium can *raise neutrophil counts* in children with chronic neutropenia and in patients receiving anticancer drugs or zidovudine (AZT).

34.3.2.3 Mechanism of Action

Although lithium has been studied extensively, the precise mechanism by which it stabilizes mood is unknown. In the past, research focused on three aspects of brain neurochemistry: (1) altered distribution of certain ions (calcium, sodium, magnesium) that are critical to neuronal function; (2) altered synthesis and release of norepinephrine, serotonin, and dopamine; and (3) effects on second messengers (eg, cyclic AMP, phosphatidyl inositol), which mediate intracellular responses to neurotransmitters. Unfortunately, this research has failed to provide a definitive explanation of how lithium works. Current neurochemical research suggests that lithium may work by (1) altering glutamate uptake and release, (2) blocking the binding of serotonin to its receptors, and/or (3) inhibiting glycogen synthase kinase-3 beta.

Recently, there has been growing interest in the neurotrophic and neuroprotective actions of lithium. As noted above, there is evidence that symptoms of BPD may result from neuronal atrophy in certain brain areas. In animal studies, “therapeutic” doses of lithium doubled the level of neurotrophic Bcl-2 proteins. In addition, lithium has been shown to facilitate regeneration of damaged optic nerves. In patients with BPD taking lithium long term, volume of the subgenual prefrontal cortex is greater than in untreated patients. Furthermore, lithium can increase total gray matter in regions known to atrophy in BPD, including the prefrontal cortex, hippocampus, and caudate nucleus. All of these studies suggest that the benefits of lithium may result at least in part from an ability to protect against neuronal atrophy and/or promote neuronal growth.

34.3.2.4 Pharmacokinetics

34.3.2.4.1 Absorption and Distribution.

Lithium is well absorbed following oral administration. The drug distributes evenly to all tissues and body fluids.

362

34.3.2.4.2 Excretion.

Lithium has a short half-life owing to rapid renal excretion. Because of its short half-life (and high toxicity), the drug must be administered in divided daily doses. Large, single daily doses cannot be used, even when a slow-release preparation is prescribed. Because lithium is excreted by the kidneys, it must be employed with great care in patients with renal impairment.

363

Renal excretion of lithium is affected by blood levels of sodium. Specifically, lithium excretion is *reduced* when levels of sodium are *low*. Why? Because the kidney processes lithium and sodium in the same way. Hence, when the kidney senses that sodium levels are inadequate, it retains lithium in an attempt to compensate. Because of this relationship, in the presence of low sodium, lithium can accumulate to toxic levels. Accordingly, it is important that sodium levels remain normal. Patients should be instructed to maintain normal sodium intake. Obviously, a sodium-free diet cannot be used. Since diuretics promote sodium loss, these agents must be employed with caution. Sodium loss secondary to diarrhea can be sufficient to cause lithium accumulation. The patient should be told about this possibility.

Dehydration will cause lithium retention by the kidneys, posing the risk of accumulation to dangerous levels. Potential causes of dehydration include hot weather and diarrhea. Counsel patients to maintain adequate hydration.

34.3.2.4.3 Monitoring Plasma Lithium Levels.

Measurement of plasma lithium levels is an essential component of treatment. *Lithium levels must be kept below 1.5 mEq/L; levels greater than this can produce significant toxicity.* For *initial* therapy of a manic episode, lithium levels should range from 0.8 to 1.4 mEq/L. Once the desired therapeutic effect has been achieved, the dosage should be reduced to produce *maintenance* levels of 0.4 to 1.0 mEq/L. Blood for lithium determinations should be drawn in the morning, 12 hours after the evening dose.

34.3.2.5 Adverse Effects

The adverse effects of lithium can be divided into two categories: (1) effects that occur at excessive lithium levels and (2) effects that occur at therapeutic lithium levels. In the discussion below, adverse effects produced at excessive lithium levels are considered as a group. Effects produced at therapeutic levels are considered individually.

34.3.2.5.1 Adverse Effects That Occur When Lithium Levels Are Excessive.

Certain toxicities are closely correlated with the concentration of lithium in blood. As indicated in [Table 33-3](#), mild responses (eg, fine hand tremor, GI upset, thirst, muscle weakness) can develop at lithium levels that are still within the therapeutic range (ie, below 1.5 mEq/L). When plasma levels exceed 1.5 mEq/L, more serious toxicities appear. At drug levels above 2.5 mEq/L, death can occur. Patients should be informed about early signs of toxicity and instructed to interrupt lithium dosing if these appear. In adherent patients, the most common cause of lithium accumulation is sodium depletion.

To keep lithium levels within the therapeutic range, plasma drug levels should be monitored routinely. Levels should be measured every 2 to 3 days at the beginning of treatment and every 1 to 3 months during maintenance therapy.

Treatment of acute overdose is primarily supportive; there is no specific antidote. The severely intoxicated patient should be hospitalized. Hemodialysis is an effective means of lithium removal and should be considered whenever drug levels exceed 2.5 mEq/L.

TABLE 33-3 Toxicities Associated with Excessive Plasma Level of Lithium

Plasma Lithium Level (mEq/L)	Signs of Toxicity
Below 1.5	Nausea, vomiting, diarrhea, thirst, polyuria, lethargy, slurred speech, muscle weakness, fine hand tremor
1.5–2	Persistent GI upset, coarse hand tremor, confusion, hyperirritability of muscles, ECG changes, sedation, incoordination
2–2.5	Ataxia, giddiness, high output of dilute urine, serious ECG changes, fasciculations, tinnitus, blurred vision, clonic movements, seizures, stupor, severe hypotension, coma, death (usually secondary to pulmonary complications)
Above 2.5	Symptoms may progress rapidly to generalized convulsions, oliguria, and death
ECG = electrocardiogram.	

34.3.2.5.2 Adverse Effects That Occur at Therapeutic Levels of Lithium.

34.3.2.5.2.1 Early Adverse Effects.

Several responses occur early in treatment and then usually subside. *Gastrointestinal effects* (eg, nausea, diarrhea, abdominal bloating, anorexia) are common but transient. About 30% of patients experience *transient fatigue, muscle weakness, headache, confusion, and memory impairment*. *Polyuria* and *thirst* occur in 30% to 50% of patients and may persist.

34.3.2.5.2.2 Tremor.

Patients may develop a fine hand tremor, especially in the fingers, that can interfere with writing and other motor skills. Lithium-induced tremor can be augmented by stress, fatigue, and certain drugs (antidepressants, antipsychotics, caffeine). Tremor can be reduced with a

beta blocker (eg, propranolol) and by measures that reduce peak levels of lithium (ie, dosage reduction, use of divided doses, or use of a sustained-release formulation).

34.3.2.5.2.3 Polyuria.

Polyuria occurs in 50% to 70% of patients taking lithium chronically. In some patients, daily urine output may exceed 3 L. Lithium promotes polyuria by antagonizing the effects of antidiuretic hormone. To maintain adequate hydration, patients should be instructed to drink 8 to 12 glasses of fluids daily. Polyuria, nocturia, and excessive thirst can discourage patients from adhering to the regimen.

Lithium-induced polyuria can be reduced with *amiloride* [Midamor], a potassium-sparing diuretic. Amiloride appears to help by reducing the entry of lithium into epithelial cells of the renal tubule. Polyuria can also be reduced with a thiazide diuretic. However, because thiazides can lower levels of sodium (see [Chapter 40](#)), and would thereby increase lithium retention, amiloride is preferred.

34.3.2.5.2.4 Renal Toxicity.

Chronic lithium use has been associated with degenerative changes in the kidney. The risk of renal injury can be reduced by keeping the dosage low and, when possible, avoiding long-term lithium therapy. Kidney function should be assessed prior to treatment and once a year thereafter.

363

34.3.2.5.2.5 Goiter and Hypothyroidism.

Lithium can reduce incorporation of iodine into thyroid hormone, and can inhibit thyroid hormone secretion. With long-term use, the drug can cause *goiter* (enlargement of the thyroid gland). Although usually benign, lithium-induced goiter is sometimes associated with *hypothyroidism*. Treatment with thyroid hormone (levothyroxine) or withdrawal of lithium will reverse both goiter and hypothyroidism. Levels of thyroid hormones—triiodothyronine (T₃) and thyroxine (T₄)—and levels of thyroid-stimulating hormone (TSH) should be measured prior to giving lithium and annually thereafter.

364

34.3.2.5.2.6 Teratogenesis.

Lithium may—or may not—be a teratogen. In older studies, lithium appeared to have significant teratogenic effects: drug use during the first trimester of pregnancy was associated with an 11% incidence of birth defects (usually malformations of the heart). However, in more recent studies, lithium showed little or no teratogenic potential.

Nonetheless, lithium is still classified in Food and Drug Administration (FDA) Pregnancy Risk Category D. To minimize any potential fetal risk, *lithium should be avoided during the first trimester of pregnancy* and, unless the benefits of therapy clearly outweigh the risks, it should be avoided during the remainder of pregnancy as well. Women of child-bearing age should be counseled to avoid pregnancy while taking lithium. Also, pregnancy should be ruled out before initiating lithium therapy.

34.3.2.5.2.7 Use in Lactation.

Lithium readily enters breast milk and can achieve concentrations that are potentially harmful to the nursing infant. Consequently, breast-feeding during lithium therapy should be discouraged.

34.3.2.5.2.8 Other Effects.

Lithium can cause mild, reversible *leukocytosis* (10,000 to 18,000 white blood cells/mm³); complete blood counts with a differential should be obtained prior to treatment and annually thereafter. Possible *dermatologic reactions* include psoriasis, acne, folliculitis, and alopecia.

34.3.2.6 Drug Interactions

34.3.2.6.1 Diuretics.

Diuretics promote sodium loss, and can thereby increase the risk of lithium toxicity. Toxicity can occur because, in the presence of low sodium, renal excretion of lithium is reduced, causing lithium levels to rise.

34.3.2.6.2 Nonsteroidal Anti-inflammatory Drugs (NSAIDs).

NSAIDs can increase lithium levels by as much as 60%. How? By suppressing synthesis of prostaglandins in the kidney, NSAIDs disrupt (increase) renal reabsorption of lithium (and also sodium), thereby causing lithium levels to rise. NSAIDs known to increase lithium levels include ibuprofen [Motrin, others], naproxen [Naprosyn], piroxicam [Feldene], indomethacin [Indocin], and celecoxib [Celebrex]. Interestingly, aspirin (the prototype NSAID) and sulindac [Clinoril] do *not* increase lithium levels. Accordingly, if a mild analgesic is needed, aspirin or sulindac would be a good choice.

34.3.2.6.3 Anticholinergic Drugs.

Anticholinergics can cause urinary hesitancy. Coupled with lithium-induced polyuria, this can result in considerable discomfort. Accordingly, patients should avoid drugs with prominent

anticholinergic actions (eg, antihistamines, phenothiazine antipsychotics, tricyclic antidepressants).

34.3.2.7 Preparations, Dosage, and Administration

34.3.2.7.1 Preparations and Administration.

Lithium is available as two salts: *lithium carbonate* and *lithium citrate*. With either salt, administration is oral. Lithium carbonate is supplied in capsules, standard tablets, and slow-release tablets. Lithium citrate is supplied in a syrup. Lithium formulations and trade names are summarized in [Table 33-4](#).

Lithium can cause gastric upset. This can be reduced by administering lithium with meals or milk.

34.3.2.7.2 Dosing.

Lithium dosing is highly individualized. Dosage adjustments are based on plasma drug levels and clinical response.

Plasma levels should be kept within the therapeutic range. Levels between 0.8 and 1.4 mEq/L are generally appropriate for *acute therapy* of manic episodes. For *maintenance therapy*, lithium levels should range from 0.4 to 1.0 mEq/L. (Levels of 0.6 to 0.8 mEq/L are effective for most patients.) To avoid serious toxicity, *lithium levels should not exceed 1.5 mEq/L*.

Knowledge of plasma drug levels is not the only guide to lithium dosing; the clinical response is at least as important. Accordingly, when evaluating lithium dosage, we must not forget to look at the patient. Laboratory tests are all well and good, but they are not a substitute for clinical assessment. For example, if blood levels of lithium appear proper but clinical evaluation indicates toxicity, there is no question as to what should be done: Reduce the dosage—despite the apparent acceptability of the dosage as reflected by plasma lithium levels.

Because of its short half-life and low therapeutic index, *lithium cannot be administered in a single daily dose*: With once-a-day dosing, peak levels would be excessive. Hence, a typical dosage is 300 mg (of lithium carbonate) taken 3 or 4 times a day. A dosage of 600 mg twice a day is acceptable, provided a slow-release formulation is employed. However, even these preparations cannot be given once daily.

TABLE 33-4 Lithium Preparations

Lithium Salt	Formulation	Lithium Content*	Trade Name
Lithium carbonate (Li ₂ CO ₃)	Capsules	4.06 mEq lithium (150 mg Li ₂ CO ₃)	(generic only)
		8.12 mEq lithium (300 mg Li ₂ CO ₃)	Lithonate
		16.24 mEq lithium (600 mg Li ₂ CO ₃)	(generic only)
	Tablets: standard	8.12 mEq lithium (300 mg Li ₂ CO ₃)	Lithotabs
	Tablets: slow-release	8.12 mEq lithium (300 mg Li ₂ CO ₃)	Lithobid
Lithium citrate	Syrup	8 mEq lithium/5 mL (equivalent to 300 mg Li ₂ CO ₃)	

* Lithium content is expressed in two ways: (1) milliequivalents (mEq) of lithium ion and (2) milligrams (mg) of the particular lithium salt of which the preparation is composed.

364

34.3.3 Antiepileptic Drugs

365

Certain antiepileptic drugs (eg, valproic acid, carbamazepine) can suppress mania and stabilize mood in patients with BPD. The efficacy of these agents is firmly established. In fact, one drug—valproic acid—is so effective that it has replaced lithium as the drug of choice for many patients. The basic pharmacology of the antiepileptic drugs and their use in seizure disorders is discussed in [Chapter 24](#). Discussion here focuses on their use in BPD.

34.3.3.1 Valproic Acid

Valproic acid* [Depakene, Depakote, Depacon, Stavzor] was the first antiseizure agent approved for BPD. The drug can control symptoms in acute manic episodes and can provide prophylaxis against recurrent episodes of mania and depression. As with lithium, benefits appear to result at least in part from neurotrophic and neuroprotective effects. In patients with BPD, valproic acid compares favorably with lithium: both drugs are highly effective, and valproate works faster and has a higher therapeutic index and a more desirable side effect profile. However, lithium is superior in one important respect: the ability to decrease suicide. Nonetheless, because of its rapid onset, efficacy, and safety, valproic acid has become a first-line treatment for BPD. The starting dosage for acute mania in adults is 250 mg 3 times a day or 500 mg once daily at bedtime. Typical maintenance dosages range from 1000 to 2500 mg/day. The target trough plasma level is 50 to 120 mcg/mL.

Although valproic acid has a higher therapeutic index than lithium and is generally better tolerated, it *can* cause serious toxicity. Of greatest concern are rare cases of thrombocytopenia, pancreatitis, and liver failure—all of which require immediate drug withdrawal. In addition, valproic acid is a teratogen, and hence should not be used during pregnancy. Gastrointestinal disturbances (nausea, vomiting, diarrhea, dyspepsia, indigestion) are common. These can be minimized by using Depakote, an enteric-coated formulation of divalproex sodium (a form of valproic acid). Despite causing GI distress, valproic acid frequently causes weight gain, a serious and chronic complication of treatment.

* As discussed in [Chapter 24](#), valproic acid is available in three closely related forms: (1) valproic acid itself [Depakene, Depacon, Stavzor]; (2) the sodium salt of valproic acid [Depakene]; and (3) divalproex sodium [Depakote], a mixture of valproic acid and its sodium salt. All three forms have identical actions. In this chapter, the term *valproic acid* refers to all three.

34.3.3.2 Carbamazepine

Carbamazepine was the first drug to be widely studied as an alternative to lithium for patients with BPD. However, it wasn't approved for BPD until 2005. Like lithium, carbamazepine reduces symptoms during manic and depressive episodes. In addition, when taken for maintenance, it can protect against recurrence of mania and depression. Like valproic acid, carbamazepine is preferred to lithium for patients with mixed mania or rapid-cycling BPD. For treatment of acute manic episodes, the dosage should be low initially (100 or 200 mg twice daily) and then gradually increased. The maximum dosage is 1600 mg/day. The target trough plasma level is 4 to 12 mcg/mL. Neurologic side effects (visual disturbances, ataxia, vertigo, unsteadiness, headache) are common early in treatment, but generally resolve despite continued drug use. Hematologic effects (leukopenia, anemia, thrombocytopenia, aplastic anemia) are relatively uncommon, but can be severe. Accordingly, complete blood counts including platelets should be obtained at baseline and periodically thereafter. Carbamazepine induces cytochrome P450 enzymes, and can thereby accelerate its own metabolism and the metabolism of other drugs (eg, oral contraceptives, warfarin, valproic acid, tricyclic antidepressants). To maintain efficacy, dosages of carbamazepine and these other drugs should be increased as needed.

TABLE 33-5 Adult Oral Dosages for Atypical Antipsychotics Used in Bipolar Disorder

Drug	Dosage
Olanzapine [Zyprexa]	<i>Acute Mania:</i> Start with 10–15 mg once daily. Increase or decrease, in 5-mg/day increments, as indicated. The effective range is 5–20 mg once daily. <i>Maintenance Therapy:</i> The effective range is 5–20 mg once daily.
Olanzapine/Fluoxetine [Symbyax]	<i>Depressive Episodes:</i> Start with 6 mg olanzapine/25 mg fluoxetine once daily in the evening. The effective range for antidepressant effects is olanzapine 6–12 mg and fluoxetine 25–50 mg.
Risperidone [Risperdal]	<i>Acute Mania:</i> Start with 2–3 mg once daily; increase to a maximum of 6 mg once daily; if needed.
Quetiapine [Seroquel]	<i>Acute Mania (with normal liver function):</i> Give 100 mg (in two divided doses) on day 1, 200 mg on day 2, 300 mg on day 3, and 400 mg on day 4. If needed, increase to 600 mg on day 5 and 800 mg on day 6. <i>Acute Mania (with liver impairment):</i> Give 25 mg on day 1, then increase by 25–50 mg/day until symptoms are controlled or side effects are intolerable, whichever comes first. <i>Depressive Episodes:</i> Give once-daily doses at bedtime as follows: 50 mg on day 1, 100 mg on day 2, 200 mg on day 3, and 300 mg on day 4; if needed, increase to 400 mg on day 5, and 600 mg on day 8.
Aripiprazole [Abilify]	<i>Acute Mania:</i> Start with 30 mg once daily and do not exceed this dose. Decrease to 15 mg once daily if needed.
Ziprasidone [Geodon]	<i>Acute Mania:</i> On day 1, give 80 mg (in two divided doses with food). On day 2, increase to 60 or 80 mg twice daily. Based on tolerability and efficacy, adjust dosage within the range of 40–80 mg twice daily.

Drug products containing carbamazepine are available under four trade names: *Carbatrol*, *Equetro*, *Epitol*, and *Tegretol*. Carbamazepine formulations with any of these names can be used for BPD. However, only one product—Equetro—is actually *approved* for BPD. Equetro is an extended-release formulation, manufactured by Shire Pharmaceuticals, that is *identical* to Carbatrol, a product approved for seizure control, also manufactured by Shire. Why use two trade names for the same formulation made by the same company? To facilitate marketing, of course. This name game is another good example of why your author wants trade names to be outlawed (see discussion of drug names in [Chapter 3](#)).

365

366

34.3.3.3 Lamotrigine

In 2003, lamotrigine [Lamictal] became a third antiepileptic agent approved for BPD. The drug is indicated for long-term maintenance therapy, with the objective of delaying or preventing affective relapses. Lamotrigine may be used alone or in combination with other mood-stabilizing agents. Side effects include headache, dizziness, double vision, and, rarely, life-threatening rashes (Stevens-Johnson syndrome, toxic epidermal necrolysis). To minimize the risk of serious rash, dosage should be low initially (25 to 50 mg/day) and then gradually increased. The target maintenance dosage is 200 mg/day (if used alone), 100 mg/day (if combined with valproate), or 400 mg/day (if combined with carbamazepine or some other inducer of P450).

34.4 ANTIPSYCHOTIC DRUGS

In patients with BPD, antipsychotic drugs are used *acutely* to control symptoms during manic episodes, and *long term* to help stabilize mood. These drugs benefit patients with or without psychotic symptoms. Although antipsychotics can be used alone, they are usually employed in combination with a mood stabilizer, typically lithium or valproic acid.

Which antipsychotics are preferred? As discussed in [Chapter 31](#), the antipsychotic drugs fall into two major groups: conventional agents (eg, haloperidol) and atypical agents (eg, olanzapine). Compared with the conventional agents, the atypical agents carry a lower risk of extrapyramidal side effects, including tardive dyskinesia. Accordingly, the atypical agents are preferred.

Six atypical antipsychotics are available, and five—*olanzapine* [Zyprexa], *quetiapine* [Seroquel], *risperidone* [Risperdal], *aripiprazole* [Abilify], and *ziprasidone* [Geodon]—are now approved for BPD. (The sixth agent—*clozapine* [Clozaril]—although highly effective in BPD, is not used owing to a risk of agranulocytosis.) All of these drugs are effective against acute mania, when used alone or combined with lithium or valproate. Currently, only one atypical agent—olanzapine—is approved for long-term maintenance therapy to prevent recurrence of mood episodes. However, the other atypical agents are probably just as effective. Dosages for patients with BPD are summarized in [Table 33-5](#).

The pharmacology of the antipsychotics is presented in [Chapter 31](#).

34.4.1 KEY POINTS

- Bipolar disorder is treated with three kinds of drugs: mood stabilizers, antipsychotic drugs, and antidepressants.

- Mood stabilizers are drugs that (1) relieve symptoms during manic and depressive episodes; (2) prevent recurrence of manic and depressive episodes; and (3) do not worsen symptoms of mania or depression, and do not accelerate the rate of cycling.
- Antipsychotic drugs are used acutely to treat manic episodes, and long term to help stabilize mood. Benefits occur in patients with and without psychotic symptoms.
- In patients with bipolar depression, using an antidepressant alone may induce mania—although the risk appears lower than previously believed. Nonetheless, to minimize any risk of mania, antidepressants should not be used alone; rather, they should be combined with a mood-stabilizing drug.
- Lithium and valproic acid are the preferred mood stabilizers for BPD.
- To minimize the risk of toxicity, lithium levels must be monitored. The trough level, measured 12 hours after the evening dose, should be less than 1.5 mEq/L.
- Common side effects that occur at therapeutic lithium levels include tremor, goiter, and polyuria.
- Lithium may be teratogenic, and hence should be avoided during the first trimester of pregnancy. Also, unless the benefits outweigh the risks, lithium should be avoided during the second and third trimesters too.
- A reduction in sodium levels will reduce lithium excretion, causing lithium to accumulate—possibly to toxic levels. Patients must maintain normal sodium intake and levels.
- Lithium levels can be increased by diuretics (especially thiazides) and by several nonsteroidal anti-inflammatory drugs.

34.4.2 Summary of Major Nursing Implications*

34.4.... LITHIUM

34.4.... Preadministration Assessment

34.4.... Therapeutic Goal

Control of acute manic episodes in patients with BPD, and prophylaxis against recurrent mania and depression in patients with BPD.

34.4....

Baseline Data

Make baseline determinations of cardiac status (electrocardiogram, blood pressure, pulse), hematologic status (complete blood counts with differential), serum electrolytes, renal function (serum creatinine, creatinine clearance, urinalysis), and thyroid function (T₃, T₄, and TSH).

34.4....

Identifying High-Risk Patients

Lithium should be *avoided* during the first trimester of pregnancy, and used with *caution* during the remainder of pregnancy and in the presence of renal disease, cardiovascular disease, dehydration, sodium depletion, and concurrent therapy with diuretics.

366

34.4....

Implementation: Administration

367

34.4....

Route

Oral.

34.4....

Administration

Advise patients to administer lithium with meals or milk to decrease gastric upset. Instruct patients to swallow slow-release tablets intact, without crushing or chewing.

34.4....

Promoting Adherence

Rigid adherence to the prescribed regimen is important. Deviations in dosage size and timing can cause toxicity. Inadequate dosing may cause relapse.

To promote adherence, educate patients and families about the nature of BPD and the importance of taking lithium as prescribed. Encourage family members to oversee lithium use, and advise them to urge the patient to visit the prescriber or a psychiatric clinic if a pattern of nonadherence develops.

When medicating inpatients, make certain each lithium dose is ingested.

Ongoing Evaluation and Interventions

Monitoring Summary

Lithium Levels.

Monitor lithium levels to ensure that they remain within the therapeutic range (0.8 to 1.4 mEq/L for initial therapy and 0.4 to 1 mEq/L for maintenance). Levels should be measured every 2 to 3 days during initial therapy, and every 1 to 3 months during maintenance. Blood for lithium determination should be drawn in the morning, 12 hours after the evening dose.

Other Parameters to Monitor.

Evaluate the patient at least once a year for hematologic status (complete blood count with differential), serum electrolytes, renal function (serum creatinine, creatinine clearance, urinalysis), and thyroid function (T₃, T₄, and TSH).

Evaluating Therapeutic Effects

Evaluate the patient for abatement of manic symptoms (eg, flight of ideas, pressured speech, hyperactivity) and for mood stabilization.

Minimizing Adverse Effects

Effects Caused by Excessive Drug Levels.

Excessive lithium levels can result in serious adverse effects (see [Table 33-3](#)). Lithium levels must be monitored (see *Monitoring Summary* above) and dosage adjusted accordingly.

Teach patients about signs of toxicity, and instruct them to withhold medication and notify the prescriber if they develop.

Renal impairment can cause lithium accumulation. Kidney function should be assessed prior to treatment and once yearly thereafter.

Sodium deficiency can cause lithium to accumulate. **Instruct patients to maintain normal sodium intake. Inform patients that diarrhea can cause significant sodium loss.** Diuretics promote sodium excretion and must be used with caution.

In the event of severe toxicity, hospitalization may be required. If lithium levels exceed 2.5 mEq/L, hemodialysis should be considered.

34.4....

Tremor.

Lithium can cause fine hand tremor that can interfere with motor skills. Tremor can be reduced with a beta blocker (eg, propranolol) and by measures that reduce peak lithium levels (dosage reduction; use of divided doses or a sustained-release formulation).

34.4....

Hypothyroidism and Goiter.

Lithium can promote goiter (thyroid enlargement) and frank hypothyroidism. Plasma levels of T₃, T₄, and TSH should be measured prior to treatment and yearly thereafter. Treat hypothyroidism with levothyroxine.

34.4....

Renal Toxicity.

Lithium can cause renal damage. Kidney function should be assessed prior to treatment and once a year thereafter. If renal impairment develops, lithium dosage must be reduced.

34.4....

Polyuria.

Lithium increases urine output. Polyuria can be suppressed with amiloride (a potassium-sparing diuretic). **Instruct patients to drink 8 to 12 glasses of fluid daily to maintain hydration.**

34.4....

Use in Pregnancy and Lactation.

Lithium may cause birth defects. The drug should be avoided during pregnancy, especially in the first trimester. **Counsel women of child-bearing age about the importance of avoiding pregnancy.** Rule out pregnancy before initiating therapy.

Lithium enters breast milk. **Advise patients to avoid breast-feeding.**

34.4....

Minimizing Adverse Interactions

34.4....

Diuretics.

By promoting sodium loss, diuretics can reduce lithium excretion, thereby causing lithium levels to rise. Monitor closely for signs of toxicity.

34.4....

Anticholinergic Drugs.

By causing urinary hesitancy, drugs with anticholinergic actions (eg, antihistamines, phenothiazine antipsychotics, tricyclic antidepressants) can intensify discomfort associated with lithium-induced diuresis.

34.4....

Nonsteroidal Anti-inflammatory Drugs.

Several NSAIDs (eg, ibuprofen, naproxen, celecoxib), but *not* aspirin or sulindac, can increase renal reabsorption of lithium, thereby causing lithium levels to rise. If a mild analgesic is needed, aspirin or sulindac would be a good choice.

* Patient education information is highlighted as **blue text**.

³⁵CHAPTER 34 Sedative-Hypnotic Drugs

The sedative-hypnotics are drugs that depress central nervous system (CNS) function. With some of these drugs, CNS depression is more generalized than with others. The sedative-hypnotics are used primarily to treat anxiety and insomnia. Because both disorders are common, the sedative-hypnotics are widely used. Agents given to relieve anxiety are known as *antianxiety agents* or *anxiolytics*; an older term is *tranquilizers*. Agents given to promote sleep are known as *hypnotics*. The distinction between antianxiety effects and hypnotic effects is often a matter of dosage: typically, sedative-hypnotics relieve anxiety in low doses and induce sleep in higher doses. Hence, a single drug may be considered both an antianxiety agent and a hypnotic agent, depending upon the reason for its use and the dosage employed.

There are three major groups of sedative-hypnotics: barbiturates (eg, secobarbital), benzodiazepines (eg, diazepam), and benzodiazepine-like drugs (eg, zolpidem). The barbiturates were introduced in the early 1900s, the benzodiazepines in the 1950s, and the benzodiazepine-like drugs in the 1990s. Although barbiturates were widely used as sedative-hypnotics in the past, they are rarely used for this purpose today, having been replaced by the newer drugs.

Before the benzodiazepines became available, anxiety and insomnia were treated with barbiturates and other *general* CNS depressants—drugs with multiple undesirable qualities: (1) These drugs are powerful respiratory depressants that can readily prove fatal in overdose. As a result, they are “drugs of choice” for suicide. (2) Because they produce subjective effects that many individuals find desirable, most general CNS depressants have a high potential for abuse. (3) With prolonged use, most of these drugs produce significant tolerance and physical dependence. (4) Barbiturates and some other CNS depressants induce synthesis of hepatic drug-metabolizing enzymes, and can thereby decrease responses to other drugs. Because the benzodiazepines are just as effective as the general CNS depressants, but do not share their undesirable properties, the benzodiazepines are clearly preferred to the general CNS depressants for treating anxiety and insomnia.

We begin the chapter by discussing the basic pharmacology of the sedative-hypnotics, and end by discussing their use in insomnia. Use of these drugs for anxiety is discussed in [Chapter 35](#).

^{35.1} BENZODIAZEPINES

Benzodiazepines are drugs of first choice for anxiety and insomnia. In addition, these drugs are used to induce general anesthesia and to manage seizure disorders, muscle spasm, panic disorder, and withdrawal from alcohol.

Benzodiazepines were introduced in the late 1950s and remain important today. Perhaps the most familiar member of the family is diazepam [Valium]. The most frequently prescribed members are lorazepam [Ativan] and alprazolam [Xanax, Niravam].

The popularity of the benzodiazepines as sedatives and hypnotics stems from their clear superiority over the alternatives: barbiturates and other general CNS depressants. The benzodiazepines are safer than the general CNS depressants and have a lower potential for abuse. In addition, benzodiazepines produce less tolerance and physical dependence and are subject to fewer drug interactions. Contrasts between the benzodiazepines and barbiturates are summarized in [Table 34-1](#).

Since all of the benzodiazepines produce nearly identical effects, we will consider the family as a group, rather than selecting a representative member as a prototype.

35.1.1 Overview of Pharmacologic Effects

Practically all responses to benzodiazepines result from actions in the CNS. Benzodiazepines have few direct actions outside the CNS. All of the benzodiazepines produce a similar spectrum of responses. However, because of pharmacokinetic differences, individual benzodiazepines may differ in clinical applications.

35.1.1.1 Central Nervous System.

All beneficial effects of benzodiazepines and most adverse effects result from depressant actions in the CNS. With increasing dosage, effects progress from sedation to hypnosis to stupor.

Benzodiazepines depress neuronal function at multiple sites in the CNS. They *reduce anxiety* through effects on the limbic system, a neuronal network associated with emotionality. They *promote sleep* through effects on cortical areas and on the sleep-wakefulness “clock.” They *induce muscle relaxation* through effects on supraspinal motor areas, including

368

Figure 34-1 **Schematic model of the GABA receptor–chloride channel complex showing binding sites for benzodiazepines and barbiturates.** The GABA receptor–chloride channel complex, which spans the neuronal cell membrane, can exist in an open or closed configuration. Binding of GABA to its receptor on the complex causes the chloride channel to *open*. The resulting inward flow of chloride ions hyperpolarizes the neuron (makes the cell highly negative inside) and thereby decreases its ability to fire. Hence GABA is an *inhibitory* neurotransmitter. Binding of a *benzodiazepine* to its receptor on the complex increases the frequency of channel opening, thereby increasing chloride influx. Hence, benzodiazepines enhance the inhibitory effects of GABA. In the absence of GABA, benzodiazepines have no effect on channel opening. The benzodiazepine-like drugs (zolpidem, zaleplon, and eszopiclone) have actions much like those of the benzodiazepines. Effects of *barbiturates* on the chloride channel are dose dependent: at low doses, barbiturates enhance the actions of GABA (by prolonging the duration of channel opening); at high doses, barbiturates directly mimic the actions of GABA.

the cerebellum. Two important side effects—*confusion* and *anterograde amnesia*—result from effects on the hippocampus and cerebral cortex.

TABLE 34-1 Contrasts Between Benzodiazepines and Barbiturates

Area of Comparison	Benzodiazepines	Barbiturates
Relative safety	High	Low
Maximal ability to depress CNS function	Low	High
Respiratory depressant ability	Low	High
Suicide potential	Low	High
Ability to cause physical dependence	Low*	High
Ability to cause tolerance	Low	High
Abuse potential	Low	High
Ability to induce hepatic drug metabolism	Low	High

* Although dependence is low in most patients, significant dependence *can* develop with long-term, high-dose use.

35.1.1.2 Cardiovascular System.

When taken *orally*, benzodiazepines have almost no effect on the heart and blood vessels. In contrast, when administered *intravenously*, even in therapeutic doses, benzodiazepines can produce profound hypotension and cardiac arrest.

35.1.1.3 Respiratory System.

In contrast to the barbiturates, the benzodiazepines are weak respiratory depressants. When taken alone in therapeutic doses, benzodiazepines produce little or no depression of respiration—and with toxic doses, respiratory depression is moderate at most. With oral therapy, clinically significant respiratory depression occurs only when benzodiazepines are combined with other CNS depressants (eg, opioids, barbiturates, alcohol).

Although benzodiazepines generally have minimal effects on respiration, they can be a problem for patients with respiratory disorders. In patients with chronic obstructive pulmonary disease, benzodiazepines may worsen hypoventilation and hypoxemia. In patients with obstructive sleep apnea (OSA), benzodiazepines may exacerbate apneic episodes. In patients who snore, benzodiazepines may convert partial airway obstruction into OSA.

35.1.2 Molecular Mechanism of Action

Benzodiazepines *potentiate the actions of gamma-aminobutyric acid (GABA)*, an inhibitory neurotransmitter found throughout the CNS. These drugs enhance the actions of GABA by binding to specific receptors in a supramolecular structure known as the GABA receptor–chloride channel complex ([Fig. 34-1](#)). Please note that benzodiazepines act only by intensifying the effects of GABA; they do not act as direct GABA agonists.

Because benzodiazepines act by amplifying the actions of endogenous GABA, rather than by directly mimicking GABA, there is a limit to how much CNS depression benzodiazepines can produce. This explains why benzodiazepines are so much safer than the barbiturates—drugs that can directly mimic GABA. Since benzodiazepines simply potentiate the inhibitory effects of endogenous GABA, and since the amount of GABA in the CNS is finite, there is a built-in limit to the depth of CNS depression the benzodiazepines can produce. In contrast, since the barbiturates are direct-acting CNS depressants, maximal effects are limited only by the amount of barbiturate administered.

35.1.3 Pharmacokinetics

35.1.3.1 Absorption and Distribution.

Most benzodiazepines are well absorbed following oral administration. Because of their high lipid solubility, benzodiazepines readily cross the blood-brain barrier to reach sites in the CNS.

35.1.3.2 Metabolism.

Most benzodiazepines undergo extensive metabolic alterations. With few exceptions, the *metabolites are pharmacologically active*. As a result, responses produced by administering a particular benzodiazepine often persist long after the parent drug has disappeared. Hence, there may be a poor correlation between the plasma half-life of the parent drug and duration of pharmacologic effects. Flurazepam, for example, whose plasma half-life is only 2 to 3 hours, is converted into an active metabolite with a half-life of 50 hours. Hence, giving flurazepam produces long-lasting effects, even though flurazepam itself is gone from the plasma in 8 to 12 hours.

369

370

TABLE 34-2 Applications of the Benzodiazepines

Generic Name [Trade Name]	Approved Applications						
	GAD [*]	Insomnia	Seizures	Muscle Spasm, Spasticity	Alcohol Withdrawal	Anesthesia Induction or Preanesthesia	Panic Disorder
Alprazolam [Xanax, Niravam]	✓						✓
Chlordiazepoxide [Librium]	✓				✓		
Clonazepam [Klonopin]			✓				✓
Clorazepate [Tranxene]	✓		✓		✓		
Diazepam [Valium, Diastat AcuDia]	✓		✓	✓	✓	✓	
Estazolam (generic only)		✓					
Flurazepam (generic only)		✓					
Lorazepam [Ativan]	✓		✓		✓	✓	✓
Midazolam [Versed]						✓†	
Oxazepam [Serax]	✓				✓		
Quazepam [Doral]		✓					
Temazepam [Restoril]		✓					
Triazolam [Halcion]		✓					

* GAD = generalized anxiety disorder.

† Midazolam, in conjunction with an opioid analgesic, is also used to produce *conscious sedation*, a semiconscious state suitable for minor surgeries and endoscopic procedures.

In patients with liver disease, metabolism of benzodiazepines can decline, thereby prolonging and intensifying responses. Because certain benzodiazepines (oxazepam, temazepam, and lorazepam) undergo very little metabolic alteration, they may be preferred for patients with hepatic impairment.

35.1.3.3 Time Course of Action.

Benzodiazepines differ significantly from one another with respect to time course. Specifically, they differ in onset and duration of action, and tendency to accumulate with repeated dosing.

Because all benzodiazepines have essentially equivalent pharmacologic actions, selection among them is based largely on differences in time course. For example, if a patient needs medication to accelerate falling asleep, a benzodiazepine with a rapid onset (eg, triazolam) would be indicated. However, if medication is needed to prevent waking later in the night, a benzodiazepine with a slower onset (eg, estazolam) would be preferred. For treatment of anxiety, a drug with an intermediate duration is desirable. For treatment of any benzodiazepine-responsive condition in the elderly, a drug such as lorazepam, which is not likely to accumulate with repeated dosing, is generally preferred.

35.1.4 Therapeutic Uses

The benzodiazepines have three principal indications: (1) anxiety, (2) insomnia, and (3) seizure disorders. In addition, they are used as preoperative medications and to treat muscle spasm, panic disorder, and withdrawal from alcohol. Although all benzodiazepines share the same pharmacologic properties, and therefore might be equally effective for all applications, not every benzodiazepine is actually employed for all potential uses. The principal factors that determine the actual applications of a particular benzodiazepine are (1) the pharmacokinetic properties of the drug itself and (2) research and marketing decisions of pharmaceutical companies. Specific applications of individual benzodiazepines are summarized in [Table 34-2](#).

35.1.4.1 Anxiety.

Benzodiazepines are drugs of first choice for anxiety. Although all benzodiazepines have anxiolytic actions, only six are marketed for this indication (see [Table 34-2](#)). Anxiolytic effects result from depressing neurotransmission in the limbic system and cortical areas. Use of benzodiazepines to treat anxiety is discussed in [Chapter 35](#).

35.1.4.2 Insomnia.

Benzodiazepines are drugs of first choice for insomnia. These drugs decrease latency time to falling asleep, reduce awakenings, and increase total sleeping time. The role of benzodiazepines in managing insomnia is discussed in depth later.

35.1.4.3 Seizure Disorders.

Four benzodiazepines—diazepam, clonazepam, lorazepam, and clorazepate—are employed for seizure disorders. Antiseizure applications are discussed in [Chapter 24](#).

35.1.4.4 Muscle Spasm.

One benzodiazepine—diazepam—is used to relieve muscle spasm and spasticity (see [Chapter 25](#)). Effects on muscle tone are secondary to actions in the CNS. Diazepam cannot relieve spasm without causing sedation.

35.1.4.5 Alcohol Withdrawal.

Diazepam and other benzodiazepines may be administered to facilitate withdrawal from alcohol (see [Chapter 38](#)). Benefits derive from cross-dependence with alcohol, which enables benzodiazepines to suppress symptoms brought on by alcohol abstinence.

35.1.4.6 Panic Disorder.

Alprazolam [Xanax, Niravam], clonazepam [Klonopin], and lorazepam [Ativan] can help patients with panic disorder, although certain antidepressants (eg, fluoxetine [Prozac]) are preferred. Drugs for panic disorder are discussed in [Chapter 35](#).

35.1.4.7 Perioperative Applications.

Three benzodiazepines—diazepam [Valium], lorazepam [Ativan], and midazolam [Versed]—are given IV for *induction of anesthesia*. In addition, midazolam (in combination with an opioid analgesic) can be used to produce *conscious sedation*—a semiconscious state suitable for endoscopic procedures and minor surgeries. Benzodiazepines are also used for *preoperative sedation*. All of these applications are discussed in [Chapter 27](#).

35.1.5 Adverse Effects

Benzodiazepines are generally well tolerated, and serious adverse reactions are rare. In contrast to barbiturates and other general CNS depressants, benzodiazepines are remarkably safe.

35.1.5.1 CNS Depression.

When taken to promote sleep, benzodiazepines cause drowsiness, lightheadedness, incoordination, and difficulty concentrating. When these effects occur at bedtime, they are

generally inconsequential. However, if sedation and other manifestations of CNS depression persist beyond waking, interference with daytime activities can result.

35.1.5.2 Anterograde Amnesia.

Benzodiazepines can cause anterograde amnesia (impaired recall of events that take place after dosing). Anterograde amnesia has been especially troublesome with *triazolam* [Halcion]. If patients complain of forgetfulness, the possibility of drug-induced amnesia should be evaluated.

35.1.5.3 Sleep Driving and Other Complex Sleep-Related Behaviors.

Patients taking benzodiazepines in sleep-inducing doses may carry out complex behaviors, and then have no memory of their actions. Reported behaviors include sleep driving, preparing and eating meals, making phone calls, and having sexual intercourse. Although these events can occur with normal doses, they are more likely when doses are excessive, and when benzodiazepines are combined with alcohol and other CNS depressants. Because of the potential for harm, benzodiazepines should be withdrawn if sleep driving is reported. To minimize withdrawal symptoms, dosing should be tapered slowly, rather than discontinued abruptly.

35.1.5.4 Paradoxical Effects.

When employed to treat anxiety, benzodiazepines sometimes cause paradoxical responses, including insomnia, excitation, euphoria, heightened anxiety, and rage. If these occur, the benzodiazepine should be withdrawn.

35.1.5.5 Respiratory Depression.

Benzodiazepines are weak respiratory depressants. Death from overdose with oral benzodiazepines alone has never been documented. Hence, in contrast to the barbiturates, benzodiazepines present little risk as vehicles for suicide. It must be emphasized, however, that although respiratory depression with *oral* therapy is rare, benzodiazepines can cause severe respiratory depression when administered *intravenously*. In addition, substantial respiratory depression can result from combining oral benzodiazepines with other CNS depressants (eg, alcohol, barbiturates, opioids).

35.1.5.6 Abuse.

Benzodiazepines have a lower abuse potential than barbiturates and most other general CNS depressants. The behavior pattern that constitutes “addiction” is uncommon among people who take benzodiazepines for therapeutic purposes. When asked about their drug use, individuals

who regularly abuse drugs rarely express a preference for benzodiazepines over barbiturates. Because their potential for abuse is low, the benzodiazepines are classified under Schedule IV of the Controlled Substances Act. This contrasts with the barbiturates, most of which are classified under Schedule II or III.

35.1.5.7 Use in Pregnancy and Lactation.

Benzodiazepines are highly lipid soluble and can readily cross the placental barrier. Use of benzodiazepines during the first trimester of pregnancy is associated with an increased risk of congenital malformations, such as cleft lip, inguinal hernia, and cardiac anomalies. Use near term can cause CNS depression in the neonate. Because they may represent a risk to the fetus, most benzodiazepines are classified in Food and Drug Administration (FDA) Pregnancy Risk Category D. Five of these drugs—estazolam, flurazepam, quazepam, temazepam, and triazolam—are in Category X. Women of child-bearing age should be warned about the potential for fetal harm and instructed to discontinue benzodiazepines if pregnancy occurs.

Benzodiazepines enter breast milk with ease and may accumulate to toxic levels in the breast-fed infant. Accordingly, these drugs should be avoided by nursing mothers.

35.1.5.8 Other Adverse Effects.

Occasional reactions include weakness, headache, blurred vision, vertigo, nausea, vomiting, epigastric distress, and diarrhea. Neutropenia and jaundice occur rarely. Rarely, benzodiazepines may cause severe allergic reactions, including angioedema and anaphylaxis.

35.1.6 Drug Interactions

Benzodiazepines undergo very few important interactions with other drugs. Unlike barbiturates, benzodiazepines do not induce hepatic drug-metabolizing enzymes. Hence, benzodiazepines do not accelerate the metabolism of other drugs.

35.1.6.1 CNS Depressants.

The CNS-depressant actions of benzodiazepines add with those of other CNS depressants (eg, alcohol, barbiturates, opioids). Hence, although benzodiazepines are very safe when used alone, they can be extremely hazardous in combination with other depressants. Combined overdose with a benzodiazepine plus another CNS depressant can cause profound respiratory depression, coma, and death. Patients should be warned against use of alcohol and all other CNS depressants.

35.1.7 Tolerance and Physical Dependence

35.1.7.1 Tolerance.

With prolonged use of benzodiazepines, tolerance develops to some effects but not others. No tolerance develops to anxiolytic effects, and tolerance to hypnotic effects is generally low. In contrast, significant tolerance develops to antiseizure effects. Patients tolerant to barbiturates, alcohol, and other general CNS depressants show some cross-tolerance to benzodiazepines.

35.1.7.2 Physical Dependence.

Benzodiazepines can cause physical dependence—but the incidence of *substantial* dependence is low. When benzodiazepines are discontinued following short-term use at therapeutic doses, the resulting withdrawal syndrome is generally mild and often goes unrecognized. Symptoms include anxiety, insomnia, sweating, tremors, and dizziness. Withdrawal from long-term, high-dose therapy can elicit more serious reactions, such as panic, paranoia, delirium, hypertension, muscle twitches, and outright convulsions. Symptoms of withdrawal are usually more intense with benzodiazepines that have a short duration of action. With one agent—*alprazolam* [Xanax, Niravam]—dependence may be a greater problem than with other benzodiazepines. Because the benzodiazepine withdrawal syndrome can resemble an anxiety disorder, it is important to differentiate withdrawal symptoms from the return of original anxiety symptoms.

The intensity of withdrawal symptoms can be minimized by discontinuing treatment gradually. Doses should be slowly tapered over several weeks or months. Substituting a benzodiazepine with a long half-life for one with a short half-life is also helpful. Patients should be warned

against abrupt cessation of treatment. Following discontinuation of treatment, patients should be monitored for 3 weeks for indications of withdrawal or recurrence of original symptoms.

371

372

35.1.8 Acute Toxicity

35.1.8.1 Oral Overdose.

When administered in excessive dosage by mouth, benzodiazepines rarely cause serious toxicity. Symptoms include drowsiness, lethargy, and confusion. Significant cardiovascular and respiratory effects are uncommon. If an individual known to have taken an overdose of benzodiazepines does exhibit signs of serious toxicity, it is probable that another drug was taken too.

35.1.8.2 Intravenous Toxicity.

When injected IV, even in therapeutic doses, benzodiazepines can cause severe adverse effects. Life-threatening reactions (eg, profound hypotension, respiratory arrest, cardiac arrest) occur in about 2% of patients.

35.1.8.3 General Treatment Measures.

Benzodiazepine-induced toxicity is managed the same as toxicity from barbiturates and other general CNS depressants. Oral benzodiazepines can be removed from the body with gastric lavage followed by ingestion of activated charcoal and a saline cathartic; dialysis may be helpful if symptoms are especially severe. Respiration should be monitored and the airway kept patent. Support of blood pressure with IV fluids and norepinephrine may be required.

35.1.8.4 Treatment with Flumazenil.

Flumazenil [Romazicon] is a competitive benzodiazepine receptor antagonist. The drug can reverse the sedative effects of benzodiazepines but may not reverse respiratory depression. Flumazenil is approved for benzodiazepine overdose and for reversing the effects of benzodiazepines following general anesthesia. The principal adverse effect is precipitation of convulsions. This is most likely in patients taking benzodiazepines to treat epilepsy and in patients who are physically dependent on benzodiazepines. Flumazenil is administered IV. Doses are injected slowly (over 30 seconds) and may be repeated every minute as needed. The first dose is 0.2 mg, the second is 0.3 mg, and all subsequent doses are 0.5 mg. Effects of flumazenil fade in about 1 hour, hence additional dosing may be required.

35.1.9 Preparations, Dosage, and Administration

35.1.9.1 Preparations and Dosage.

Preparations and dosages for *insomnia* are presented later in the chapter. Preparations and dosages of benzodiazepines used for other disorders are presented in [Chapter 24](#) (Drugs for Epilepsy), [Chapter 25](#) (Drugs for Muscle Spasm and Spasticity), [Chapter 27](#) (General Anesthetics), and [Chapter 35](#) (Management of Anxiety Disorders).

35.1.9.2 Routes.

All benzodiazepines can be administered orally. In addition, three agents—diazepam, chlordiazepoxide, and lorazepam—may be administered parenterally (IM and IV). When used for sedation or induction of sleep, benzodiazepines are almost always administered by mouth.

Pharmacology for Nursing Care, 7th Edition

Parenteral administration is reserved for emergencies, including acute alcohol withdrawal, severe anxiety, and status epilepticus.

35.1.9.2.1 Oral.

Patients should be advised to take oral benzodiazepines with food if gastric upset occurs. Also, they should be instructed to swallow sustained-release formulations intact, without crushing or chewing. Patients should be warned not to increase the dosage or discontinue therapy without consulting the prescriber.

For treatment of insomnia, benzodiazepines should be given on an intermittent schedule (eg, 3 or 4 days a week) in the lowest effective dosage for the shortest duration required. This will minimize physical dependence and associated drug-dependency insomnia.

35.1.9.2.2 Intravenous.

Intravenous administration is hazardous and must be performed with care. Life-threatening reactions (severe hypotension, respiratory arrest, cardiac arrest) have occurred. In addition, IV administration carries a risk of venous thrombosis, phlebitis, and vascular impairment.

To reduce complications, the following precautions should be taken: (1) inject the drug slowly; (2) take care to avoid intra-arterial injection and extravasation; (3) if direct venous injection is impossible, make the injection into infusion tubing as close to the vein as possible; (4) follow the manufacturer's instructions regarding suitable diluents for preparing solutions; and (5) have facilities for resuscitation available.

35.1.9.2.3 Intramuscular.

If IM administration is needed, *lorazepam* is the preferred benzodiazepine to use, owing to consistent absorption from IM sites. Absorption of IM diazepam is erratic and may be delayed. Accordingly, IM diazepam should be avoided.

35.2 BENZODIAZEPINE-LIKE DRUGS

Three benzodiazepine-like drugs are available: zolpidem, zaleplon, and eszopiclone. All three are preferred agents for treating insomnia. They are not indicated for anxiety. These drugs are structurally different from benzodiazepines, but nonetheless share the same mechanism of action: They all act as *agonists at the benzodiazepine receptor site* on the GABA receptor–chloride channel complex. These drugs are highly effective hypnotics, and have a low potential for tolerance, dependence, or abuse.

35.2.1 Zolpidem

Zolpidem [Ambien, Ambien CR, Zolpimist], our most widely used hypnotic, is approved only for short-term management of insomnia. However, although approval is limited to short-term use, many patients have taken the drug long term with no apparent tolerance or increase in adverse effects. All zolpidem formulations have a rapid onset, and hence can help people who have difficulty falling asleep. In addition, the extended-release formulation—Ambien CR—can help people who have difficulty maintaining sleep.

Although structurally unrelated to the benzodiazepines, zolpidem binds to the benzodiazepine receptor site on the GABA receptor–chloride channel complex and shares some properties of the benzodiazepines. Like the benzodiazepines, zolpidem can reduce sleep latency and awakenings and can prolong sleep duration. The drug does not significantly reduce time in rapid-eye-movement (REM) sleep and causes little or no rebound insomnia when therapy is discontinued. In contrast to the benzodiazepines, zolpidem lacks anxiolytic, muscle relaxant, and anticonvulsant actions. Why? Because zolpidem doesn't bind with all benzodiazepine receptors. Rather, binding is limited to the benzodiazepine₁ subtype of benzodiazepine receptors.

Zolpidem is rapidly absorbed following oral administration. Plasma levels peak in 2 hours. The drug is widely distributed, although levels in the brain remain low. Zolpidem is extensively metabolized to inactive compounds that are excreted in the bile, urine, and feces. The elimination half-life is 2.4 hours.

Zolpidem has a side effect profile like that of the benzodiazepines. *Daytime drowsiness and dizziness* are most common, and these occur in only 1% to 2% of patients. Like the benzodiazepines, zolpidem has been associated with *sleep driving* and other *sleep-related complex behaviors*. At therapeutic doses, zolpidem causes little or no respiratory depression. Safety in pregnancy has not been established. According to the FDA, zolpidem may pose a small risk of anaphylaxis and angioedema.

Short-term treatment is not associated with significant tolerance or physical dependence.

372

Withdrawal symptoms are minimal or absent. Similarly, the abuse liability of zolpidem is low.

373

Accordingly, the drug is classified under Schedule IV of the Controlled Substances Act.

Like other sedative-hypnotics, zolpidem can intensify the effects of other CNS depressants. Accordingly, patients should be warned against combining zolpidem with alcohol and all other drugs that depress CNS function.

Zolpidem is available in immediate-release tablets (5 and 10 mg) as *Ambien*, extended-release tablets (6.25 and 12.5 mg) as *Ambien CR*, and an oral spray (5 and 10 mg) as *Zolpimist*. With the

immediate-release tablets and oral spray, the usual dose is 10 mg. The initial dose should be reduced to 5 mg for elderly and debilitated patients and for those with hepatic insufficiency. With the extended-release tablets, the usual dose is 12.5 mg (or 6.25 mg for elderly or debilitated patients). All formulations have a rapid onset, and hence should be taken just before bedtime. This timing will promote sleep while minimizing daytime sedation.

35.2.2 Zaleplon

Zaleplon [Sonata] is the first representative of a new class of hypnotics, the pyrazolopyrimidines. The drug is approved only for short-term management of insomnia, but prolonged use does not appear to cause tolerance. Like zolpidem, zaleplon binds to the benzodiazepine₁ receptor site on the GABA receptor–chloride channel complex, and thereby enhances the depressant actions of endogenous GABA. In contrast to zolpidem, zaleplon has a very rapid onset and short duration of action, and hence is good for helping patients fall asleep, but not for maintaining sleep.

Zaleplon is rapidly and completely absorbed from the GI tract. However, because of extensive first-pass metabolism, bioavailability is only 30%. A large or high-fat meal can delay absorption substantially. Plasma levels peak about 1 hour after administration and then rapidly decline, returning to baseline in 4 to 5 hours. Zaleplon is metabolized by hepatic aldehyde oxidase prior to excretion in the urine. Its half-life is just 1 hour.

Because of its kinetic profile, zaleplon is well suited for people who have trouble falling asleep, but not for people who can't maintain sleep. The drug can also help people who need a sedative in the middle of the night: Because of its short duration, zaleplon can be taken at 3:00 AM without causing hangover when the alarm goes off at 7:00 AM.

Zaleplon is well tolerated. The most common side effects are headache, nausea, drowsiness, dizziness, myalgia, and abdominal pain. Like the benzodiazepines, zaleplon has been associated with rare cases of sleep driving and other complex sleep-related behaviors. Respiratory depression has not been observed. Physical dependence is minimal, the only sign being mild rebound insomnia the first night after drug withdrawal. Next-day sedation and hangover have not been reported. Like the benzodiazepines, zaleplon has a low potential for abuse, and hence is classified as a Schedule IV drug.

Cimetidine (a drug for peptic ulcer disease) inhibits hepatic aldehyde oxidase, and can thereby greatly increase levels of zaleplon. Accordingly, dosage of zaleplon must be reduced if these drugs are used concurrently.

Zaleplon is available in 5- and 10-mg capsules. The usual dose is 10 mg. The dose should be reduced to 5 mg for (1) the elderly, (2) small individuals, (3) patients with liver impairment, and

(4) patients taking cimetidine. The maximum dose is 20 mg. Dosing is usually done just before retiring. However, dosing may also be done after going to bed on nights when sleep fails to come.

35.2.3 Eszopiclone

Eszopiclone [Lunesta], approved in 2005, is the *S*-isomer of zopiclone, a drug used for years in Canada and Europe. Like zaleplon and zolpidem, eszopiclone binds selectively with the benzodiazepine₁ receptor on the GABA receptor–chloride channel complex, and thereby enhances the depressant actions of endogenous GABA.

Eszopiclone is approved for treating insomnia, with no limitation on how long it can be used. This contrasts with zaleplon and zolpidem, which are approved for short-term use only. Does this mean that eszopiclone is safer than the other two drugs, or less likely to promote tolerance? Not necessarily. It only means that the manufacturer of eszopiclone conducted a prolonged (6-month) study, whereas the manufacturers of the other two drugs did not. In that prolonged study, eszopiclone reduced sleep latency and nighttime awakening, increased total sleep time and sleep quality, had no significant effect on sleep architecture, and showed no indication of tolerance.

Eszopiclone is rapidly absorbed after oral dosing, reaching peak blood levels in 1 to 2 hours. The drug undergoes extensive hepatic metabolism, primarily by CYP3A4 (the 3A4 isozyme of cytochrome P450). The resulting inactive (or weakly active) metabolites are excreted in the urine. The elimination half-life is 6 hours.
